Problems? Sure there are. Desflurane is sufficiently pungent that our dream of having a "lightning-fast" volatile agent for mask inductions in children will not be realized with this agent. Mask inductions with desflurane in adults and children have been associated with severe coughing and laryngospasm as detailed several places in this Colloquium. Our dream of having a volatile agent that is not a cardiovascular depressant is also not realized with desflurane, despite the fact that there may actually be transient cardiovascular stimulation at relatively fast rates of change in concentration. As its low oil-gas solubility (19:1) predicts, desflurane's potency is only about one-fifth that of isoflurane (MAC between 6% and 7%); a fact that in itself is not necessarily a

0003-2999/92/$5.00

drawback; i.e., there will still be plenty of "oxygen space." Nonetheless, the anesthesiologist will need to develop new mental habits and "time constants." Incremental changes in inspired concentration will often need to be more than 1% at a time, but the time necessary for such an inspired concentration change to produce a clinical effect is much shorter than with the other volatile agents. If your "time constant," i.e., the time you expect to elapse before hemodynamic changes occur, is "set" for isoflurane, you can be unpleasantly surprised at how fast desflurane acts.

Desflurane boils at 23.5°C, i.e., literally in your hand. The required vaporizer is heated and pressurized, with elegant (expensive) electronic controls and safeguards. It probably is *more* accurate than any vaporizer yet produced, owing to the maintenance of a constant temperature and the metering of the agent as a gas, but the fact that it is a new type of vaporizer may be daunting to some.

This Supplement to *Anesthesia & Analgesia* contains reviews that were first presented at a recent colloquium on desflurane held in Florida and sponsored by Anaquest. The presentations were designed to attempt to summarize current knowledge about desflurane in the areas of pharmacokinetics (Dr. Eger); metabolism and toxicity (Dr. Koblin); cardiovascular effects (Dr. Warltier); induction and emergence in adults and pediatric patients (Dr. Smiley); central nervous system effects (Dr. Young); and use in outpatient anesthesia (Dr. White). The presenters at the Colloquium authored the reviews published in this Supplement, but it is to be emphasized that the data summarized in these review articles were gathered from the work of many others. Because the Colloquium was chaired by Dr. Ronald D. Miller of San Francisco, who is also Editor-in-Chief of *Anesthesia & Analgesia*, Dr. Miller asked me, as Associate Editor-in-Chief, to assume editorial control of this Supplement. I was not present at the Colloquium at which these presentations were given and have not directly participated in any of the clinical trials of desflurane.

This Supplement of *Anesthesia & Analgesia* is sponsored by an educational grant from *Anaquest Inc, a Subsidiary of BOC Health Care Inc.* The grant was made to the International Anesthesia Research Society (IARS). *Anesthesia & Analgesia* is the official journal of that Society. No financial benefit from this grant will accrue to any of the authors of the articles contained in this Supplement, or to me as its Editor.

The introduction of desflurane into clinical practice in the United States is anticipated soon, though FDA approval has not been granted as of this writing (May 1992). After careful consideration, the Editorial Board of *Anesthesia & Analgesia*, with the approval of the Board of Trustees of the IARS, agreed that if reviews pertaining to animal and especially human trials of desflurane could be obtained in timely fashion, and if these reviews could be editorially accepted for publication, then *Anesthesia & Analgesia* would publish them collected as a Supplement to the journal.

Some may opine that this is too "close" a relationship with a pharmaceutical manufacturer. It is accepted that the best, indeed the only valid defense against any allegation of conflict of interest is *full and complete disclosure*. I believe the above statements constitute such disclosure. Further, I have gone to considerable effort to assure that the articles contained in this Supplement contain balanced interpretations of the available data. The educational grant made by Anaquest Inc to support publication of this Supplement was made with the full agreement of all parties that there would be no interference with the editorial process. I think the reader will find the presentations balanced and supported by available data. Also included after each article is an edited transcription of the discussion that was held after each presentation at the original Colloquium. I have edited this discussion only in that spoken language has been rendered suitable for publication—I have tried very hard not to alter content of the remarks.

After all that . . . back to desflurane. Will every practicing anesthesiologist want to try the first new volatile halogenated anesthetic to be introduced in almost 20 years? Certainly we will. Whether we will "like" it, and for what kinds of procedures, only time will tell. One thing is certain, anyone who wants to learn to use it will want to be armed with as much data from prior experience as possible. Hopefully, this Supplement will provide a knowledge base to allow us to determine this new agent's place in our pharmacologic toolbox.

Desflurane Animal and Human Pharmacology: Aspects of Kinetics, Safety, and MAC

Edmond I. Eger II, MD

Department of Anesthesia, University of California—San Francisco, San Francisco, California

Substitution of fluorine for the single chlorine atom in isoflurane produces the new anesthetic, desflurane. This seemingly small change produces several pharmacologic changes. The potency of desflurane (MAC equals 6.0% in middle-aged patients) is one-fifth that of isoflurane (1.15%), with MAC for each agent decreased by aging, hypothermia, or the addition of depressants such as midazolam, fentanyl, or nitrous oxide. Some properties are similar: desflurane and isoflurane both depress respiration and neuromuscular contractility, and higher concentrations (e.g., 6%–8% desflurane) of both agents have a pungency that can provoke breath holding, laryngospasm, and salivation, particularly in infants and children. Of great importance, the substitution of fluorine for chlorine markedly decreases blood (desflurane blood-gas partition coefficient 0.42) and tissue solubility (e.g., brain-blood partition coefficient 1.3) relative to isoflurane (values 1.4 and 1.6, respectively). As a result, desflurane alveolar concentrations may be adjusted more rapidly and precisely; desflurane enters and leaves the lungs and tissues more rapidly; and recovery is quicker both for the short (first 10–20 min) and long (0.5–1.5 h) term. This greater precision of control and more rapid recovery are consistent with trends for new drug development in anesthesiology.

(Anesth Analg 1992;75:S3–9)

The drugs that we use in anesthesia are changing. New drugs, such as atracurium, vecuronium, and propofol, have a shorter duration of action and thereby allow greater control over their effects. Desflurane fits this mold. The properties of desflurane, especially those of control and resistance to degradation, promise significant differences from presently available inhaled anesthetics. A discussion of these aspects of pharmacology occupies several of the reports that follow the present account. Some discussions of the pharmacology of desflurane are omitted. For example, there is little or no discussion of its effect on respiration or neuromuscular transmission. These omissions are deliberate: the effects of desflurane on these systems do not differ materially from those of isoflurane and enflurane; these properties are likely to be known to the reader. The respiratory-depressant properties of desflurane are similar to those of isoflurane and enflurane (1–5). Similarly, although desflurane decreases contractility and impairs neuromuscular conduction, thus enhancing the relaxation produced by muscle relaxants, there are no appreciable differences from the effects of isoflurane or enflurane (6–9).

The MAC of desflurane differs from that of other potent agents. Substitution of fluorine for chlorine in isoflurane produces desflurane and, concurrently, decreases potency (10). In rats, the MAC of desflurane is 5.7% (11) to 7.1% (12), in dogs 7.2% (13), in rabbits 8.9% (13), in pigs 10% (14), and in adult humans 6%–7% (1).

The MAC of desflurane decreases with increasing age (Figure 1) (1,15,16). As with other potent inhaled anesthetics (17–19), infants have the highest MAC (15,16). The MAC progressively decreases after a few months of life, in the 45-yr-old patient reaching a value approximately 60% of that of the infant (1). At all age levels, 60% nitrous oxide decreases the MAC of desflurane by approximately 3% desflurane (1,16,20).

As expected, drugs used to supplement anesthesia decrease the MAC. Fentanyl decreases the MAC (20,21) in a dose-dependent fashion at lower serum concentrations but apparently reaches a ceiling at higher levels (21). Fentanyl produces comparable decreases in isoflurane MAC (20). Similarly, midazolam decreases the MAC of desflurane. A premedicant dose of 0.05 mg/kg of midazolam decreases the MAC by 22% without changing the time to recovery (22).

In rats, an increased duration of anesthesia with

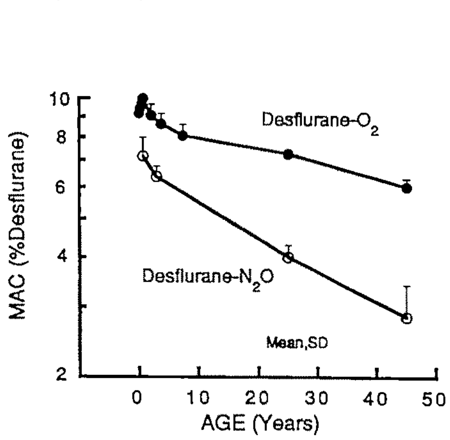

Figure 1. Aging influences desflurane MAC in humans. The MAC reached its zenith at <1 yr of age, decreasing by 40% over the next 45 yr. A parallel effect was seen with nitrous oxide added (1,15,16).

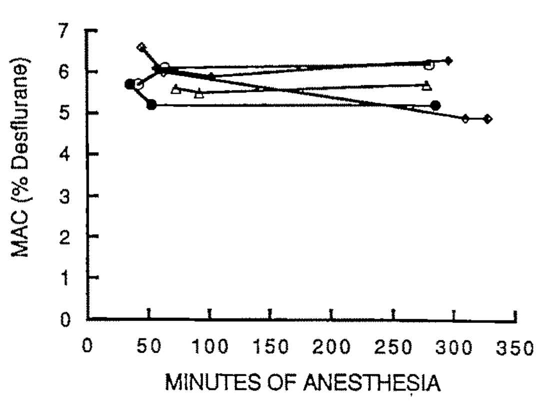

Figure 2. In rats, desflurane MAC measured immediately after anesthesia induction did not differ from that measured after 5 h. Hypothermia was imposed during the interval between these measurements, but the values shown were all obtained in normothermic rats (11).

desflurane does not appreciably change the MAC (Figure 2) (11). As with other anesthetics, MAC decreases with decreased body temperature. In rats, a 10°C decrease in temperature from 38°C decreases the MAC by 42% (Figure 3) (11).

The MAC-awake (the concentration of desflurane that permits an appropriate response to command in 50% of subjects) is 2.42% ± 0.49% (mean ± sd) desflurane (23). The ratio MAC-awake/MAC equals 0.33 ± 0.07 and suggests that desflurane may be a potent hypnotic.

The conversion of isoflurane to desflurane by substitution of a fluorine for a chlorine atom changes much more than anesthetic potency. Indeed, it was predicted that the substitution would produce a much less soluble compound with markedly different kinetics. Results from various investigations indicate that this is so.

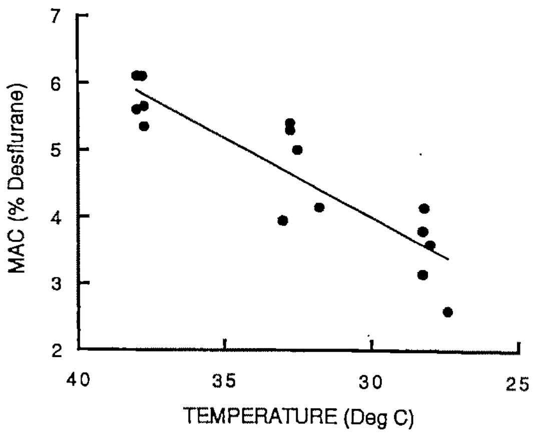

Figure 3. In contrast to the lack of an effect of duration of anesthesia, hypothermia decreased MAC in rats by 0.24% ± 0.04% (mean ± sd) desflurane per °C. Desflurane MAC at 28°C is 58% of the MAC at 38°C (11).

The low desflurane blood-gas partition coefficient, namely 0.42 (24), suggests that its kinetics should approximate those of nitrous oxide (blood-gas partition coefficient 0.47) rather than those of potent but more soluble inhaled anesthetics, such as isoflurane, enflurane, and halothane (Table 1). The increase and decrease of the alveolar concentration of desflurane during induction of and recovery from anesthesia should be more rapid. Similarly, lower tissue-blood partition coefficients for desflurane predict more rapid tissue elimination (Table 1) (25).

Studies in humans and animals confirm these predictions (23,26–28). The alveolar concentration of desflurane (FA) increases toward the concentration inspired (FI) more rapidly (i.e., the FA/FI ratio approaches 1.0 more rapidly) than with other potent anesthetics (Figure 4) (23,26,27). However, despite the near identity of their partition coefficients, the increase in FA/FI is more rapid with nitrous oxide than with desflurane because of augmentation provided nitrous oxide by the concentration effect (29). The results depicted in Figure 4 came from studies in which nitrous oxide was administered at an inspired concentration of 65% and desflurane at only 2%.

Similarly, during elimination, the rate of decrease of the desflurane alveolar concentration (relative to the last alveolar concentration during anesthetic administration (FAO)) exceeds that of all other potent inhaled anesthetics (Figure 5) (26,27). Because of lower tissue-blood partition coefficients for desflurane, the difference between desflurane and other anesthetics widens with increasing duration of elimination (Figure 6). After 5 days, the FA/FAO ratio for desflurane is one-tenth that of sevoflurane, which in turn has an FA/FAO ratio approximately one-third that of isoflurane or halothane. Results from studies in swine confirm these results in humans (28).

Percutaneous loss of other inhaled anesthetics exceeds that of desflurane, but such loss does not influence pharmacokinetics in humans for any agent (30,31). For all anesthetics, visceral losses from an

Table 1. Human Blood-Gas and Tissue-Blood Partition Coefficients of Inhaled Anesthetics[a]

Blood or tissue	Desflurane	Sevoflurane	Isoflurane	Halothane
Blood	0.42 ± 0.02	0.68 ± 0.05	1.46 ± 0.09	2.54 ± 0.18
Brain	1.3 ± 0.1	1.7 ± 0.1	1.6 ± 0.1	1.9 ± 0.2
Heart	1.3 ± 0.2	1.8 ± 0.2	1.6 ± 0.2	1.8 ± 0.3
Liver	1.3 ± 0.1	1.8 ± 0.2	1.8 ± 0.2	2.1 ± 0.3
Kidney	1.0 ± 0.1	1.2 ± 0.2	1.2 ± 0.2	1.0 ± 0.2
Muscle	2.0 ± 0.6	3.1 ± 1.0	2.9 ± 1.0	3.4 ± 1.4
Fat	27 ± 3	48 ± 6	45 ± 6	51 ± 10

For the blood-gas partition coefficients, $n = 11$ (desflurane), 19 (sevoflurane), 16 (isoflurane), and 15 (halothane). For the tissues studied, $n = 10$ (liver, kidney), 8 (muscle, heart, fat), and 6 (brain).
Values are shown as mean ± SD.
[a]Data are from Yasuda et al. (25), Strum and Eger (40), and Eger and Eger (42).

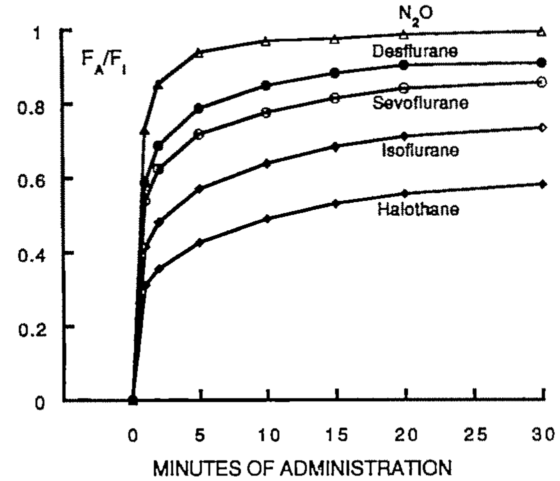

Figure 4. In humans, alveolar concentration (FA) of desflurane increased toward inspired concentration (FI) more rapidly than that of other potent inhaled anesthetics. Except for nitrous oxide, the position of each graph is consistent with the blood-gas partition coefficient of each agent. Nitrous oxide had a more rapid increase than desflurane because its increase (but not that of desflurane) was influenced by the concentration effect (29).

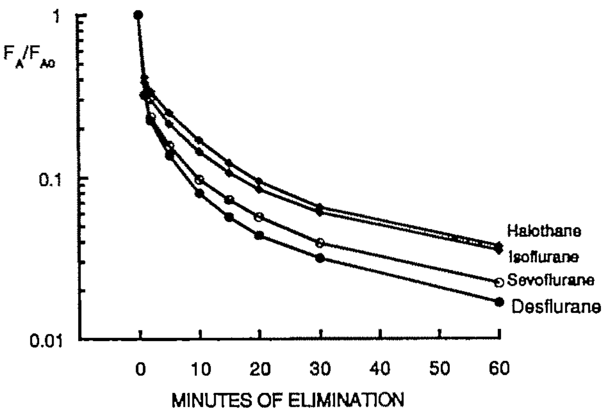

Figure 5. As defined by the decreased alveolar concentration relative to the last alveolar concentration found during anesthesia (FAO), desflurane is eliminated in humans more rapidly than are other potent agents.

opened abdomen or thorax are larger than cutaneous losses (32). Again, the rate of loss for desflurane is less than that for other potent agents. Similarly, despite the greater rate of loss, the total movement from viscera to air does not materially influence the kinetics of any of the anesthetics.

The more rapid increase and decrease of desflurane in alveoli is reflected in the brain. In rabbits, the increase in cerebral anesthetic partial pressure (CC) relative to FI is most rapid with desflurane, less with isoflurane, and slowest with halothane (33). Similarly, cerebral anesthetic elimination (CC/FAO) proceeds more rapidly with desflurane than with isoflurane or halothane (Figure 7).

These data suggest that induction of and recovery from anesthesia with desflurane may be more rapid than with other potent inhaled anesthetics. This prediction is correct for recovery but not for induction. Although volunteers given "square-wave" concentrations of up to 5.4% desflurane breathed ". . . without coughing, breath-holding, salivation or other untoward respiratory response" (34), such concentrations are less than those required for induction of anesthesia. Concentrations of 6%–8% can evoke coughing, breath holding, laryngospasm, and salivation (1,35). The airways of children are irritated as much as the airways of adults by the pungency of desflurane (36,37). Irritation is at least as great (and may be greater) with desflurane as with isoflurane (35). Consistent with these studies of airway irritability, the pungency of desflurane slows induction of anesthesia by inhalation (37).

Although pungency limits rate of induction with desflurane, it does not limit rate of recovery. Studies of recovery in animals are of particular interest, because studies in humans may be confounded by factors such as use of adjuvant drugs or imposition of surgery. Studies in animals also permit precise control of anesthetic dose and duration.

Rate of recovery from anesthesia was studied in rats (38) by noting time from termination of anesthetic administration to successful completion of a

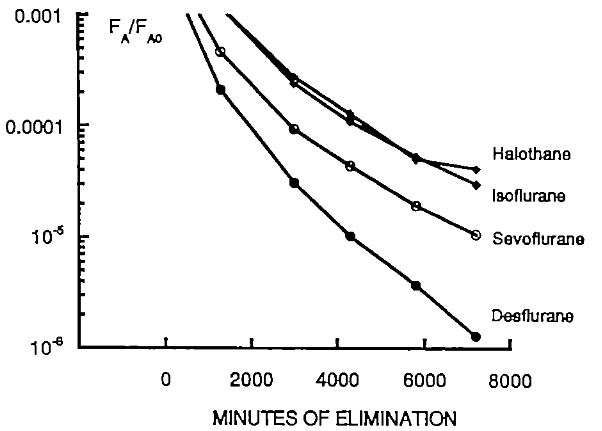

Figure 6. As recovery progresses, differences between desflurane and other agents portrayed in Figure 5 increased due to smaller tissue-blood partition coefficients of desflurane. After 5 days, FA/FAO of desflurane is less than one-tenth that for the other agents. (Abbreviations as in Figures 4 and 5.)

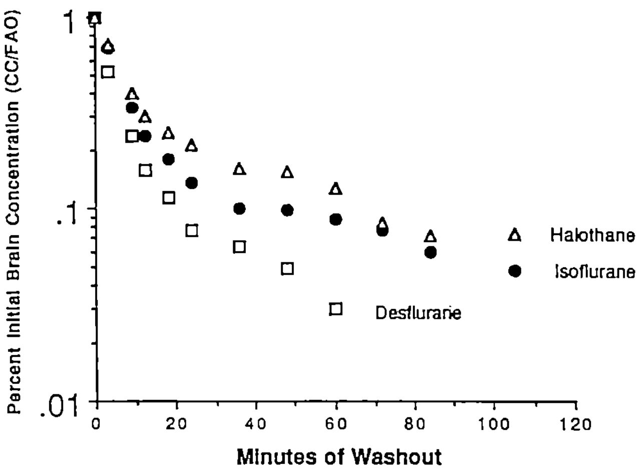

Figure 7. In live rabbits, nuclear magnetic resonance measurements of anesthetics demonstrate cerebral elimination of desflurane that is severalfold more rapid than that of isoflurane or halothane (33).

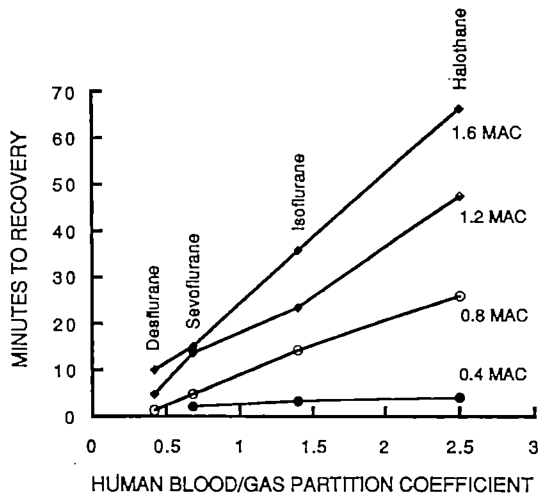

Figure 8. For a given concentration of anesthetic and duration of administration in rats, recovery from anesthesia occurred at a rate that is a rectilinear function of solubility (38). The slopes defining this relationship increased with increased anesthetic concentration. The points at a blood-gas partition coefficient of 0.42 are for desflurane, at 0.69 for sevoflurane, at 1.4 for isoflurane, and at 2.5 for halothane.

task demanding muscle coordination (the Rotarod test [39]). Anesthetics tested were desflurane, sevoflurane (blood-gas partition coefficient 0.69) (40), isoflurane (1.4) (41,42), and halothane (2.4) (42). For a given MAC multiple and duration of anesthesia, rate of recovery was inversely related to blood solubility and, therefore, was always most rapid with desflurane (Figure 8). Although increased duration of anesthesia or increased concentration lengthened recovery time for all anesthetics, the increase was least with desflurane.

Rate of recovery after a given dose and duration correlates with the blood-gas partition coefficient (Figure 8). These data indicate that blood-gas partition coefficients of 0.3–0.4 provide near-maximal rates of recovery. Extrapolation of each graph yields a zero intercept (of the abscissa) at partition coefficients of 0.3–0.4. At these partition coefficients, recovery rate cannot be accelerated further by decreasing solubility. Recovery at such low blood-gas partition coefficients is likely to be affected by cerebral rather than pulmonary clearance. The results of these studies of elimination and recovery in animals have implications to patient management that will be discussed by others in this Colloquium.

Anesthetics can dissolve in circuit components. Such solution can retard anesthetic administration and elimination (43,44). Because desflurane is less soluble in plastic and rubber components found in anesthetic circuits (45), such solution will have less effect on desflurane kinetics than on kinetics of other potent agents. Desflurane washes into and out of an anesthetic circuit (without connection to a patient) more rapidly than isoflurane (45). Although the difference between the two agents is significant, uptake and elimination of anesthetic for either agent are too small to materially affect anesthesia.

In summary, the molecular structure of desflurane distinguishes this new agent from presently available potent inhaled anesthetics. Desflurane is less potent, having a MAC that is five times greater than the MAC of isoflurane. It is much less soluble in tissues and blood, having a blood-gas partition coefficient that is one-third that of isoflurane. The pungency of desflurane prevents it from providing a faster induction of anesthesia, but its solubility properties permit closer control of anesthetic depth and more rapid recovery from anesthesia than is possible with presently available agents.

DISCUSSION

DR. JOHN KAMPINE (Milwaukee): You commented that it is your observation that MAC-awake correlates with creation of amnesia. Is there a difference among those three agents that you indicated on the slide insofar as their ability to produce amnesia relating to MAC-awake?

DR. EDMOND I. EGER II (San Francisco): Not too much in relation to MAC-awake for desflurane and isoflurane. It would appear that nitrous oxide is less of an amnestic agent than is isoflurane, there being a factor of 2 difference between the two.

DR. KAMPINE: You showed the slide that indicated the constancy of desflurane anesthesia over time, but I did not hear you comment about how this compares with other agents.

DR. EGER: Other agents (isoflurane, halothane, and cyclopropane) are similarly constant.

DR. KAMPINE: Some studies indicate differences in physiologic responses at constant levels of anesthesia for prolonged periods of time, and there are differences of opinion about what causes that. I do not think it has ever been resolved. Is desflurane the same or different with regard to that property of the halogenated agents?

DR. EGER: There are some differences, late versus early, but they are relatively small. Some would suggest increased beta activity, but we did not test that. There are differences in peripheral resistance, and there are some differences in heart rate, I believe, but the majority of cardiovascular effects are not particularly different with regard to early versus late.

DR. SUJIT PANDIT (Ann Arbor): You showed two slides on washout curves; looking at halothane and isoflurane, despite the fact that their solubilities are so different, their washout was almost identical. Yet, in recovery, isoflurane was much faster. Is there anything that I am missing apart from the solubility, something that makes it a quicker recovery?

DR. EGER: The difference between isoflurane and halothane, we believe, is related to a difference in their metabolic degradation, with isoflurane not being degraded and halothane being degraded. The concentrations that were applied during the studies in human volunteers, the ones where you remarked on the identity of the washout curves, were concentrations at relatively low levels. We know that the metabolism of halothane is a saturable phenomenon in which higher concentrations produce a limit to the rate at which metabolism occurs, the Vmax being associated with a concentration of perhaps 1/20th to 1/50th of MAC itself. Thus, if you apply higher concentrations of halothane and of isoflurane, you will be more apt to reveal the difference between the two agents, and we did apply higher concentrations in rats. That is speculation, but I believe that it accounts for the difference you noted.

DR. JERROLD LERMAN (New York): With respect to desflurane kinetics, you suggested that its lower solubility would allow a more rapid adjustment of anesthesia depth. There is no question that elimination will be a reflection of the drug's solubility. However, the washin of this anesthetic, or rather the induction of anesthesia in allowing us to reach greater depths of anesthesia, should be no different than it is with other agents because of overpressure. If we do not use overpressure, then desflurane would allow us greater control, but in clinical terms, this drug will not allow us to achieve greater anesthesia depth more rapidly than any other more soluble inhaled agent.

DR. EGER: You bring up a good point, and I stand corrected. It is true that we can raise anesthesia level equally as rapidly with isoflurane or halothane or, for that matter, even with methoxyflurane, as we can with desflurane, if we are prepared to supply sufficient overpressure. The difference, though, is that the stability of the alveolar value you obtain using a higher pressure will be less with a more soluble agent. If you apply overpressure, you will have a constantly rising concentration with a more soluble agent, unless you carefully titrate to the level that you want. If you apply a level of desflurane, you go to that level and stay there, because of its lower solubility. That brings up another point. Do we need to have a desflurane analyzer for this new agent? My answer is that it would be nice to have one, but if we are talking about need (i.e., relative need), we have less need for an analyzer for this agent than with any other potent inhaled agent because what you give (i.e., inspired) is what you get (expired). The difference between delivered concentration and what is in the patient's alveoli, blood, and brain is going to be less with this agent than with other agents. If you have an accurate vaporizer, you have a good idea of alveolar concentration; as well as that in the brain.

DR. JOSEPH R. ARTUSIO, JR. (New York): Why does changing one chlorine for one fluorine atom change the biologic potency so significantly in this compound?

DR. EGER: If you change from chlorine to fluorine in any organic compound, you decrease lipid solubility, which, as the Meyer-Overton rule would predict, should decrease potency. The change in potency is essentially identical to what you would predict in terms of lipid solubility. The next question is, why does the conversion to fluorine change lipid solubility? I am not enough of a physical chemist to answer that question.

DR. DONALD WALLACE (Dallas): Has single-breath induction been tested with desflurane?

DR. EGER: Yes, single-breath induction has been tested. Anesthesia can be induced very rapidly with desflurane.

DR. ARTUSIO: We looked at single-breath induction. We observed considerable breath holding when the subject takes a single breath at a concentration of 1 or 2 MAC. If you induce anesthesia slowly, you can achieve similar anesthesia with much less upper airway irritation.

DR. EGER: I would add that in studies by Dr. Ronald Jones, 6% desflurane was administered as a square wave. He observed no coughing, no breath holding, and no secretions.

DR. ROBERT G. MERIN (Houston): Has the respiratory response to surgical incision been studied with desflurane? Does the incision partially antagonize the anesthetic?

DR. IRA RAMPIL (San Francisco): We did not examine it rigorously. My impression during surgical anesthesia was that respiration increased if it had been slow. This did not appear to be different from isoflurane. Dr. Yasuda studied the circulatory response to stimulation, which seemed to be abolished at deeper levels of anesthesia (i.e., 1.6 or 1.7 MAC levels). If the respiratory responses are similar, it may be that desflurane does differ from isoflurane in that aspect.

DR. RONALD D. MILLER (San Francisco): You concluded that desflurane was outstanding and that a skillful clinician could save costs by eliminating use of muscle relaxants. What data did you present to support that conclusion?

DR. EGER: I said that neuromuscular effects of desflurane and isoflurane were essentially identical. I then reasoned that if you could deepen anesthesia without concern for delaying recovery, you could take advantage of the property of desflurane or isoflurane that allows essentially complete paralysis at deeper levels. Desflurane and isoflurane or halothane provide relaxation sufficient to permit endotracheal intervention. Deeper levels of anesthesia, Dr. Caldwell has shown, diminish neuromuscular transmission. We believe you could perform almost any procedure without muscle relaxants if you are willing to give a deep enough level of anesthesia with this compound.

DR. R. D. MILLER: You have stated that you can do the same thing with isoflurane, is that correct?

DR. EGER: Yes.

DR. R. D. MILLER: I cannot speak about desflurane because I have not administered desflurane, but with isoflurane, it is not the delayed recovery that prevents me from administering higher concentrations. It is predominantly the cardiovascular effects. Is that true with desflurane?

DR. EGER: Yes. I think it would also be true. If cardiovascular effects are your concern, then you may not be able to administer deeper levels. On the other hand, with desflurane we can now dispense with nitrous oxide and obtain the (muscle relaxant) benefit of desflurane at lighter levels of anesthesia, which we are not inclined to do with isoflurane because of the potential for delaying recovery.

Characteristics and Implications of Desflurane Metabolism and Toxicity

Donald D. Koblin, PhD, MD

Departments of Anesthesia, Veterans Administration Medical Center and University of California—San Francisco, San Francisco, California

---

The metabolism of desflurane has been assessed both in animals and humans by measuring the appearance of fluoride metabolites (fluoride ion, nonvolatile organic fluoride, trifluoroacetic acid) in blood and urine. Desflurane administered to rats (either pretreated or not pretreated with phenobarbital or ethanol) for 3.2 MAC-hours and to swine for 5.5 MAC-hours produced fluoride ion levels in blood that were almost indistinguishable from values measured in control animals. In contrast, a significant 17% increase in plasma fluoride ion concentration in swine was detected 4 h after exposure to desflurane. In human studies, desflurane administered to patients (3.1 MAC-hours) and volunteers (7.35 MAC-hours) resulted in postanesthesia serum fluoride in concentrations that did not differ from background fluoride ion concentrations. Similarly, postanesthetic urinary excretion of fluoride ion and organic fluoride in volunteers was comparable to preanesthetic excretion rates. Small but statistically significant levels of trifluoroacetic acid were found in both serum and urine from volunteers after exposure to desflurane. Peak serum concentrations averaging 0.38 ± 0.17 μM trifluoroacetic acid (mean ± SD) and peak urinary excretion rates averaging 0.169 ± 0.107 μmol/h were detected in volunteers 24 h after desflurane exposure. Although these increases in trifluoroacetic acid after exposure to desflurane were statistically significant, they are approximately 10-fold less than levels seen after exposure to isoflurane. Desflurane strongly resists biodegradation, and only a small amount is metabolized in animals and humans.

(Anesth Analg 1992;75:S10–6)

Desflurane (formerly I-653) has several desirable characteristics, including the capacity to produce rapid induction and emergence and flexibility in adjusting depth of anesthesia (1–5). Another desirable attribute of a volatile anesthetic is that the compound should resist biotransformation and be devoid of organ-specific toxicity (1). One might predict that desflurane would be a relatively stable molecule, as it differs from isoflurane (relatively resistant to degradation) only by substitution of a fluorine atom for a chlorine atom. Fluorine substitution for other halogens generally tends to increase biologic stability. Such stability is reflected in vitro by increased resistance by desflurane to degradation by soda lime compared with other volatile anesthetics (6).

Metabolism of desflurane is of interest because of potential connections between metabolism and toxicity. Toxicity might result from generation of fluoride ion after metabolic breakdown (e.g., impaired renal function) (7) or from breakdown products that covalently bind to proteins and lipids (e.g., hepatic toxicity) (8). The metabolism of desflurane has been examined both in animals and humans. The animal studies allow control of variables (e.g., diet, medications) that are difficult or impossible to control in the perioperative clinical setting and also allow modeling of various conditions (e.g., induction of liver enzymes) that might promote biotransformation. Studies in humans are also required, because marked species differences may exist in drug metabolism (9). Safety of an anesthetic in animals does not ensure safety in humans.

Animal Studies

In rats, serum fluoride ion concentration was measured after administration of desflurane (I-653) for 2 h at an inspired concentration of 1.6 MAC (10) (Figure 1). Rats were either not pretreated or were pretreated with phenobarbital (1 mg/mL in drinking water for 5 days) or ethanol (16% [vol/vol] in drinking solution for 14 days) to induce production of liver enzymes. Rats pretreated with phenobarbital exhibited a small but statistically significant increase in serum fluoride

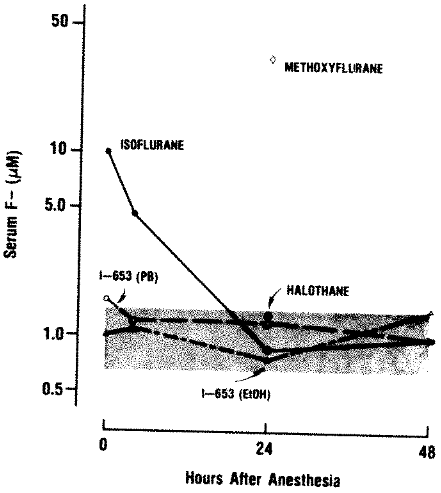

Figure 1. Serum concentrations of fluoride ion in rats pretreated with phenobarbital (PB) or ethanol (EtOH) and anesthetized with 1.6 MAC desflurane (I-653) for 2 h. The shaded rectangular area represents the mean value (1.0 μM) ± SD (0.37 μM) of serum fluoride ion in control rats pretreated with phenobarbital but not exposed to anesthetic. For animals given desflurane, only the value measured immediately after exposure (1.6 ± 0.5 μM; $n = 8$) in the phenobarbital-pretreated rats significantly differed from control. Serum fluoride concentrations achieved after exposure of phenobarbital-pretreated rats to isoflurane, halothane, and methoxyflurane are from data in Koblin et al. (10).

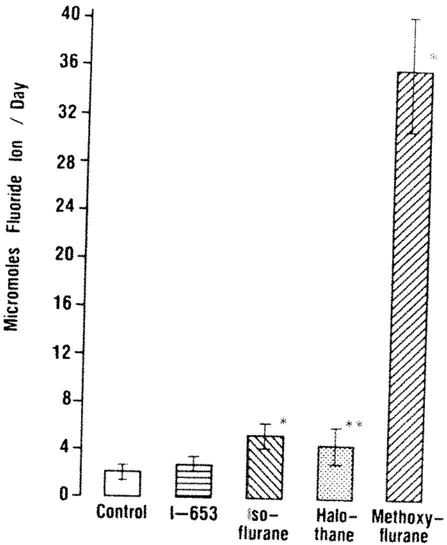

Figure 2. Twenty-four-hour excretion of fluoride ion in urine of rats pretreated with phenobarbital and anesthetized with 1.6 MAC desflurane (I-653), isoflurane, halothane, or methoxyflurane for 2 h. Control rats were pretreated with phenobarbital but not exposed to anesthetic. Error bars represent ± SD. *$P < 0.001$; **$P < 0.05$. (Figure constructed from data in Koblin et al. [10].)

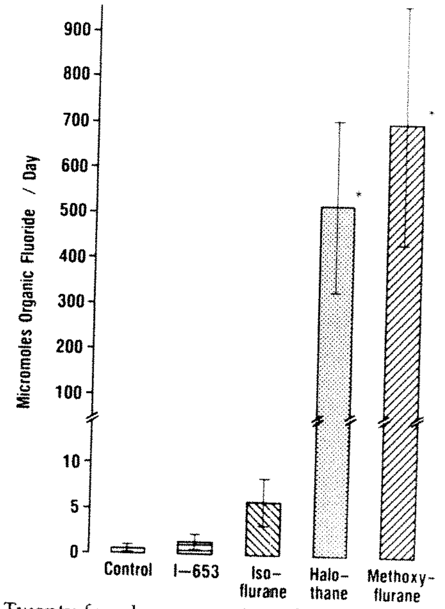

Figure 3. Twenty-four-hour excretion of nonvolatile organic fluoride in urine of rats pretreated with phenobarbital and anesthetized with 1.6 MAC desflurane (I-653), isoflurane, halothane, or methoxyflurane for 2 h. Control rats were pretreated with phenobarbital but not exposed to anesthetic. Error bars represent ± SD. Note discontinuity in ordinate for halothane and methoxyflurane. *$P < 0.001$. (Figure constructed from data in Koblin et al. [10].)

ion concentration immediately after, but not 4, 24, or 48 h after, desflurane exposure (10) (Figure 1). No increased fluoride ion could be detected in the serum of either nonpretreated or ethanol-pretreated rats after desflurane exposure (Figure 1). Rats pretreated with phenobarbital and given 1.6 MAC isoflurane for 2 h had peak serum levels of fluoride ion seven- to tenfold higher than unanesthetized control rats or rats given desflurane for an equivalent number of MAC-hours. Marked increases in serum fluoride ion also occurred after exposure to methoxyflurane (Figure 1). Urinary excretion of fluoride ion was not significantly increased in rats pretreated with phenobarbital and exposed to desflurane, whereas urinary fluoride ion excretion did increase after exposure to the other volatile agents (Figure 2). Similarly, urinary excretion of nonvolatile organic fluoride in rats pretreated with phenobarbital was not elevated in rats given desflurane (Figure 3). Rats pretreated with ethanol and exposed to desflurane demonstrated 24-h excretion of urinary organic fluoride nearly ten times greater than in controls (10).

In swine, fluoride ion concentrations were measured in plasma samples taken before, immediately after, and 4 h after exposure to either desflurane or isoflurane (11). Each anesthetic was administered at concentrations between 0.7 and 1.6 MAC to a total dose of approximately 5.5 MAC-hours for each agent. Plasma fluoride ion concentrations immediately after and 4 h after exposure to isoflurane were approximately 300% greater than values obtained in awake swine before anesthesia (Figure 4). In contrast, swine given desflurane had no detectable elevations in plasma fluoride concentration immediately after an-

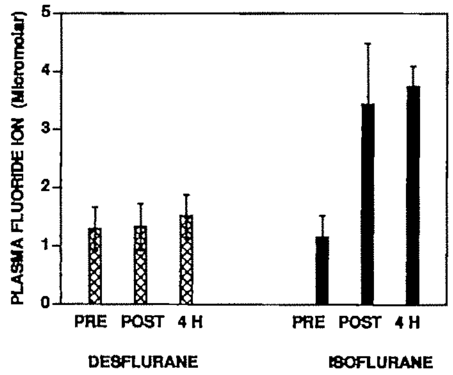

Figure 4. Plasma concentrations of fluoride ion in swine before (PRE), immediately after (POST), and 4 h after anesthesia with desflurane or isoflurane for 5.5 MAC-hours. For desflurane, the value for 4 h after anesthesia (1.51 ± 0.36 μM; n = 8) was significantly higher than that obtained in awake swine before anesthesia (1.29 ± 0.37 μM). Error bars represent ± SD. (Figure constructed from data in Koblin et al. [11].)

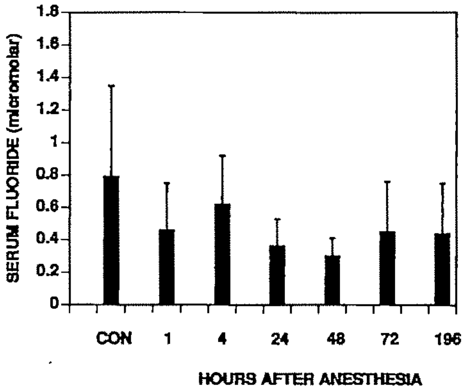

Figure 5. Serum concentrations of fluoride ion in 10 young male human volunteers before anesthesia (CON) and at various times after anesthesia with desflurane (average concentration of 3.6% administered for approximately 90 min). No value after anesthesia differed significantly from before anesthesia. Means are given. Error bars represent + SD. (Figure constructed from data in Jones et al. [17].)

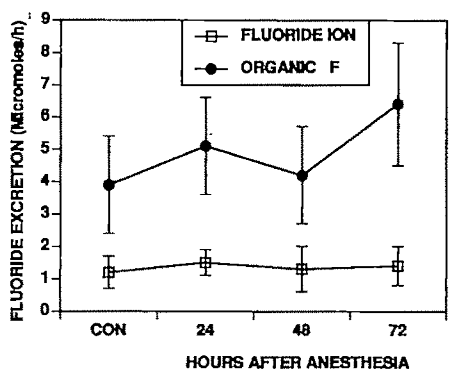

Figure 6. Excretion of fluoride ion and nonvolatile organic fluoride in urine of volunteers before anesthesia (CON) and at 24, 48, and 72 h after anesthesia with desflurane (average concentration 3.6% administered for approximately 90 min). No value after anesthesia differed significantly from before anesthesia. Means are given. Error bars represent ± SD. (Figure constructed from data in Jones et al. [17].)

esthesia but had a (significant) 17% increase in plasma fluoride ion concentration 4 h after anesthesia (Figure 4).

In vitro, the biotransformation of desflurane in a guinea pig liver slice culture system was minimal, with sixfold less fluoride ion produced from desflurane than from isoflurane (12). These results are consistent with the findings in rats and indicate that desflurane is metabolized less than isoflurane.

The resistance of desflurane to metabolic breakdown is associated with a lack of tissue toxicity. In rats pretreated with phenobarbital and exposed for 1 h to 12% O_2 and no anesthesia (control) or to 1.2 MAC desflurane, isoflurane, or halothane, no hepatic injury occurred in control rats or those given desflurane (13). In contrast, 100% of the halothane-exposed and 20% of the isoflurane-exposed rats had hepatic injury (13). No tissue damage in brain, pituitary, lung, heart, duodenum, pancreas, kidney, or liver attributable to desflurane could be detected in rats given a total of six 2-h exposures over two consecutive weeks to 1.6 MAC desflurane in oxygen (14). In swine receiving 5.5 MAC-hours of desflurane (or isoflurane) with or without several anesthetic adjuvants, no elevation in plasma alanine aminotransferase activities was detected immediately after anesthesia or 1 day after or 4–7 days after desflurane, again implying that desflurane did not cause hepatic injury (15). In a guinea pig liver slice culture system, 2.2 mM desflurane caused a mild reduction in tissue K^+ content and decreased protein synthesis (12). The effects of desflurane were less than those of isoflurane (12). The concentration (2.2 mM) of desflurane used in these studies was relatively high, corresponding to a partial pressure of approximately 25% of 1 atm, or approximately four times MAC (16).

Human Studies

The first studies to test for possible metabolic breakdown of desflurane in humans were performed by Jones et al. (17). Ten volunteers exposed to an average concentration of 3.6% desflurane for approximately 90 min exhibited no increases in serum fluoride ion (Figure 5) or in urinary fluoride excretion (Figure 6). These initial studies in humans did not provide evidence for the metabolism of desflurane, but they may not have constituted a sufficient test because of the limited duration and concentrations of desflurane that were applied. The studies were repeated in volunteers given prolonged exposure to desflurane, sometimes at high concentrations (18). Trifluoroacetic acid, a sensitive marker of desflurane metabolism that was not assayed in the early studies,

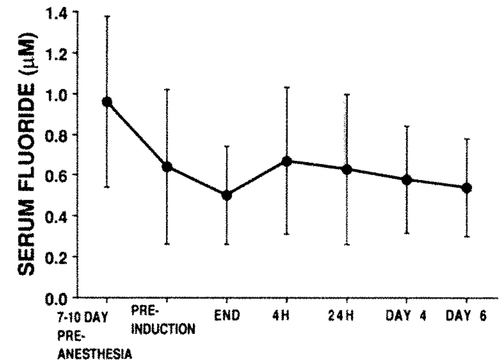

Figure 7. Serum fluoride ion concentrations in volunteers anesthetized with desflurane (7.35 ± 0.81 MAC-hours). Values were obtained 7–10 days before anesthesia ($n = 12$); immediately before anesthesia ($n = 13$); at end of anesthesia ($n = 8$); and at 4 h ($n = 12$), 24 h ($n = 13$), 4 days ($n = 13$), and 6 days ($n = 13$) after anesthesia. Error bars indicate ± SD. There was no statistically significant change between preanesthetic and postanesthetic concentrations of serum fluoride ion. (Reproduced from Sutton et al. [18] with permission from the International Anesthesia Research Society.)

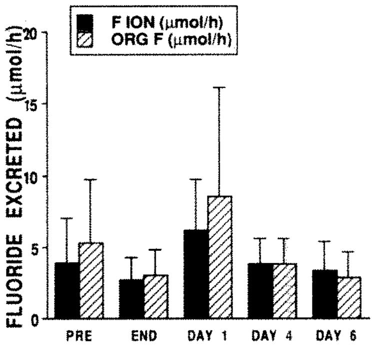

Figure 8. Urinary excretion rates of fluoride ion and organic (ORG) fluoride in volunteers anesthetized with desflurane (7.35 ± 0.81 MAC-hours). Values were obtained 7–10 days before anesthesia ($n = 11$); at end of anesthesia ($n = 5$); and at 24 h ($n = 13$), 4 days ($n = 13$), and 6 days ($n = 12$) after anesthesia. Error bars indicate + SD. There was no statistically significant change between preanesthetic and postanesthetic urinary excretion rates of either fluoride ion or organic fluoride. (Reproduced from Sutton et al. [18] with permission from the International Anesthesia Research Society.)

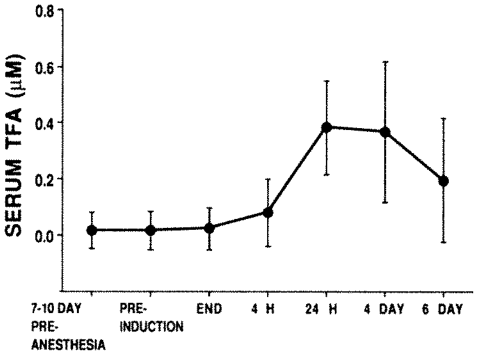

Figure 9. Serum trifluoroacetic acid (TFA) concentrations in volunteers anesthetized with desflurane (7.35 ± 0.81 MAC-hours). Values were obtained 7–10 days before anesthesia ($n = 12$); immediately before anesthesia ($n = 13$); at the end of anesthesia ($n = 9$); and at 4 h ($n = 11$), 24 h ($n = 13$), 4 days ($n = 13$), and 6 days ($n = 13$) after anesthesia. Error bars indicate ± SD. Trifluoroacetic acid levels were significantly elevated, maximal (0.38 ± 0.17 μmol/L) at 24 h after anesthesia, and remained significantly elevated above background at 6 days after desflurane anesthesia. (Reproduced from Sutton et al. [18] with permission from the International Anesthesia Research Society.)

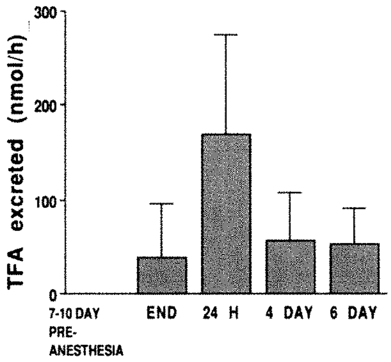

Figure 10. Urinary excretion rates of trifluoroacetic acid (TFA) in volunteers anesthetized with desflurane. Values were obtained at 7–10 days before anesthesia ($n = 12$); at the end of anesthesia ($n = 7$); and at 24 h ($n = 13$), 4 days ($n = 13$), and 6 days ($n = 11$) after anesthesia. Error bars indicate + SD. The excretion rate of trifluoroacetic acid was significantly elevated above background just after anesthesia. The excretion rate was maximal (0.169 ± 0.107 μmol/h) at 24 h after anesthesia and remained significantly increased 6 days after anesthesia. (Reproduced from Sutton et al. [18] with permission from the International Anesthesia Research Society.)

was measured after prolonged exposure to desflurane (18).

Thirteen volunteers anesthetized with desflurane for an average of 6.81 ± 0.55 h (±SD) (total dose of desflurane of 7.35 ± 0.81 MAC-hours) did not increase postanesthesia serum fluoride ion concentrations compared with background levels (18) (Figure 7). Also, urinary excretion of fluoride ion and organic fluoride in these volunteers did not significantly increase after prolonged exposure to desflurane (Figure 8). Trifluoroacetic acid did appear in the serum of volunteers exposed to desflurane (Figure 9). Serum trifluoroacetic acid levels were significantly elevated 24 h after desflurane exposure and remained elevated in 6 of 13 volunteers 6 days after desflurane exposure (Figure 9). Urinary excretion of trifluoroacetic acid increased significantly above a nondetectable background rate in volunteers (Figure 10). This increase was detected in four volunteers immediately after desflurane anesthesia and was found in all volunteers 24 h after anesthesia. Urinary excretion of trifluoroacetic acid was maximal 24 h after desflurane anesthesia and was still evident 6 days after anesthesia (Figure 10).

Patients were given desflurane without increasing fluoride ion levels in serum. In 26 ASA physical status I and II patients given desflurane for an average of 3.08 MAC-hours, concentrations of fluoride ion in serum immediately after the operation and on postoperative days 1 and 3 did not differ from values obtained before anesthesia (18). These results were confirmed in a separate study in which 12 patients were given desflurane for approximately 2 MAC-hours with no detectable increases in plasma fluoride immediately after surgery compared with the preoperative levels (19).

The resistance of desflurane to biodegradation is also apparent in isolated human tissue. Microsomes prepared from livers of organ donors were examined for capacity to defluorinate methoxyflurane, sevoflurane, enflurane, isoflurane, and desflurane (20). Of these volatile agents, the least amount of fluoride production was seen with desflurane (20).

Humans given desflurane exhibited no evidence of tissue toxicity. Liver function tests (serum levels of total and unconjugated bilirubin, alanine aminotransferase, aspartate aminotransferase, alkaline phosphatase, and γ-glutamyltranspeptidase) were unchanged in volunteers (17) and patients (21). Renal function tests (urinalysis, plasma urea, plasma creatinine, creatinine clearance, and excretion of retinol-binding protein and β-*N*-acetyl-D-glucosaminidase) also remained normal after desflurane given to volunteers (17) and patients (21).

Discussion and Conclusion

The close structural resemblance of desflurane to isoflurane makes it reasonable to expect desflurane metabolism to resemble that of isoflurane. Isoflurane metabolism is thought to involve breakdown by cytochrome P-450 to yield fluoride ion and certain organofluorine products that may be ultimately converted to trifluoroacetic acid (22). Thus, if desflurane is metabolized, increased amounts of fluoride ion and organic fluoride products (specifically trifluoroacetic acid) should appear in blood and urine after exposure.

Increased blood concentrations of fluoride ion after desflurane anesthesia could only be detected in phenobarbital-pretreated rats immediately after anesthetic exposure (Figure 1) and in nonpretreated swine 4 h after desflurane anesthesia (Figure 4). These increases, though significant, were small. No increased serum fluoride levels could be detected in humans given desflurane (Figures 5 and 7). Definitive evidence for metabolism of desflurane in humans is provided by appearance of trifluoroacetic acid in serum (Figure 9) and in urine (Figure 10) after desflurane exposure.

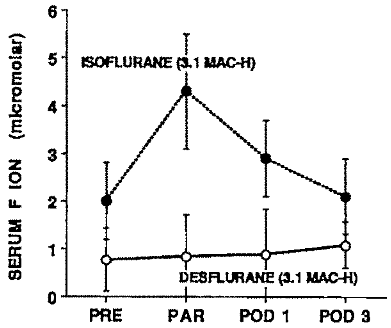

Figure 11. Serum fluoride ion concentrations in patients anesthetized with desflurane from Sutton et al. (18) compared with Mazze et al. (23), where patients were anesthetized with isoflurane. Error bars indicate ± SD. Serum fluoride levels were increased above background after exposure to isoflurane. There was no significant increase in serum fluoride ion concentrations after exposure to desflurane. PRE, before anesthesia; PAR, postanesthesia recovery; POD, postoperative day. (Reproduced from Sutton et al. [18] with permission from the International Anesthesia Research Society.)

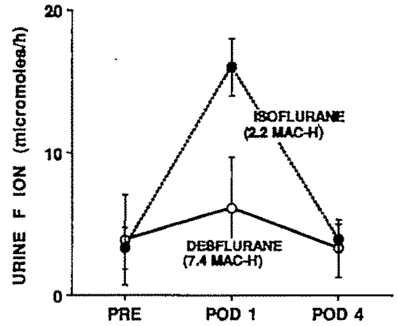

Figure 12. Urinary excretion rates of fluoride ion in volunteers receiving desflurane from Sutton et al. (18) compared with Hitt et al. (24), where patients were anesthetized with lower average doses of isoflurane. Error bars indicate ± SD. Fluoride ion excretion rate increased above background after isoflurane exposure. There was no significant increase in urinary fluoride ion excretion rate after desflurane exposure. (Reproduced from Sutton et al. [18] with permission from the International Anesthesia Research Society.)

Inability to detect elevated levels of fluoride ion in serum and urine after desflurane exposure contrasts with the findings of previous studies of isoflurane (23,24), which demonstrated elevated concentrations of fluoride ion in serum (Figure 11) and urine (Figure 12) of surgical patients. Higher concentrations of fluoride ion in urine were found after anesthesia with isoflurane, even though lower average doses of isoflurane (24) than desflurane were administered (Figure 12). Smiley et al. (19) reported a significant increase in plasma fluoride ion concentration at the end of an operation in patients receiving isoflurane but not in those receiving desflurane, suggesting that desflurane resists biodegradation more than isoflurane.

Mean serum trifluoroacetic acid concentrations (Figure 9) and mean urine trifluoroacetic acid excretion rates (Figure 10) in volunteers at 24 h, 4 days, and 6 days after exposure to desflurane were significantly elevated, with a peak mean serum concentration of 0.38 μM at 24 h. This serum trifluoroacetic acid concentration after desflurane anesthesia is approximately 1000-fold lower than the concentration of approximately 500 μM achieved after the administration of 0.44%–1.57% end-expired halothane for 2 h to patients undergoing intraabdominal surgery (25). Comparison with isoflurane is difficult because only limited data are available for trifluoroacetic acid production after isoflurane administration in humans. In patients who have received isoniazid, peak serum trifluoroacetic acid concentrations are on the order of 10 μM after isoflurane anesthesia (26). The peak mean excretion rate of trifluoroacetic acid in urine after exposure to desflurane (0.169 μmol/h [Figure 10]) is approximately 100-fold less than that observed after exposure of patients to lower average doses of isoflurane (approximately 50 μmol/h [23]).

The findings in selected animal and human studies of slight increases in fluoride ion or trifluoroacetic acid levels above background after exposure to desflurane demonstrate that a small degree of metabolism does occur. This presumes that extent of anesthetic metabolism is proportional to serum fluoride ion, organic fluoride, and trifluoroacetic acid concentrations in serum and urine. Although this assumption is reasonable, it is possible that higher levels of metabolites might have resulted under conditions that promote synthesis of hepatic microsomal enzymes. For example, in rats pretreated with ethanol (10), excretion of nonvolatile organic fluoride in urine for 1 day after desflurane exposure was approximately ten times greater than control. The possibility also remains that desflurane degradation products could be sequestered (e.g., in bone or liver), or covalently bind to tissues and not appear in blood, or that breakdown products are excreted by the lungs rather than in serum or urine. Such processes do not occur to a large extent, because mass balance studies performed in human volunteers demonstrate complete recovery of desflurane (27).

Low levels of fluoride metabolites in serum and urine after desflurane anesthesia suggest, but do not prove, that desflurane is unlikely to be tissue toxic. This has been confirmed in animal (12–15) and human studies (17,21). A theoretical potential for desflurane hepatotoxicity by cross-sensitivity with other inhaled anesthetics cannot be excluded (8). The mechanism of cross-sensitivity might be production of low levels of trifluoroacetic acid after desflurane administration, with subsequent covalent reaction between trifluoroacetic acid and protein to form hapten (antigen) (Figure 13). If a patient previously received a different volatile anesthetic (e.g., halothane, isoflurane) that undergoes metabolism to trifluoroacetic acid, and if that resulted in antibodies directed against trifluoroacetyl antigens, then these antibodies could theoretically react against newly formed trifluoroacetyl antigens after hepatic degradation of desflurane and cause liver damage (8). This possibility is extremely remote and has yet to be demonstrated for isoflurane.

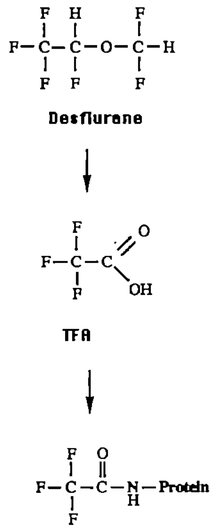

Figure 13. Theoretical production of trifluoroacetyl protein hapten (antigen) after hepatic degradation of desflurane to trifluoroacetic acid (TFA).

DISCUSSION

DR. RONALD D. MILLER (San Francisco): At what point do problems occur with production of fluoride metabolites; that is, at what point do they not occur? Do we have problems with isoflurane in this regard?

DR. DONALD D. KOBLIN (San Francisco): Isoflurane is thought to produce minimal effects from its metabolism, but such effects are possible. For instance, in a recently published article (Murray et al., Anesth Analg 1992;74:236–40), plasma fluoride concentrations during and after prolonged exposure to isoflurane (19 MAC-hours) reached as high as 70 μmol in the serum, a concentration that is associated with nephrotoxicity. Although there was no clinical evidence of renal dysfunction in that report, you become concerned at those fluoride ion concentrations.

DR. JERROLD LERMAN (New York): I take exception to the suggestion that a single plasma or serum level of fluoride ion is associated with nephrotoxicity. I think from a pharmacologic point of view, we are concerned about the area under the concentration-time profile (i.e., how long the kidney is exposed to various concentrations of fluoride ion), not isolated peak values.

DR. ROBERT G. MERIN (Houston): Sensitivities to fluoride ion levels vary. What you really need is an antidiuretic hormone (ADH) challenge test as a sensitive method to detect renal dysfunction. I do not believe there has been a clinically proved case of nephrogenic diabetes insipidus with enflurane. My question is, what about the possible formation of a hapten when trifluoroacetic acid reacts with proteins? Is that something we have to be concerned about? Are we back to halothane-type concerns?

DR. EDMOND I. EGER II (San Francisco): With regard to Dr. Lerman's comment, the area under the curve and peak height of serum fluoride concentrations are both inadequate measures. Obviously, if kidney damage were only related to the area under the curve, we would all be in trouble, because we are chronically exposed to levels of anywhere from 1 to 5 μM fluoride ion. So it cannot simply be area under the curve. As has been pointed out, it cannot simply be due to the peak concentration achieved. In answer to the comment that enflurane nephrotoxicity has never really been shown; I agree that it has not. With desflurane, I do not think it is nephrotoxicity that should concern us; rather, it is hepatotoxicity. Direct hepatotoxicity from desflurane is unlikely, because there simply is not a sufficient amount broken down. On the other hand, because trifluoroacetic acid results from desflurane metabolism, a risk could be that of hapten formation. As Dr. Merin implied, the amount of hapten that is likely to be formed from desflurane metabolism surely is less than that from isoflurane, and he questions whether there has ever been a valid case of isoflurane-induced hepatotoxicity. Although there has not yet been a definitive study, I think we can say that to date we have not found a proved case of isoflurane hepatotoxicity. If it is that rare with isoflurane, we are likely to have trouble finding a case with desflurane if the hepatotoxicity is related to the combination of trifluoroacetic acid with protein.

DR. CHARLES COTÉ (Boston): There are circumstances where prolonged anesthesia will take place. In our hospital we perform finger reimplants that can last anywhere from 12 to 48 h. Almost always, these patients are anesthetized with a potent agent because of the projected duration of surgery and because we do not want to administer large amounts of narcotic. As another example, there are reports of using potent agents to treat refractory status epilepticus as well as refractory status asthmaticus.

DR. KOBLIN: There have been studies in which isoflurane was administered for up to 2 days to control convulsive status epilepticus refractory to standard therapy (Kofke et al. Anesthesiology 1989;71:653–9). Serum fluoride concentrations measured in those studies were on the order of 10 μM and were without clinically apparent adverse effects.

Cardiovascular and Respiratory Actions of Desflurane: Is Desflurane Different From Isoflurane?

David C. Warltier, MD, PhD, and Paul S. Pagel, MD

Departments of Anesthesiology, Pharmacology, and Medicine, Medical College of Wisconsin, and Zablocki Veterans Administration Medical Center, Milwaukee, Wisconsin

The cardiovascular and respiratory effects of desflurane are reviewed. In experimental animals, desflurane has been shown to produce hemodynamic effects comparable to those produced by isoflurane. Desflurane increases heart rate and decreases both mean arterial pressure and systemic vascular resistance while maintaining cardiac output. In some but not all studies, desflurane has appeared to maintain arterial pressure and systemic vascular resistance to a somewhat greater degree than equianesthetic concentrations of isoflurane. Otherwise, desflurane and isoflurane produce strikingly similar effects on systemic, coronary, renal, hepatic, and cerebral circulation. In addition, desflurane and isoflurane have nearly identical actions on a variety of indices of left ventricular systolic and diastolic function. Although desflurane may cause coronary vasodilation in dogs, no evidence of "coronary steal" has been observed in a canine model of multivessel coronary artery disease. In humans, desflurane produces alterations in systemic hemodynamics that have many similarities to those produced in animals. No differences between the cardiovascular actions of desflurane and isoflurane have been identified in volunteers during spontaneous or controlled ventilation with and without nitrous oxide. Desflurane and isoflurane also produce similar hemodynamic effects during induction and maintenance of anesthesia in a wide variety of clinical settings. To date, no direct evidence of desflurane-related myocardial ischemia or increased cardiovascular morbidity has been observed in patients with coronary artery disease. Desflurane depresses ventilation in animals and humans. Dose-related decreases in tidal volume and increases in respiratory rate, arterial carbon dioxide tension, dead space/tidal ventilation ratio, and intrapulmonary shunt fraction have all been observed in volunteers. These effects are similar to those produced by other currently used volatile anesthetics, including isoflurane. Desflurane, like isoflurane, also appears to be a mild respiratory irritant. Thus, the cardiorespiratory effects of the new volatile anesthetic, desflurane, are remarkably similar to those produced by isoflurane.

(Anesth Analg 1992;75:S17–31)

Desflurane (difluoromethyl-1-fluoro-2,2,2-trifluoroethyl ether [I-653]) is the first new volatile anesthetic to undergo clinical trials in the United States in almost 20 yr. A structural analogue of isoflurane, desflurane possesses remarkable metabolic stability (1–4) and has very low blood- and tissue-gas partition coefficients (5,6), which may facilitate rapid anesthetic induction, alterations in anesthetic depth, and emergence. The hemodynamic actions of desflurane and its effects on respiratory function have been explored in experimental animals and in humans over the past 4 yr. The purpose of this review is to summarize those investigations describing the cardiovascular and respiratory actions of desflurane and to compare and contrast these effects with those produced by isoflurane.

Cardiovascular Actions of Desflurane in Experimental Animals

Using chronically instrumented swine mechanically ventilated to maintain normocarbia, Weiskopf et al. (7) examined the cardiovascular effects of desflurane at end-tidal concentrations of 0.8, 1.2, and 1.6 MAC and directly compared these effects to those produced by near-equianesthetic concentrations of isoflurane. Desflurane caused an increase in heart rate that was greatest at 0.8 MAC, with dose-related decreases in mean arterial pressure. Cardiac output was maintained at the low concentration of desflurane but decreased in dose-related fashion at 1.2 and 1.6 MAC. Decreased systemic vascular resistance

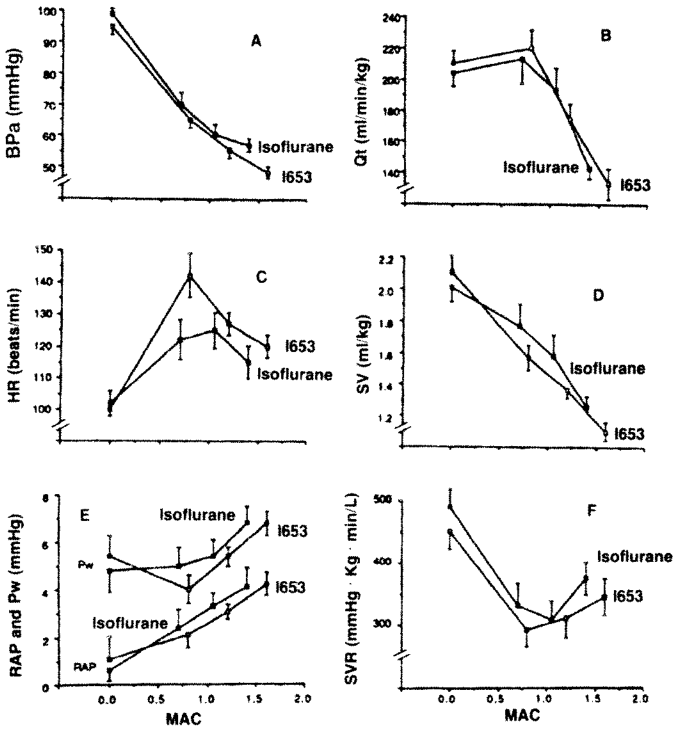

Figure 1. Hemodynamic effects of desflurane (I-653) (*open squares*) and isoflurane (*solid squares*) in chronically instrumented swine: **(A)** mean aortic blood pressure (BPa); **(B)** cardiac output (Qt); **(C)** heart rate (HR); **(D)** stroke volume (SV); **(E)** right atrial pressure (RAP) and pulmonary capillary wedge pressure (Pw); **(F)** systemic vascular resistance (SVR). (Modified from original figure of Weiskopf et al. [7]. With permission of authors and publisher.)

(SVR) was observed at the lowest concentration but was not further depressed at higher concentrations. Right atrial pressure and pulmonary capillary wedge pressure increased dose dependently (Figure 1). This implied depression of systemic hemodynamics and myocardial function; however, desflurane did not affect overall tissue perfusion, because oxygen transport and consumption and mixed venous oxyhemoglobin saturation were essentially unchanged from the conscious state at all levels of anesthetic depth. In addition, no alterations in base excess or blood lactate levels were observed during desflurane anesthesia, consistent with maintenance of adequate cellular perfusion. The cardiovascular effects of desflurane were not distinguishable from those produced by near-equianesthetic isoflurane concentrations.

Weiskopf et al. (8) subsequently explored the cardiovascular safety of high concentrations of desflurane and isoflurane in swine. Using the ratio of lethal to anesthetic concentration as an index of margin of safety, the authors determined that the ratio of fatal anesthetic concentration to MAC for desflurane was less (2.5) than the ratio for isoflurane (3.0) but greater than the ratio reported for halothane (2.0) (9). They speculated that the concentration of desflurane producing cardiovascular collapse was greater than that resulting in apnea, and thus cardiovascular compromise during spontaneous ventilation was considered unlikely. The dose-response relationships produced by desflurane and isoflurane for heart rate, mean aortic blood pressure, and cardiac output were similar except in concentrations >1.5 MAC, where these variables were better maintained with isoflurane than with desflurane. This study suggested that desflurane may produce more profound cardiovascular depression than isoflurane when administered in concentrations >1.5 MAC. As in the previous investigation (7), however, mixed venous oxyhemoglobin saturation and the ratio of oxygen transport to oxygen consumption remained constant in both groups up to 2 MAC and decreased only when the anesthetic concentration was increased to near-fatal concentrations, indicating that compromise of tissue perfusion occurred only at very high concentrations of either agent.

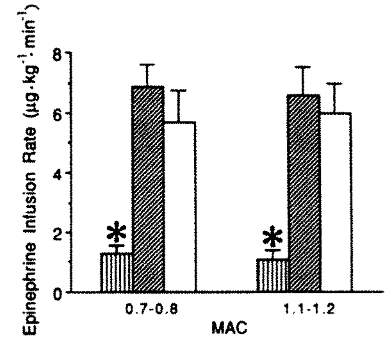

Figure 2. Intravenous infusion rates of epinephrine required to produce greater than three premature ventricular contractions per minute in swine anesthetized with desflurane (*hatched bar*), isoflurane (*open bar*), and halothane (*vertically striped bar*) at 0.7–0.8 and 1.1–1.2 MAC. Anesthetic concentration used did not alter rate of epinephrine infusion required to produce ventricular ectopy. *Significantly ($P < 0.05$) different from epinephrine infusion rate producing premature ventricular contractions in desflurane group. (Original figure from Weiskopf et al. [10]. Reproduced with permission of authors and publisher.)

Weiskopf et al. (10) investigated the arrhythmogenic potential of desflurane in response to administration of epinephrine in swine. The rate of infusion of epinephrine needed to cause premature ventricular contractions during anesthesia with desflurane was similar to that required during equianesthetic isoflurane anesthesia. Epinephrine infusions resulted in similar increases in mean arterial pressures and heart rate in both desflurane and isoflurane groups. Ventricular ectopy occurred at lower infusion rates of epinephrine when swine were anesthetized with halothane (Figure 2).

Weiskopf et al. (11) also studied the cardiovascular effects of drugs commonly administered during anesthesia in the presence of desflurane or isoflurane in swine. Atracurium, succinylcholine, and atropine plus edrophonium had no cardiovascular effects in swine anesthetized with 1.2 MAC desflurane or isoflurane. Fentanyl (50 and 100 μg/kg IV) caused no cardiovascular effects during either anesthetic, except for a modest increase in SVR at the high dose. Sixty percent nitrous oxide caused no cardiovascular changes during desflurane anesthesia but did increase SVR and decrease cardiac output and stroke volume during isoflurane anesthesia. Thiopental (2.5 and 5.0 mg/kg IV) decreased mean aortic blood pressure, cardiac output, stroke volume, and SVR during both anesthetics without altering heart rate or filling pressures. Naloxone (100 μg/kg IV) decreased SVR and increased cardiac output during both desflurane and isoflurane anesthesia but increased heart rate only during isoflurane anesthesia. In summary, anesthetic adjuvants used in usual clinical doses during desflurane anesthesia did not produce unexpected or potentially disadvantageous cardiovascular effects. Desflurane and isoflurane again produced similar hemodynamic alterations in both anesthetic groups.

The cerebral and systemic hemodynamic effects of desflurane in acutely instrumented dogs were reported in three investigations by Milde and coworkers (12–14). Desflurane was found to produce significant decreases in cerebrovascular resistance and increased cerebral blood flow consistent with cerebral vasodilation (12). Desflurane also caused dose-related decreases in mean arterial pressure and SVR with relative maintenance of cardiac index, supporting the findings of Weiskopf et al. (7) in swine. Similar hemodynamic actions were also observed in the response of canine cerebral circulation to hyperventilation during desflurane anesthesia (13). Desflurane also provided adequate cerebral perfusion to meet the demands of cerebral oxygen consumption during profound desflurane-induced hypotension (mean arterial pressure 40 mm Hg) (14). These parallel decreases in cerebral blood flow, and oxygen consumption, and maintenance of adequate cerebral perfusion were similar to those previously described for halothane and isoflurane (15,16); however, the systemic hemodynamic effects produced by desflurane differed from those previously reported (7,8,10–12). The decrease in mean arterial pressure observed by Milde and Milde (14) resulted primarily from decreased cardiac output and not reduced SVR. This relative maintenance of SVR occurred despite high end-tidal concentrations of desflurane (15.5% ± 0.3% [mean ± SEM]; 2.2 MAC) and suggested that desflurane-induced hypotension resembled that produced by halothane (15) and not isoflurane (16). This conclusion is not entirely consistent, however, because adequate tissue perfusion was maintained during desflurane-induced hypotension similar to findings observed during isoflurane-induced hypotension (16). These results are in contrast to those observed when halothane was used to decrease blood pressure, because anaerobic metabolism was observed at high halothane concentrations (15). No changes in heart rate occurred with desflurane administration in the investigation by Milde and Milde (14), in contrast to previous studies (7,8,10–12) that indicated that desflurane may inhibit baroreceptor reflex functions similar to halothane but not isoflurane. High baseline heart rates were observed in this acute experimental preparation that used neuromuscular blockade with pancuronium. Although the systemic hemodynamic effects of desflurane were not directly compared with those produced by isoflurane in this study (14), the results suggested that important differences may exist between these agents.

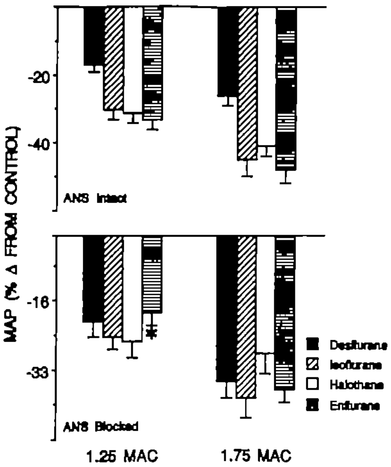

Figure 3. Histograms depicting effects of volatile anesthetics (1.25 and 1.75 MAC) on mean arterial pressure (MAP) in autonomically (ANS) intact versus blocked chronically instrumented dogs. All values significantly ($P < 0.05$) different from baseline conscious control. Desflurane reduced MAP less ($P < 0.05$) than isoflurane, enflurane, or halothane in ANS intact dogs (*upper panel*). Effect was abolished with ANS blockade (*lower panel*). *Significantly ($P < 0.05$) different from same anesthetic at same concentration in ANS intact dogs. (Original figure from Pagel et al. [17]. Reproduced with permission of authors and publisher.)

The systemic and coronary hemodynamic actions of desflurane were studied in the presence and absence of intact autonomic nervous system function and directly compared with the effects produced by isoflurane, halothane, and enflurane in chronically instrumented dogs in an investigation by Pagel et al. (17). Although many similarities between the hemodynamic effects of desflurane and isoflurane were identified, some differences between these anesthetics were noted as well. Desflurane maintained mean arterial pressure to a greater degree than did equianesthetic concentrations of isoflurane (up to 1.75 MAC) (Figure 3). Whereas isoflurane produced decreased SVR, no changes in resistance were ob-

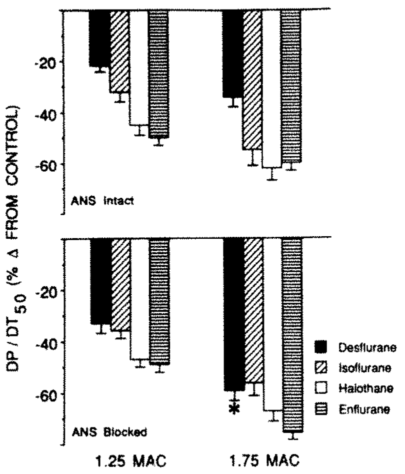

Figure 4. Histograms depicting effects of volatile anesthetics (1.25 and 1.75 MAC) on left ventricular dP/dt$_{50}$ (an index of myocardial contractility) in autonomically (ANS) intact versus blocked chronically instrumented dogs. All values are ($P < 0.05$) different from baseline conscious control. Desflurane reduced dP/dt$_{50}$ significantly less ($P < 0.05$) than isoflurane, halothane, or enflurane in ANS intact dogs (*upper panel*). Effect was abolished by ANS blockade (*lower panel*). *Significantly ($P < 0.05$) different from same anesthetic at same concentration in ANS intact dogs. (Original figure from Pagel et al. [17]. Reproduced with permission of authors and publisher.)

served with desflurane, supporting the findings of Milde and Milde (14). Desflurane appeared to maintain myocardial contractility, as assessed by left ventricular peak positive dP/dt and dP/dt$_{50}$ to a greater extent than did equianesthetic concentrations of isoflurane in dogs with intact autonomic nervous system function (Figure 4). These differences between isoflurane and desflurane were abolished with pharmacologic autonomic nervous system blockade (Figures 3 and 4), suggesting that desflurane may produce less depression of sympathetic tone and autonomic reflexes than isoflurane and therefore result in greater maintenance of mean arterial pressure and contractile function at similar levels of anesthetic depth. In general, desflurane also caused less cardiovascular depression than did equianesthetic concentrations of halothane or enflurane. Both desflurane and isoflurane also increased diastolic coronary blood flow velocity (measured with a Doppler ultrasonic flow transducer) and decreased diastolic coronary vascular resistance, indicating that desflurane, like isoflurane, but not halothane or enflurane, may produce coronary vasodilation. In contrast to isoflurane, when heart rate was prevented from increasing during autonomic nervous system blockade, desflurane caused no change in coronary flow.

Merin et al. (18), in a concurrent investigation, also examined the effects of desflurane and isoflurane on cardiovascular dynamics and regional blood flow in the chronically instrumented dog. They (18) demonstrated that desflurane and isoflurane produced nearly identical hemodynamic effects at several equianesthetic concentrations, including similar decreases in mean arterial pressure and myocardial contractility, as assessed by left ventricular peak positive dP/dt. These results were in contrast to the findings of Pagel et al. (17) in dogs but supported the observations of Weiskopf et al. (7,8,10,11) in swine. Merin et al. (18) also reported that desflurane and isoflurane produced similar increases in coronary blood flow and decreases in coronary vascular resistance. Desflurane maintained hepatic arterial flow (measured with a Doppler flow probe) and hepatic vascular resistance. In contrast, isoflurane produced an increase and decrease, respectively, in these variables. The combined total hepatic blood flow (portal plus hepatic arterial) was significantly decreased by desflurane at high concentrations, reflecting decreased portal flow. In contrast, total hepatic blood flow was unchanged by isoflurane. Neither desflurane nor isoflurane significantly affected renal blood flow; calculated renal vascular resistance was decreased by both anesthetics. The effects of desflurane on hepatic and renal perfusion have also been recently examined in our laboratory with use of radiolabeled microspheres (J. C. Hartman et al., unpublished data). Preliminary findings of this investigation support those reported by Merin et al. (18).

Because desflurane may produce mild coronary vasodilation similar to isoflurane, the theoretical potential exists for this new anesthetic to produce redistribution of coronary collateral blood flow away from ischemic myocardium ("coronary steal") during an increase in blood flow to normal zones (19). Hartman et al. (20) studied the effects of desflurane on regional distribution of myocardial blood flow (by the radioactive microsphere technique) in a chronically instrumented canine model of multivessel coronary artery disease. This investigation indicated that desflurane did not redistribute blood flow away from collateral-dependent myocardium to normal regions by a coronary steal mechanism when heart rate and mean arterial pressure were restored to postocclusion control levels (Figure 5). Similar results were obtained in previous investigations in this model with isoflurane (21,22) in direct contrast to use of adenosine, a potent coronary vasodilator that produces pronounced coronary steal despite correction of heart rate and mean arterial pressure to control values.

The effects of desflurane versus isoflurane on left ventricular mechanics during systole and diastole have been examined by Pagel et al. (23,24). Myocardial contractility was studied in chronically instrumented dogs with pharmacologic autonomic nervous system blockade (23). Contractility was evaluated by means of the preload recruitable stroke work versus

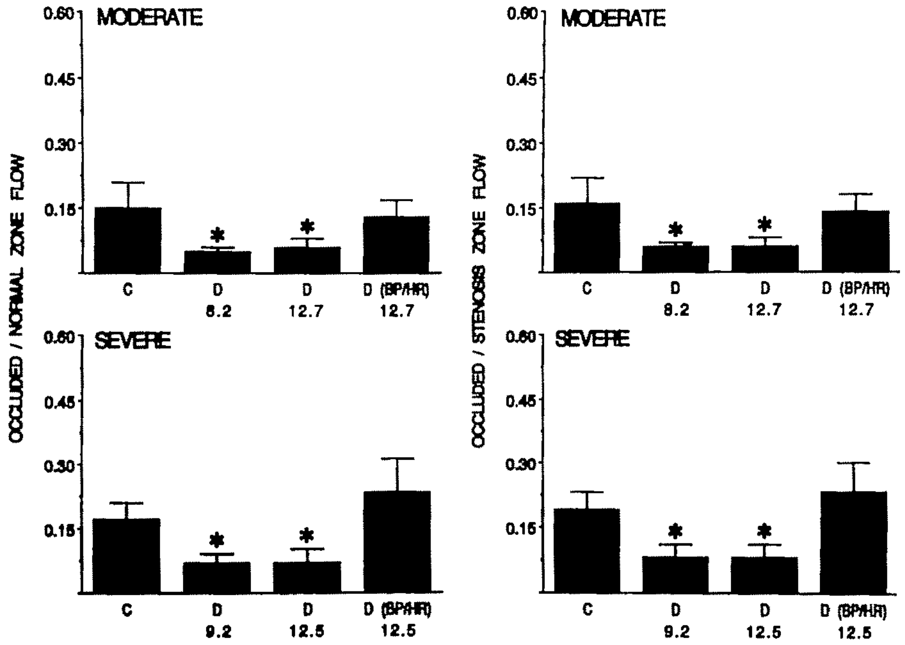

Figure 5. Occluded/normal zone (*left panels*) and occluded/stenotic zone (*right panels*) ratios of myocardial blood flow in chronically instrumented dogs with moderate (*top panels*) or severe (*bottom panels*) left circumflex coronary artery stenosis. Data obtained during conscious state (C), during two concentrations of desflurane (D), and with blood pressure and heart rate returned to levels present in conscious state (BP/HR) during high concentration of desflurane. *Significantly ($P < 0.05$) different from the conscious state. (Modified from original figures of Hartman et al. [20]. With permission from the International Anesthesia Research Society.)

end-diastolic segment length relationship, a linear and relatively afterload-insensitive extension of the Frank-Starling concept that has been shown to be a reliable index of inotropic state in conscious (25, 26) and anesthetized dogs (26). The preload recruitable stroke work versus end-diastolic segment length relationship was calculated from left ventricular pressure-segment-length loops generated by sequential constriction of the inferior vena cava with a hydraulic vascular occluder. The preload recruitable stroke work versus end-diastolic segment-length slope decreased similarly when equianesthetic concentrations of desflurane and isoflurane were administered, indicating equivalent direct decreases in myocardial contractility (Figure 6). Boban et al. (27), using isolated guinea pig hearts, recently demonstrated that desflurane and isoflurane produced similar degrees of myocardial depression in vitro.

The effects of desflurane, isoflurane, and halothane on left ventricular diastolic function in chronically instrumented dogs were also examined by Pagel et al. (24). Diastolic function has been shown to significantly influence systolic performance in several pathologic states, including ischemic heart disease, left ventricular hypertrophy, and cardiomyopathy (28–30). Using analysis of left ventricular pressure-segment-length loops, Pagel et al. (24) demonstrated that desflurane, isoflurane, and halothane prolonged isovolumetric relaxation to a similar extent, as evaluated with an invasively derived time constant of relaxation (Figure 7). In addition, although halothane impaired passive ventricular filling, desflurane and isoflurane had no effect on ventricular compliance (Figure 8). Thus, desflurane and isoflurane appeared to produce equivalent depression of ventricular function during diastole as well as systole.

In summary, although desflurane and isoflurane produce similar cardiovascular effects, some subtle differences between these agents were noted in experimental animals. Desflurane appeared to maintain mean arterial pressure to a greater degree than equianesthetic concentrations of isoflurane in some investigations (14,17). Isoflurane produced dose-related decreases in SVR consistent with peripheral vasodilation, but desflurane did not uniformly do so in acutely (14) and chronically instrumented dogs (17). Otherwise, the similarities in cardiovascular effects produced by these agents were striking (31). Desflurane and isoflurane produced nearly indistinguishable changes in systemic, coronary, renal, hepatic, and cerebral hemodynamics. Although desflurane may produce some degree of coronary vasodilation in dogs (17,18), no evidence of coronary steal was noted in a canine model of multivessel coronary artery disease (20). No differences between these agents were identified when left ventricular systolic and diastolic function were examined in vivo (23,24) and in vitro (27).

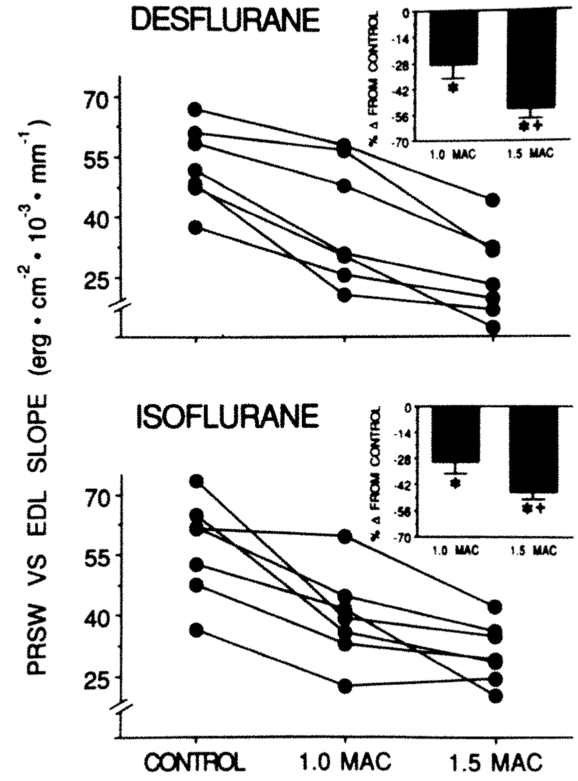

Figure 6. Preload recruitable stroke work (PRSW) versus end-diastolic segment length (EDL) slope for each chronically instrumented dog ($n = 7$) during conscious control and 1.0 and 1.5 MAC desflurane (*top panel*) and isoflurane (*bottom panel*). *Insets* depict data represented as percent change from control. *Significantly ($P < 0.05$) different from control. †Significantly ($P < 0.05$) different from 1.0 MAC. No differences were observed between desflurane and isoflurane groups at either anesthetic concentration. (Original figure from Pagel et al. [23]. Reproduced with permission of authors and publisher.)

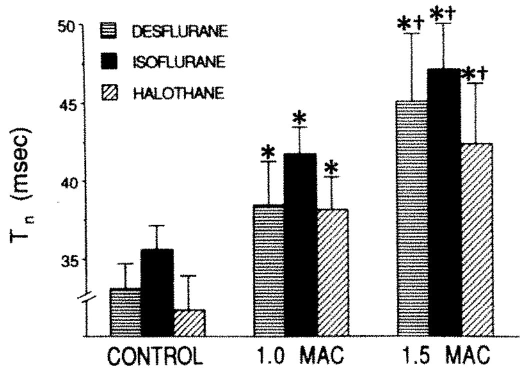

Figure 7. Histograms depicting effects of desflurane, isoflurane, and halothane on time constant of isovolumetric relaxation calculated assuming a nonzero asymptote of ventricular pressure decay (T_n) in chronically instrumented dogs with autonomic nervous system blockade. *Significantly ($P < 0.05$) different from the conscious control. †Significantly ($P < 0.05$) different from 1.0 MAC. No differences among desflurane, isoflurane, or halothane groups at either anesthetic concentration were observed. (Original figure from Pagel et al. [24]. Reproduced with permission of the authors and publisher.)

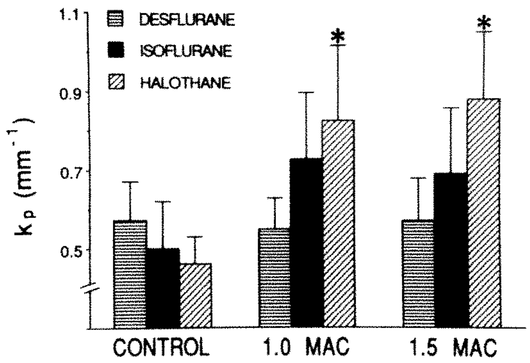

Figure 8. Histograms depicting effects of desflurane, isoflurane, and halothane on regional chamber stiffness (k_p, an index of ventricular compliance) in chronically instrumented dogs with autonomic nervous system blockade. *Significantly ($P < 0.05$) different from the conscious control. (Adapted from data of Pagel et al. [24]. With permission of authors and publisher.)

Cardiovascular Actions of Desflurane in Humans

Since the first report of the use of desflurane in humans by Jones et al. (32) in January 1990, numerous investigations have documented the hemodynamic effects of this new agent in a variety of clinical settings. Weiskopf et al. (33) studied the cardiovascular actions of desflurane in volunteers mechanically ventilated to maintain normocarbia. Desflurane caused dose-dependent decreases in mean arterial pressure and SVR and increases in right heart filling pressures and heart rate. These findings were similar to those described in earlier laboratory investigations from this group (7,8,10,11) and were also similar to the effects produced by isoflurane (Figure 9) when this agent underwent clinical trials (34). In addition, desflurane did not change cardiac index, left ventricular ejection fraction, or velocity of left ventricular circumferential fiber shortening (Vcfs), as assessed by echocardiography (Figure 10). These findings suggested that desflurane may produce less depression of myocardial contractility than other halogenated agents in humans. Mixed venous oxyhemoglobin saturation, oxygen consumption, and the ratio of oxygen transport to oxygen consumption remained constant in this study, indicating that desflurane maintained adequate tissue perfusion despite producing significant declines in perfusion pressure.

It has been established that duration of halothane and enflurane anesthesia affects hemodynamic profiles (35,36). Therefore, Weiskopf et al. (33) also studied the cardiovascular actions of desflurane after prolonged anesthesia (7 h). In general, prolonged anesthesia with desflurane resulted in less cardiovascular depression than during the first 90 min of anesthesia (33). Indices of cardiac filling, including

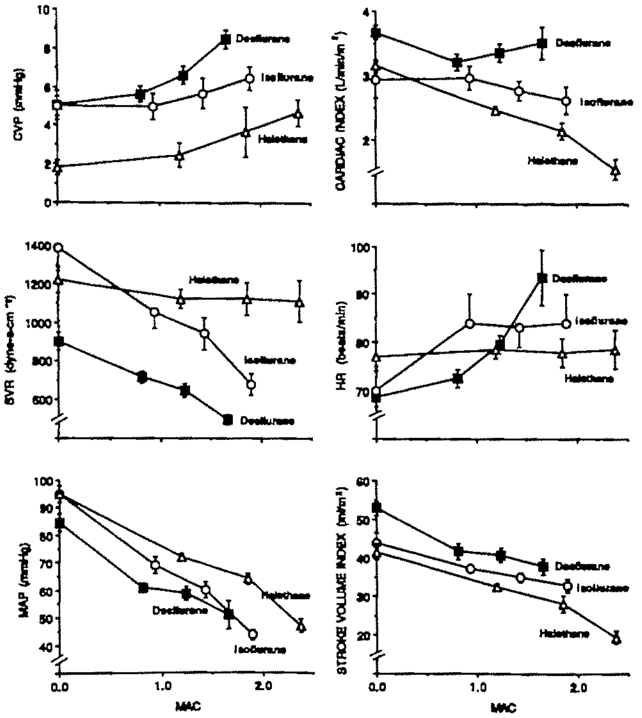

Figure 9. Central venous pressure (CVP), cardiac index, systemic vascular resistance (SVR), heart rate (HR), mean arterial pressure (MAP), and stroke volume index during conscious state (0 MAC) and during three steady-state concentrations of desflurane (33), isoflurane (34), and halothane (35) in three groups of healthy male volunteers. (Modified from original figure of Weiskopf et al. [33]. With permission from the International Anesthesia Research Society.)

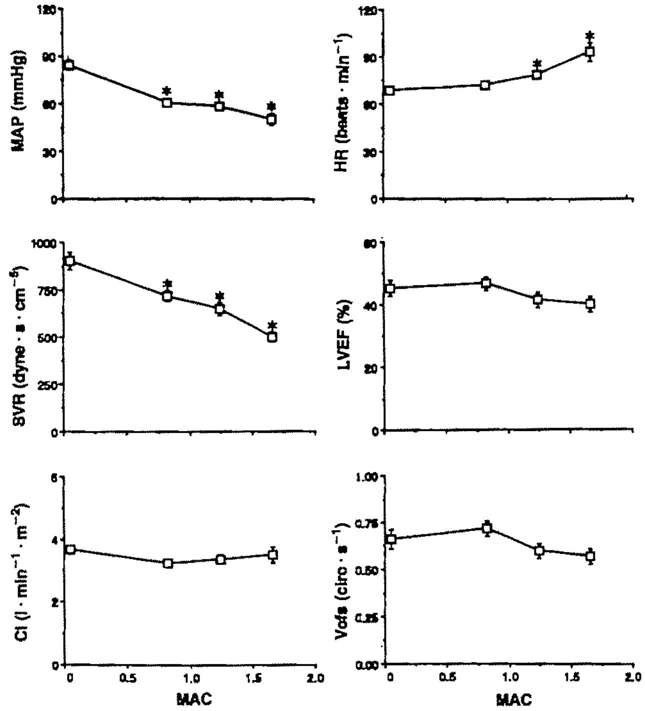

Figure 10. Mean arterial blood pressure (MAP), heart rate (HR), systemic vascular resistance (SVR), left ventricular ejection fraction (LVEF), cardiac index (CI), and velocity of left ventricular circumferential fiber shortening (Vcfs) during the conscious state (0 MAC) and during three steady-state concentrations of desflurane anesthesia in healthy male volunteers ($n = 12$). *Significantly ($P < 0.05$) different from conscious values. (Modified from original figures of Weiskopf et al. [33]. With permission from the International Anesthesia Research Society.)

central venous pressure and left ventricular cross-sectional area (as assessed by echocardiography), did not differ between the early and late periods at either 0.83 or 1.66 MAC desflurane. In contrast, heart rate and cardiac index were higher after prolonged anesthetic exposure at both concentrations than during the first 90 min. Other variables, including left ventricular ejection fraction, Vcfs, and skeletal muscle blood flow, did not change during prolonged anesthesia. No detrimental changes in peripheral tissue perfusion or oxygen consumption were identified as functions of duration of desflurane anesthesia.

The hemodynamic effects of combined desflurane and nitrous oxide anesthesia were studied in male volunteers by Cahalan et al. (37). Desflurane-nitrous oxide anesthesia caused dose-dependent decreases in mean arterial pressure, cardiac index, SVR, and left ventricular stroke work index (Figure 11), plus increases in pulmonary arterial and central venous pressures. No significant changes in heart rate were observed when desflurane was combined with nitrous oxide (Figure 11). The combination of these two agents also modestly increased left ventricular end-diastolic cross-sectional area and decreased Vcfs, systolic wall stress, and left ventricular ejection fraction, indicating myocardial depression. These authors also studied the effects of desflurane and nitrous oxide after prolonged anesthetic administration and, as in the previous investigation (33), found somewhat less cardiovascular depression after prolonged exposure. No evidence of circulatory insufficiency was found in any volunteer at any time. In addition, no segmental left ventricular wall motion abnormalities, ST-segment changes, or cardiac arrhythmias developed during administration of desflurane-nitrous oxide anesthesia, indicating that this combination probably did not cause myocardial ischemia in normal subjects.

The cardiovascular actions of desflurane with and without nitrous oxide during spontaneous ventilation were also studied in male volunteers by Weiskopf et al. (38). Desflurane anesthesia (in the presence and absence of nitrous oxide) decreased minute ventilation, increased carbon dioxide partial pressure, and produced somewhat different cardiovascular effects than those previously described (33,37). Desflurane alone caused decreased mean arterial pressure and SVR as well as increased heart rate, cardiac index,

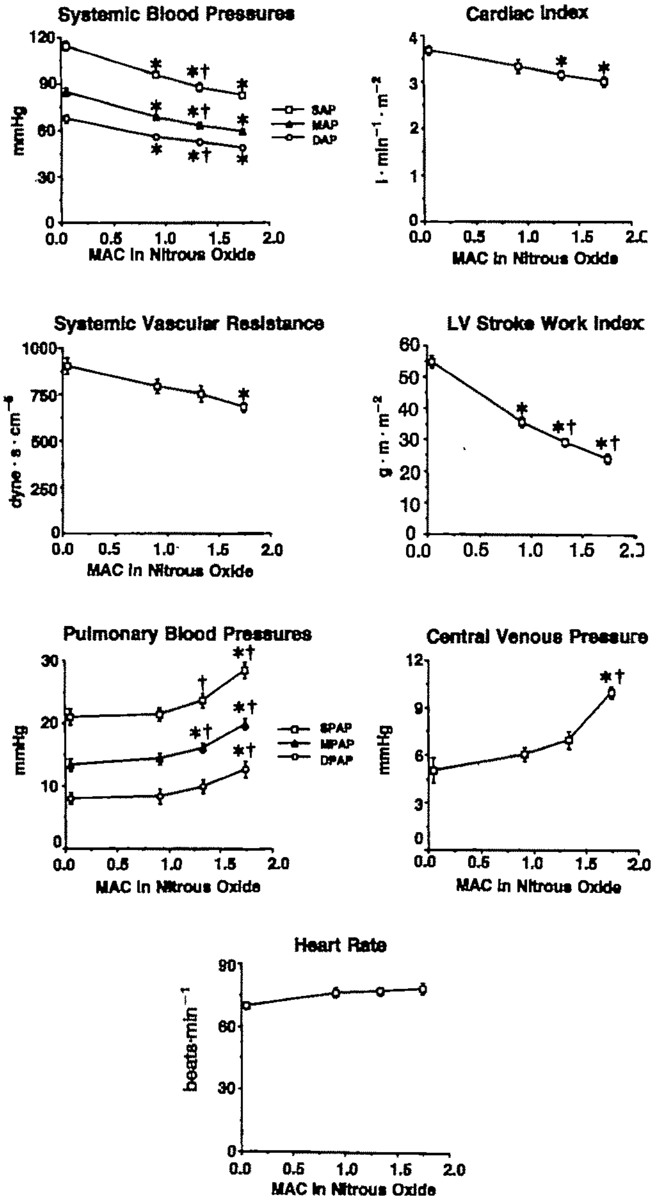

Figure 11. Systemic blood pressures, systemic vascular resistance, cardiac index, left ventricular (LV) stroke work index, pulmonary arterial pressures, central venous pressure, and heart rate in healthy volunteers in the conscious state and during three steady-state concentrations of desflurane-nitrous oxide anesthesia. *Significantly ($P < 0.05$) different from conscious values. †Significantly ($P < 0.05$) different when compared with previous levels of anesthesia. (Modified from original figures of Cahalan et al. [57]. With permission from the International Anesthesia Research Society.)

and central venous pressure. Left ventricular ejection fraction and Vcfs increased when desflurane was administered alone but did not change when desflurane was combined with nitrous oxide. Administration of desflurane to spontaneously breathing volunteers also produced increases in oxygen transport, the ratio of oxygen transport to oxygen consumption, mixed venous partial pressure of oxygen, and venous oxyhemoglobin saturation, indicating enhanced tissue oxygen delivery and maintenance of adequate tissue perfusion. The cardiovascular changes produced by desflurane with and without nitrous oxide during spontaneous ventilation differed from those observed during controlled ventilation. Increased cardiac index, central venous pressure, left ventricular ejection fraction, Vcfs, oxygen transport, and the ratio of oxygen transport to oxygen consumption increased in spontaneously breathing volunteers, in contrast to results obtained when ventilation was controlled (37). These findings can be attributed to direct desflurane-induced cardiovascular depression plus indirect hypercarbia-induced sympathetic stimulation. Differences in hemodynamic effects produced by desflurane during spontaneous versus controlled ventilation were also similar to those previously observed with isoflurane (39).

Cardiovascular responses to tetanic ulnar nerve stimulation were investigated in male volunteers during desflurane anesthesia by Yasuda et al. (40). Ulnar nerve stimulation produced increases in heart rate, mean arterial pressure, cardiac output, and pulmonary arterial pressures at 0.8 and 1.2 MAC desflurane. These hemodynamic responses were attenuated at 1.66 MAC. Desflurane and nitrous oxide produced attenuation of the peak response of heart rate and cardiac output but not mean arterial pressure. These results were consistent with previous findings for enflurane but not for halothane or an anesthetic that incorporated nitrous oxide and opioids (41).

Several investigations have been undertaken to determine the efficacy and safety of desflurane in patients with coronary artery disease. Thomson et al. (42) directly compared desflurane with isoflurane in patients undergoing coronary artery bypass graft surgery. After anesthetic induction with thiopental and fentanyl, desflurane or isoflurane was administered to maintain systolic blood pressure within 70%–100% and heart rate <120% of preanesthetic levels. Vasoactive drugs or additional fentanyl was used to control hemodynamics if end-tidal anesthetic concentrations between 0 and 2 MAC could not maintain hemodynamics within these predefined limits. The cardiovascular actions of desflurane and isoflurane before cardiopulmonary bypass were very similar (Figure 12). In addition, anesthetic requirements needed to maintain stable hemodynamics were indistinguishable between desflurane and isoflurane groups. During stressful stimuli (e.g., intubation or sternotomy), systolic pressure increased significantly more during isoflurane than during desflurane anesthesia. No differences in the incidence of electrocardiographic changes indicative of myocardial ischemia before cardiopulmonary bypass, perioperative myo-

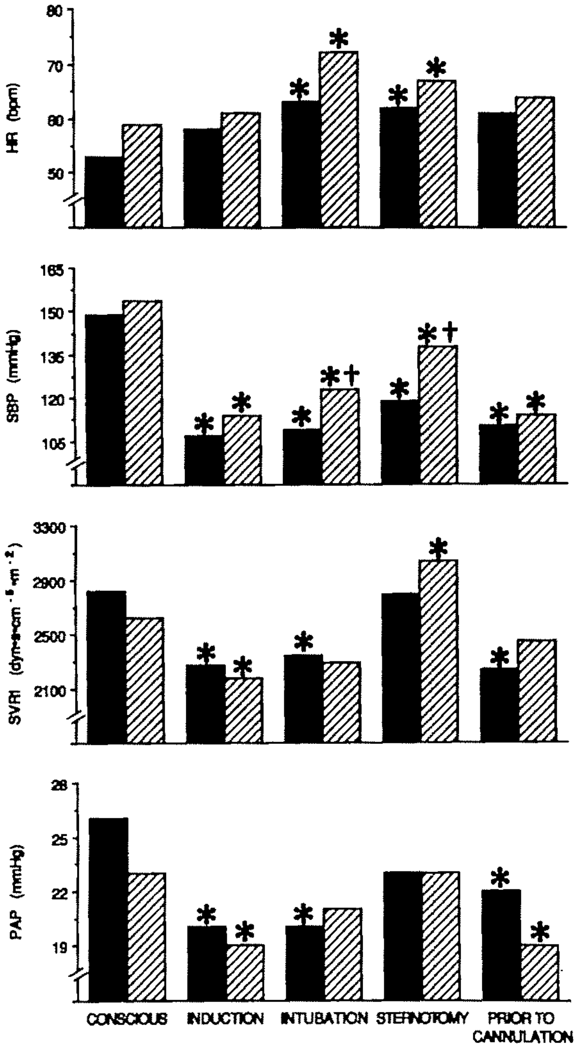

Figure 12. Heart rate (HR), systolic blood pressure (SBP), systemic vascular resistance index (SVRI), and pulmonary arterial pressure (PAP) in two groups of patients anesthetized with either desflurane (*solid bars*) or isoflurane (*hatched bars*) undergoing elective coronary artery bypass surgery. *Significantly ($P < 0.00083$) different from conscious values. †Significant ($P < 0.0071$) difference between groups. (Modified from data of Thomson et al. [42]. With permission of authors and publisher.)

cardial infarction, or perioperative mortality were identified between desflurane and isoflurane groups.

Helman et al. (43) also examined the impact of desflurane in patients with coronary artery disease by comparing the risk of myocardial ischemia during desflurane versus sufentanil anesthesia. Myocardial ischemia was detected by continuous Holter electrocardiography (before, during, and 48 h after surgery) and echocardiography (two-dimensional precordial and transesophageal before and after induction of anesthesia, respectively) during strict control of systemic hemodynamics in patients undergoing elective coronary artery bypass graft surgery. The authors reported that hemodynamic profiles produced by desflurane and sufentanil were similar. A trend toward increased incidence of ischemia detected by electrocardiographic changes and regional wall motion abnormalities occurred in the desflurane group in the induction period during increases in heart rate and arterial pressure. Desflurane was considered satisfactory for maintenance, during which hemodynamics were generally well controlled by desflurane and risk of ischemic events was not significantly increased. No differences between desflurane and sufentanil were identified when adverse cardiac outcome (ventricular failure requiring intraaortic balloon pump placement, myocardial infarction, or cardiac death) was considered. They suggested that myocardial ischemia risk was not increased with desflurane anesthesia compared with sufentanil anesthesia if hemodynamic variables were carefully controlled.

Desflurane and isoflurane were also studied in patients undergoing coronary artery bypass graft surgery by Ross et al. (44). Similar changes in systemic hemodynamics during induction, endotracheal intubation, skin incision, sternotomy, and prebypass and postbypass periods and at the end of surgery occurred during desflurane or isoflurane anesthesia. Isoflurane did produce significant declines in mean pulmonary artery and pulmonary capillary wedge pressures compared with desflurane at the end of induction. These results may indirectly indicate that desflurane produced greater cardiac depression during the early periods of anesthesia, perhaps because it equilibrated more rapidly than isoflurane. No changes in pulmonary artery pressures were observed at subsequent periods. Spiess et al. (45) also found desflurane and isoflurane to produce nearly identical hemodynamic actions before and after cardiopulmonary bypass when the concentration of either agent was adjusted to maintain surgical anesthesia.

T. K. Rao et al. (unpublished data) compared desflurane and isoflurane in patients undergoing repair of abdominal aortic aneurysms. These patients may be at risk for myocardial ischemia because of a high incidence of concomitant coronary artery disease. Isoflurane and desflurane produced nearly identical hemodynamic actions in this population. ST-segment changes and perioperative cardiovascular morbidity incidence was equivalent between the two anesthetic groups (T. K. Rao, unpublished data). These findings suggest that desflurane may be safe for patients undergoing abdominal aortic aneurysm resection.

Because desflurane has very low blood- and tissue-gas partition coefficients (1,2), it may be useful for rapid inhalation induction (although airway irritation may limit efficacy) and decreased emergence time after anesthesia, especially in outpatients (46–49).

Van Hemelrijck et al. (46) reported that the combination of desflurane and nitrous oxide produced changes in heart rate and systolic blood pressure similar to those produced by propofol and nitrous oxide in patients undergoing outpatient laparoscopy. Ghouri et al. (47) studied the recovery profile after desflurane-nitrous oxide versus isoflurane-nitrous oxide in outpatients. These authors reported equal numbers of adverse intraoperative cardiovascular events (defined as change in heart rate or blood pressure >20% of preinduction baseline value) between anesthetic groups. Azad et al. (50) found that equianesthetic end-tidal concentrations of desflurane and isoflurane (1.7 MAC) produced similar changes in heart rate and systolic and diastolic blood pressure when administered before and immediately after endotracheal intubation in outpatients. Excellent intubating conditions without neuromuscular blockers were reported with both anesthetics (50). The cardiovascular actions of desflurane were also studied in outpatients by Fletcher et al. (51). Inhalation induction with desflurane produced increased heart rate and systolic blood pressure similar to that caused by intravenous induction with thiopental. When isoflurane and desflurane were combined with nitrous oxide, similar hemodynamic profiles were present immediately before incision and in the first 5 min after beginning surgery. Both desflurane and isoflurane effectively blunted hemodynamic responses to surgical incision when administered at 1.3 MAC. In summary, a growing body of evidence supports the contention that desflurane produces systemic hemodynamic effects very similar to those produced by isoflurane in outpatients undergoing brief surgical procedures.

Preliminary investigations have reported cardiovascular effects of desflurane in other groups. Bartkowski et al. (52) studied systemic hemodynamics before surgical stimulation and found that desflurane produced a hemodynamic response identical to isoflurane. Similar alterations in systemic hemodynamics were also observed when desflurane and isoflurane were administered to elderly patients in a study by McMillan et al. (53). Use of opioids to treat intraoperative hypertension and tachycardia was greater with isoflurane than with desflurane in this investigation (53). This may indicate that desflurane produces greater (or quicker) suppression of sympathetic responses to surgical stimulation than does isoflurane. This conclusion must be qualified, because equianesthetic concentrations of desflurane and isoflurane were not administered (53). Battito et al. (54) also showed that desflurane and isoflurane produced similar hemodynamic effects in surgical patients. The cardiovascular responses to desflurane anesthesia in infants and children were studied by Taylor and Lerman (55). Desflurane decreased systolic arterial pressure before and after skin incision, but no significant changes in heart rate were observed. The authors concluded that desflurane produced stable hemodynamics when used as an induction agent and as a maintenance agent with nitrous oxide in infants and children (55).

Respiratory Effects of Desflurane

The capacity of desflurane to alter spontaneous ventilation has been noted in experimental animals. In pigs anesthetized with desflurane, normocarbia is maintained up to 1.2 MAC, but apnea occurs at end-tidal anesthetic concentrations between 1.2 and 1.6 MAC. Isoflurane produced similar respiratory depression, although the apneic threshold (defined as absence of ventilation for 1 min) for isoflurane was >1.6 MAC, in contrast to desflurane (I. J. Rampil et al., unpublished data). The apneic threshold in dogs anesthetized with desflurane was also slightly less than with isoflurane (2.38 vs 2.5 MAC) (Anaquest, unpublished data).

Lockhart et al. (56) described desflurane-induced depression of spontaneous ventilation with and without nitrous oxide in humans. Desflurane produced dose-dependent decreases in tidal volume and increases in respiratory rate (Figure 13) and depressed the ventilatory response to carbon dioxide in dose-related fashion with and without nitrous oxide. Arterial CO_2 tension (Pa_{CO_2}) increased with depth of anesthesia in both groups. The Pa_{CO_2} was significantly higher with desflurane alone than with desflurane plus nitrous oxide at 1.24 and 1.66 MAC. Minute ventilation decreased only at the highest level (1.66 MAC) of anesthesia with desflurane alone, and apnea occurred in two patients at an end-tidal concentration of 12%. The ratio of dead-space ventilation to tidal ventilation (V_D/V_T) and intrapulmonary shunt fraction ($\dot{Q}s/\dot{Q}t$) increased in dose-related fashion with desflurane with and without nitrous oxide.

Lockhart et al. (56) indicated that desflurane was a ventilatory depressant and that its effect on ventilation was comparable to that of other inhaled anesthetics (57,58). With deeper anesthesia, depression of ventilation observed with desflurane was most comparable to that previously reported for enflurane (57) (i.e., was greater than that previously reported for isoflurane [58]).

The low solubility of desflurane has stimulated interest in the potential of this agent for inhalation induction. Van Hemelrijck et al. (46) described a high incidence of breath holding, apnea, and coughing during inhalation induction with desflurane. Oral secretions were a problem in three patients who had

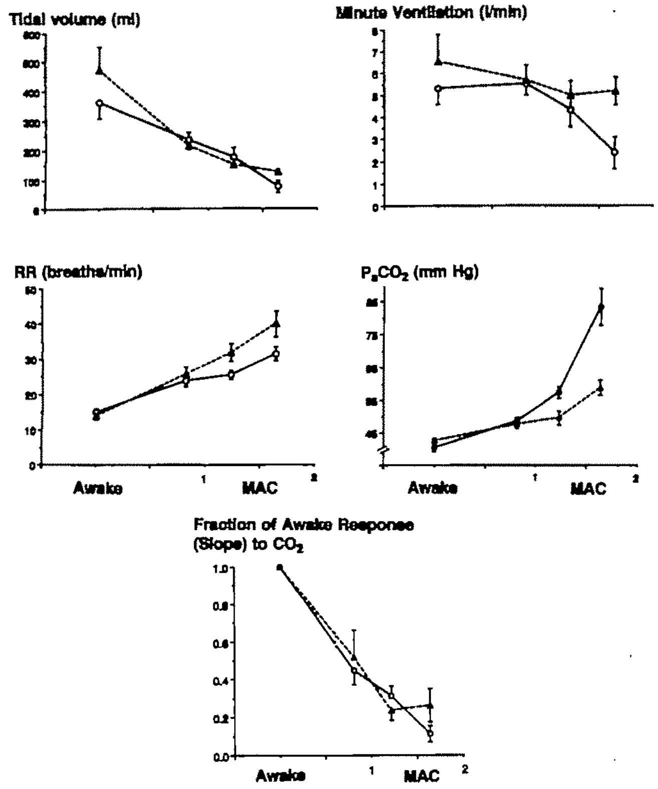

Figure 13. Effects of three steady-state concentrations of desflurane on tidal volume, respiratory rate (RR), minute ventilation, arterial carbon dioxide tension ($Paco_2$), and response to CO_2 in the presence (*solid triangles*) and absence (*open circles*) of 60% nitrous oxide in healthy male volunteers. (Modified from original figures of Lockhart et al. [56]. With permission of authors and publisher.)

anesthesia induced with desflurane, suggesting that this agent was a respiratory irritant. Rampil et al. (59) reported that 61% of patients had secretions requiring suction in a study of the effects of age or nitrous oxide on desflurane MAC. In addition, 50% of patients had persistent coughing, 34% manifested partial laryngospasm, and 29% exhibited breath-holding behavior (59). Incidence of these effects did not differ in the presence of nitrous oxide. Welborn et al. (60) also reported increased coughing, breath holding, and secretions during inhalation induction with desflurane compared with halothane in pediatric ambulatory patients. Therefore, although desflurane possesses biophysical characteristics advantageous for use as an inhalation induction agent, its airway irritability may limit the rate at which this volatile anesthetic can be delivered. Premedication with midazolam or fentanyl or a single-breath induction technique may improve patient tolerance to, and decrease airway irritability during, inhalation induction (61,62).

Conclusions

The investigations completed to date have shown that desflurane produces a systemic hemodynamic profile in volunteers and patients almost indistinguishable from its structural analogue isoflurane. No significant differences between the cardiovascular actions of desflurane and isoflurane were identified in volunteers during spontaneous and controlled ventilation with and without nitrous oxide. No evidence of desflurane-induced myocardial ischemia or desflurane-mediated increases in cardiovascular morbidity in patients with coronary artery disease have been demonstrated. Desflurane and isoflurane also produce similar hemodynamic effects during induction and maintenance of anesthesia in outpatients and pediatric and geriatric patients during a variety of surgical procedures. Rapid changes in anesthetic depth are easier to produce and may allow prevention or rapid treatment of hemodynamic alterations.

Desflurane produces depression of ventilation in experimental animals and in humans. Like isoflurane, desflurane also appears to be a mild respiratory irritant. Because only a limited number of studies have been performed to date examining the effects of desflurane on respiration, no firm conclusions with regard to the relative actions of desflurane and isoflurane on respiration can be established at present.

We thank Mimi Mick for her assistance in the preparation of this manuscript.

DISCUSSION

DR. EUGENE ORNSTEIN (New York): As part of the study we performed, we have had patients who were given 1 MAC desflurane and oxygen for 30–45 min, after which the concentration of desflurane was increased to 1.5 MAC. This was without surgery, and we were very impressed with the transient responses in both heart rate and blood pressure. These patients were presumably fully anesthetized; yet they had significant heart rate and blood pressure increases. I was wondering if the San Francisco group found these transients?

DR. DAVID C. WARLTIER (Milwaukee): What was your initial concentration before jumping to 1.5 MAC, Dr. Weiskopf?

DR. RICHARD WEISKOPF (San Francisco): One MAC. In our human volunteer studies, we did see occasional transients (i.e., changes in heart rate) as we went from one concentration to another, but they were transient. We did not consider that to be a potential problem, so we did not study that in any sort of prospective manner. I cannot really make any further comment on it other than we did see it from time to time.

DR. BEVERLY PHILIP (Boston): What about the induction period before steady state? What cardiovascular changes were seen even if they are not being reported here from the investigative groups? My question concerns both the volunteers who had less premedication and the surgical patients. I am also asking what fentanyl dose these patients might have had to cause a difference, if there was one.

DR. WARLTIER: We have limited experience with this, but if you do an inhalation induction, during induction you will see hypertension and tachycardia. This can be blunted significantly by pretreatment with either thiopental or fentanyl.

DR. JACQUELINE M. LEUNG (San Francisco): One of the peculiar effects of desflurane that has not really been mentioned here yet is the seemingly biphasic effect on hemodynamics. That is, induction and maintenance seem somewhat different. Our experience in our 200-patient study, where half of the patients received desflurane, demonstrated that despite the fact that patients were receiving controlled ventilation and had no apparent airway irritation and no signs of excitement, there were nonetheless significant increases in *pulmonary* blood pressure. Pulmonary wedge pressure increased by an average of 50% and pulmonary artery diastolic pressure by an average of 100%. Systemic systolic pressures increased an average of 20%. I should say that in these patients, >50% required esmolol to control their systemic and pulmonary blood pressures.

DR. RONALD D. MILLER (San Francisco): Is this during an inhalation induction?

DR. LEUNG: We quickly abandoned inhalation induction after the first few patients. We used a sleep dose of thiopental, breathed them down if you will, titrated in the muscle relaxant, and then incrementally increased the desflurane concentration as per protocol. We wanted to uncover the coronary effects of this drug, so we did not use any prophylactic narcotic as a lot of studies had done and as we previously did in another study using isoflurane, where we used fentanyl as an adjuvant. I should also mention that differences in myocardial ischemia were seen primarily during induction, detected only by two sensitive continuous modalities of measurement, namely, Holter monitoring and transthoracic echo.

DR. R. D. MILLER: What did you mean by differences in myocardial ischemia? Different between what and what?

DR. LEUNG: The difference between desflurane anesthesia and the control group given high-dose sufentanil.

DR. WARLTIER: I think that is what we would expect; namely, better control of hemodynamics with sufentanil than with desflurane. What MAC were you using?

DR. LEUNG: Our mean end-tidal concentration of desflurane on induction was approximately 10%.

DR. WARLTIER: I think that is to be expected and goes back to the use of adjuncts with desflurane for control of systemic hemodynamics. Of course, hypertension and tachycardia are ordinarily seen on induction in experimental animals and are totally eliminated by autonomic nervous system blockade.

DR. WEISKOPF: A question for Dr. Leung. When you saw what looked like sympathetic stimulation during induction, approximately what was the end-tidal concentration of desflurane?

DR. LEUNG: I'll defer to Dr. Helman.

DR. JAMES HELMAN (San Francisco): As we got above 6%–7% desflurane, with continued increments, the hemodynamics continued to increase with almost a linear relationship.

DR. WEISKOPF: At some point that stimulation defervesced. What was the range where you saw the stimulation and when did it go away?

DR. HELMAN: It actually did not spontaneously defervesce. Our study design was to keep systolic blood pressure within <120% of its ward control and to maintain a heart rate of <120%. We therefore treated the stimulation with esmolol or nitroprusside, or both. It actually did not abate until after the patient was tracheally intubated.

DR. WEISKOPF: At what concentrations?

DR. HELMAN: An end-tidal concentration of 10%. Some patients required an end-tidal concentration of up to 16%–17%.

DR. WARLTIER: One of the things that is very interesting about that is that the stimulation is reflected not just in heart rate, but also in systolic blood pressure as well. It is not simply a baroreflex, for example, a decrease in systolic pressure causing a reflex increase in heart rate by an agent that might affect the autonomic nervous system less than another agent. This is something different from that and also different from isoflurane, I agree.

DR. WEISKOPF: One of the major differences between the Helman-Leung study and other studies is that Drs. Helman and Leung used an almost pure inhaled anesthetic for those coronary bypass patients. This is not what we would usually do clinically. A question I would like to ask Dr. Warltier is, from what you have summarized very nicely, would you expect that desflurane would probably be a negative inotropic drug in patients with heart failure, with preexisting cardiac disease?

DR. WARLTIER: Absolutely, no question about it. Just like any volatile anesthetic would be, this drug is a negative inotrope.

DR. WEISKOPF: Even though it looks like it supports circulation a little better in healthy patients than isoflurane, we would not expect that to be true in the patient we are talking about, would we?

DR. WARLTIER: If we are talking about a patient with heart failure who has a higher sympathetic tone to begin with, this drug may not increase sympathetic tone more than that. Instead, you will see its direct effects, and so I would expect it would exacerbate heart failure much like any other volatile anesthetic.

DR. RICHARD M. SMILEY (New York): With regard to the discussion we are having about excitement or sympathetic overactivity, I think we should keep in mind that all volatile anesthetics probably, or even definitely, have a period of excitement associated with their onset, and that some of the differences we are talking about may be due to kinetic differences in the onset of these drugs. There may conceivably be some difference in which centers are first anesthetized, perhaps some inhibitory centers.

DR. MICHAEL DAMASK (New Jersey): Looking at 60 patients undergoing triple A resections, all had a significant amount of fentanyl preoperatively, up to 10 μg/kg, and the differences that Drs. Helman and Leung brought out in terms of ischemia, increased heart rate, and increased pulmonary pressures were not seen in these other studies. In the large multicenter program in which researchers looked at ASA physical status III and IV patients, the cardiovascular differences between isoflurane and desflurane were really not clinically significant at the time points at which data were recorded.

DR. ROBERT HUDSON (Winnipeg): Just some comments on our own study: I would not want anyone to draw the conclusion from our data that the small dose of thiopental we used (approximately 2 mg/kg) and a somewhat larger dose of fentanyl (approximately 10 μg/kg) necessarily changed the intrinsic cardiovascular response to either desflurane or isoflurane. We have seen in the studies that were just reviewed that the problems, if that's what they are, with desflurane tend to occur at fairly high concentrations, >1.2 MAC or so, particularly with increases in heart rate. In our clinical study, we did not really get up to those concentrations because we did not need them to maintain blood pressure within our stated ranges. We therefore have not tested the hypothesis that pretreatment modifies the intrinsic response to a given concentration of desflurane or, in fact, isoflurane.

DR. WARLTIER: I agree. If this stimulation does occur at higher MAC levels it needs to be studied. In addition, we need to investigate directly, comparing desflurane to isoflurane, not to sufentanil in the same patient population at these higher MACs of volatile agents.

DR. KENNETH ZAHL (New York): There is always underlying concern about cardiovascular safety. But for the clinician, let's say you are doing a relatively straightforward case. You are not going to have pulmonary artery catheters or echocardiography. Often, you will have only a three-lead electrocardiogram. You have to get the patient anesthetized. The relevant question is whether or not you can safely overpressure the patient with 2 or 3 MAC like you can with enflurane, isoflurane, or halothane? There are many patients who will not be heavily monitored and who will have only peripheral blood pressure cuffs and pulse oximeters. In the chronically instrumented dog, you have a preparation where you are blocking any potential beta stimulation. If there is a beta-stimulation mechanism involved (i.e., sympathetic stimulation), could you design another protocol to detect that? Maybe to obtain, not necessarily coronary steal, but other myocardial variables of ischemic propensity with higher doses of desflurane in the chronically instrumented dog.

DR. WARLTIER: We studied desflurane in the absence versus the presence of autonomic nervous system blockade in dogs. There is certainly no direct beta stimulation by any volatile anesthetic. That is also easy to show in isolated tissue preparations, which is the classic way to show beta-agonist-type activity. We have always believed that, at least in the dog, desflurane seems to interfere with autonomic reflexes to a lesser extent than the other volatile agents, although I really do not have a solid basis for that other than just seeing what happens during induction and heart rates in comparison to arterial pressures at the various MAC levels.

DR. WEISKOPF: I guess I still fail to understand the difference between Drs. Leung and Mangano's study and the results in our volunteers, in that at approximately 10%, which is roughly 1.4–1.5 MAC end-tidal concentration, they saw cardiovascular stimulation, whereas in our volunteers we did not. Obviously, there is a disparity for which I do not have an answer.

Effects of Desflurane on the Central Nervous System

William L. Young, MD

Department of Anesthesiology, Columbia University, New York, New York

Desflurane causes dose-dependent decreases in cerebrovascular resistance and cerebral metabolic rate of oxygen consumption ($CMRo_2$), suggesting that desflurane is a cerebral arteriolar dilator with global flow-metabolism coupling similar to halothane and isoflurane. Desflurane is also similar to isoflurane in that cerebrovascular responsivity to carbon dioxide appears to be maintained. In the dog, arterial hypotension to 40 mm Hg induced with 2.4 MAC desflurane resulted in global decreases in cerebral blood flow of 60% and $CMRo_2$ of 20%. Concentrations of cerebral metabolites of high-energy phosphates were not significantly deranged. The intracranial pressure data from humans are controversial. Desflurane and oxygen at 1 MAC caused sustained increases in cerebrospinal fluid pressure (maximum of 19 ± 6 mm Hg) in patients undergoing craniotomy for mass lesion despite prior establishment of hypocapnia. In a more recent study, the same investigators reported similar cerebrospinal fluid pressures before and after 0.5 MAC of either isoflurane or desflurane in 50% N_2O. The electroencephalographic effects of desflurane are similar to those of isoflurane in humans, and burst suppression is easily achieved. There are no data available concerning possible interactions between desflurane and the outcome of a cerebral ischemic event. Similar to other potent volatile agents, desflurane can cause cerebral vasodilation and may result in intracranial pressure changes in vulnerable patients, but if adequate hyperventilation and depth of anesthesia are maintained, it is probably safe to use desflurane in a manner similar to isoflurane in patients with decreased intracranial compliance.

(Anesth Analg 1992;75:S32–7)

Relatively few studies have addressed the impact of desflurane on physiologic processes in the central nervous system; the available evidence points to a pattern of effects similar to that seen with isoflurane.

The most striking difference between desflurane and currently available potent agents is a more rapid cerebral washin and washout. This is predictable, based on the low solubility of the agent and has been elegantly confirmed by Lockhart et al. (1) using ^{19}F nuclear magnetic resonance spectroscopy. These authors utilized a 30-min washin and 120-min washout to examine cerebral (nuclear magnetic resonance) and alveolar (gas chromatography) concentrations. Desflurane exhibited faster elimination than did isoflurane and halothane. Hysteresis between alveolar and brain concentrations was similar for all three agents.

Effects on Cerebral Blood Flow and Metabolism

Desflurane's effects on cerebral blood flow (CBF) and cerebral metabolic rate for O_2 ($CMRo_2$) have been examined in dogs (2). Lutz et al. used the venous outflow CBF method and sagittal sinus sampling to determine the arteriovenous difference in O_2 content and examined the dose-response of desflurane at 0.5, 1.0, 1.5, and 2.0 MAC in six dogs (2). At higher MAC concentrations, arterial blood pressure support with phenylephrine was necessary to maintain constant values. Their results are summarized in Figure 1.

There was a dose-dependent decrease in cerebrovascular resistance regardless of arterial blood pressure support (Figure 1). With arterial blood pressure support, CBF increased at the two highest MAC multiples (Figure 2). Similar to other potent agents, this suggests that desflurane is a cerebral arteriolar dilator. The $CMRo_2$ progressively declined with increasing MAC (Figure 3), as is seen with isoflurane in this range (3,4). It seems reasonable to assume persistent global flow-metabolism coupling, as seen with halothane and isoflurane (5). Autoradiographic studies that document regional effects of desflurane on flow and metabolism patterns have not yet been reported.

Desflurane, as expected, maintains cerebrovascular responsivity to carbon dioxide ($CVRco_2$). Over the $Paco_2$ range of approximately 22–40 mm Hg, Lutz et al. (6) reported appropriate $CVRco_2$ at three MAC levels in dogs. In Figure 4, the 1 MAC values are compared with 1 MAC isoflurane in the dog for both venous outflow

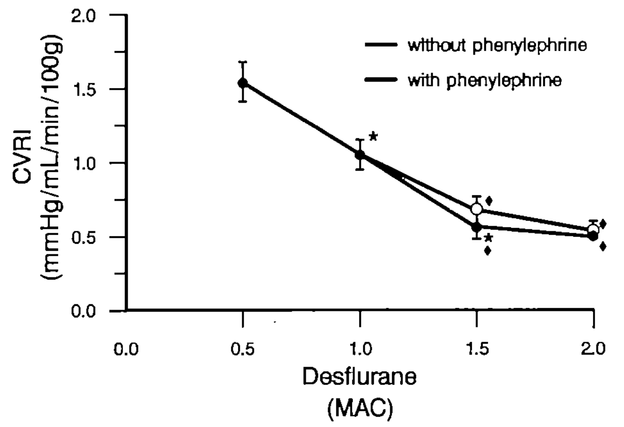

Figure 1. Effect of desflurane on cerebrovascular resistance index (CVRI). Desflurane produced a dose-dependent decrease that was unaffected by the phenylephrine infusion. Mean ± SE ($n = 6$). *Significantly different from value obtained at 0.5 MAC ($P < 0.05$). (♦) Significantly different from value obtained at 1.0 MAC ($P < 0.05$). (Data from Lutz et al. [2].)

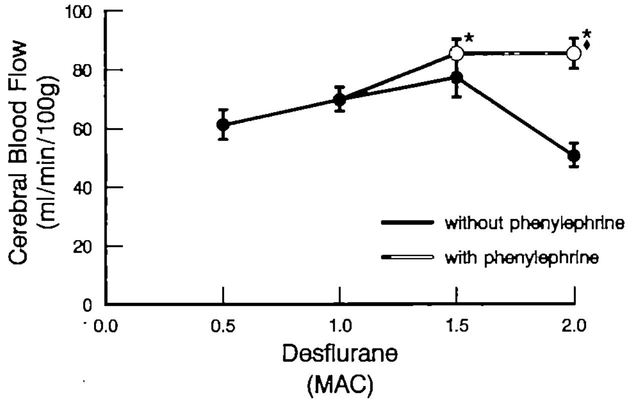

Figure 2. Effect of desflurane on cerebral blood flow. With blood plasma support, desflurane produced a dose-related increase in cerebral blood flow. Mean ± SE ($n = 6$). *Significantly different from value obtained at 0.5 MAC ($P < 0.05$). (♦) Significantly different from value obtained at 1.0 MAC ($P < 0.05$). (Data from Lutz et al. [2].)

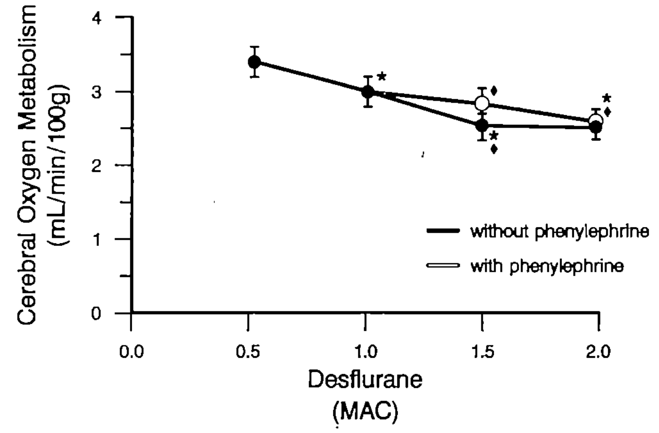

Figure 3. Effect of desflurane on cerebral metabolic rate for O_2 ($CMRo_2$). Desflurane produced a significant dose-related decrease in $CMRo_2$ from 0.5 to 2.0 MAC. Phenylephrine had no significant effect on $CMRo_2$. Mean ± SE ($n = 6$). *Significantly different from value obtained at 0.5 MAC ($P < 0.05$). (♦) Significantly different from value obtained at 1.0 MAC ($P < 0.05$). (Data from Lutz et al. [2].)

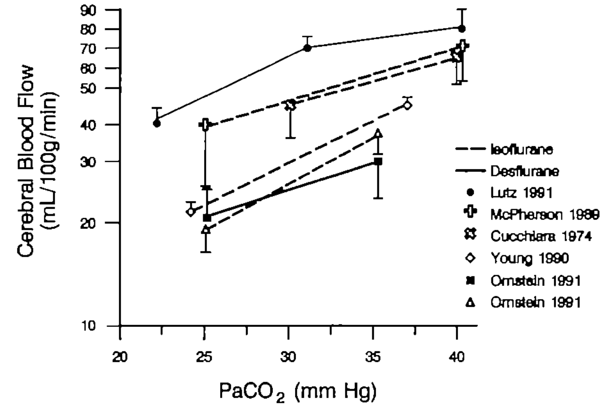

Figure 4. Comparison of cerebrovascular reactivity to carbon dioxide ($CVRco_2$) for isoflurane and desflurane. *Top three graphs*, animal studies; *bottom three graphs*, human studies. The $CVRco_2$ appears to be similar for both agents. (Animal data from Lutz et al. [6], Cucchiara et al. [7], and McPherson et al. [8]; human data from Young et al. [10] and Ornstein et al. [9].)

CBF methodology (7) and use of radiolabeled microspheres (8).

The only human CBF data currently available were reported by Ornstein et al. (9) who utilized intravenous ^{133}Xe. They compared desflurane and isoflurane on CBF at two concentrations (1.0 and 1.5 MAC) in an air/oxygen mixture during hypocapnia in 12 patients undergoing craniotomy for tumor. They also assessed $CVRco_2$ at 1.25 MAC. There was no difference between isoflurane and desflurane at the two different MAC levels (Figure 5), and $CVRco_2$ was similar for both (Figure 4). Desflurane's effect on human $CVRco_2$ (10) is similar to that reported for isoflurane (9).

Desflurane-Induced Hypotension

Milde and Milde (11) examined the systemic and cerebral effects of arterial hypotension induced with desflurane in 11 dogs (Figure 6). Baseline measurements were obtained at 1 MAC and hypotension to 50 mm Hg (2.2 MAC) and 40 mm Hg (2.4 MAC). At a 40%–50% decrease in cardiac index, there was approximately a 20% decrease in $CMRo_2$. The CBF decreased 36% and 60% at mean arterial pressures of 50 and 40 mm Hg, respectively. After hypotensive periods, cerebral metabolite concentrations of adenosine triphosphate, phosphocreatine, and lactate were within the range of normal canine values for their laboratory, although lactate was moderately increased. They concluded that there was adequate perfusion to maintain $CMRo_2$ during desflurane-induced hypotension. Desflurane appears similar to isoflurane (12) in that hypotension can be easily induced and maintained, as shown in Figure 6.

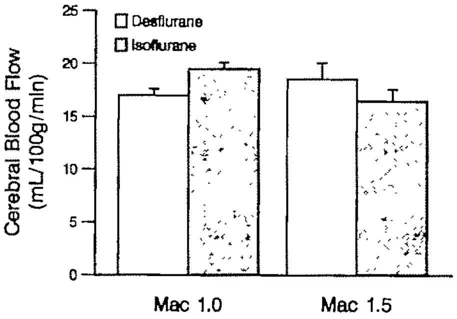

Figure 5. Cerebral blood flow dose-response for isoflurane (air/O_2) and desflurane (air/O_2). There was no difference between the two agents at either MAC level. (Data from Ornstein et al. [9].)

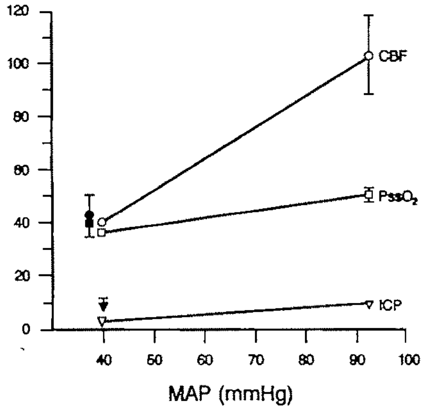

Figure 6. Cerebral effects of desflurane-induced hypotension in dogs. Changes in cerebral blood flow (mL·100 $g^{-1}·min^{-1}$), sagittal sinus O_2 tension ($PssO_2$, mm Hg), and intracranial pressure (ICP, mm Hg) are shown (*open symbols*). (Data from Milde and Milde [11]. Values are compared with data for isoflurane (*filled symbols*) at a similar level of hypotension from a previous study by Newberg et al. [12].)

Effects on Intracranial Pressure

In dogs without intracranial pathology, the aforementioned studies of Lutz et al. (2,6) and Milde and Milde (11) showed trivial effects on intracranial pressure (ICP). The data from Lutz et al. are summarized in Figure 7.

Data from humans with intracranial mass lesions are more controversial. Muzzi et al. (13) studied 10 patients with mass lesions who before induction of anesthesia underwent lumbar subarachnoid needle drainage that allowed measurement of lumbar cerebrospinal fluid pressures (LCSFP). There was no control group. Awake baseline LCSFP before induction of anesthesia was 11 ± 4 (mean ± SD) mm Hg. The LCSFP decreased after thiopental and showed variable increases after tracheal intubation. After 1 MAC desflurane was added (7.1% ± 0.6% in air/oxygen), sustained increases in LCSFP were observed in all patients until the dura was incised at $Paco_2$ of 26 ± 2 mm Hg. Maximal LCSFP at 45–75 min was 19 ± 6 ($P < 0.002$), range 13–33 mm Hg. The authors concluded that LCSFP increases after desflurane despite previous establishment of hypocapnia.

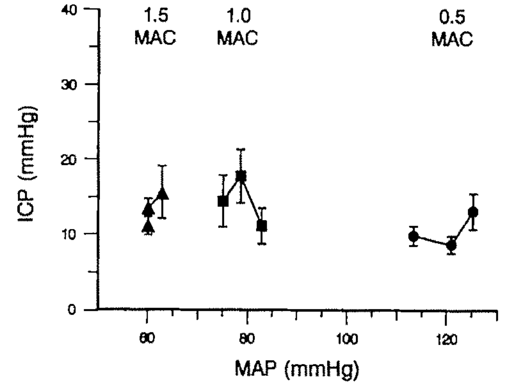

Figure 7. Intracranial pressure (ICP) response to three levels of desflurane at three levels of hypocapnia. Data points at each MAC level represent hypocapnia, normocapnia, and hypercapnia. Because of dose-related decreases in blood pressure, each of the three levels of hypocapnia, normocapnia, and hypercapnia are plotted as a function of mean arterial pressure (MAP). There were no differences at any level of desflurane or $Paco_2$. (Data from Lutz et al. [6].)

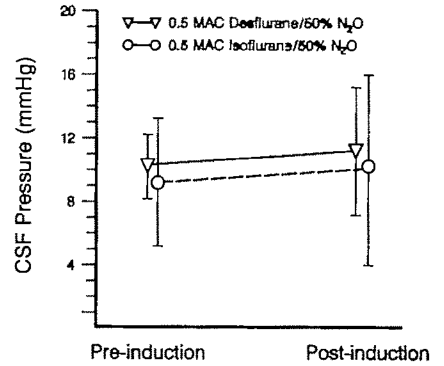

Figure 8. Effect of anesthetic induction on cerebrospinal fluid (CSF) pressure with isoflurane or desflurane in the presence of N_2O. There was no difference between agents before or after induction. (Data from Muzzi et al. [14].)

In a more recent study using similar methodology, the same group reported LCSFP before and after 0.5 MAC of either isoflurane or desflurane in 50% N_2O (14). As shown in Figure 8, there was no appreciable change in LCSFP with either regimen.

It is difficult to reconcile these two clinical studies, except that the latter was done with N_2O and half as much desflurane. Because desflurane, similar to isoflurane, causes no change in CBF with MAC levels used clinically, it is possible that there is some effect of desflurane to increase cerebral blood volume, independent of its effect (or lack thereof) on cerebral arteriolar resistance, perhaps by venodilation. There is no clinical evidence that operative conditions are different with desflurane versus isoflurane (W. L. Young and E. Ornstein, unpublished observations, 1991).

There is one study in progress to attempt to sort out the issue of ICP increases. Preliminary observations suggest that addition of either isoflurane or desflurane

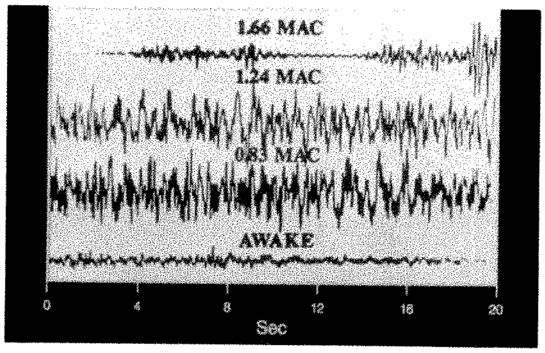

Figure 9. Human EEG during desflurane anesthesia. (The EEG patterns for desflurane in humans are strikingly similar to those of isoflurane.) (Data from Rampil et al. [17].)

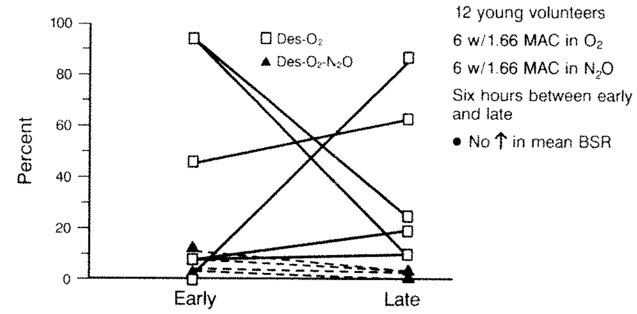

Figure 10. Burst suppression rate during desflurane (Des) anesthesia. No evidence for "EEG tolerance." (Data from Rampil et al. [17].)

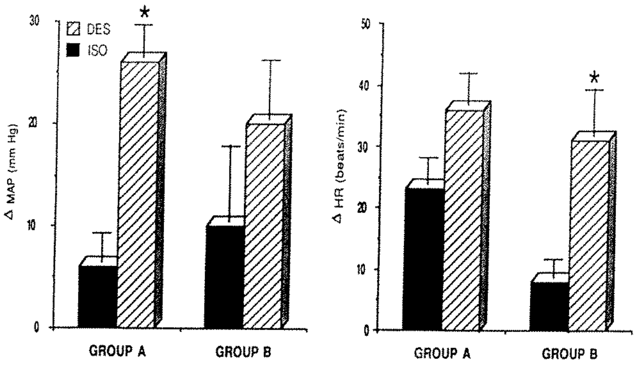

Figure 11. Systemic hemodynamic changes from preinduction to 5–6 min after induction. $^*P < 0.05$. Group A, nonneurosurgical patients from Smiley et al. (19); group B, neurosurgical patients from Ornstein et al. (9). There was a trend for desflurane (DES) patients to have more pronounced heart rate and blood pressure changes after induction (see text for further explanation). ISO, isoflurane. (Data from Fleischer et al. [20]).

(in oxygen) results in similar effects on LCSFP, although LCSFP increases are sometimes seen with either agent (Z. Ebrahim, personal communication, 1992).

Whatever the outcome of present and future studies, desflurane is clearly a potent cerebral vasodilator that must be used carefully in patients with decreased intracranial compliance. The net vasodilation of desflurane is, in a fashion similar to isoflurane, a balance between its direct dilating effects and the increase in vascular tone associated with its ability to suppress cerebral metabolic activity. Patients at greatest risk for increased ICP with desflurane might be those with the greatest previous depression of $CMRo_2$, as is the case for isoflurane (15).

Electroencephalographic Effects

In swine, Rampil et al. (16) demonstrated dose-related depression of electroencephalographic (EEG) activity up to and including burst suppression, comparable to effects seen with an equipotent dose of isoflurane. These authors further investigated the effects of 6%, 9%, and 12% desflurane (0.83, 1.24, and 1.66 MAC) in O_2 and 3%, 6%, and 9% desflurane in 60% N_2O in O_2 in 12 healthy human volunteers. They further studied hypercapnia and hypocapnia and attempted to provoke excitatory activity by loud handclapping (17). The EEG effects of desflurane were roughly similar to those of isoflurane in humans (Figure 9). There was no epileptiform activity. As in the swine model, desflurane significantly suppressed EEG activity; prominent burst suppression was observed at MAC levels >1.24. Addition of N_2O predictably lessened the depressant effect of desflurane on the EEG.

A topic of some controversy is the occurrence of EEG tolerance to the cerebral effects of desflurane. Lutz et al. (2) and Milde and Milde (11) reported EEG tolerance to desflurane, the animals progressing from relative EEG quiescence to more awake patterns over 30–60 min in their canine preparations despite constant $CMRo_2$ and anesthetic concentrations. In contrast, Rampil and colleagues (17,18) found no evidence of tolerance in either humans or swine. They contended that the nature of the EEG sampling (burst suppression being a nonstationary phenomenon) or interspecies differences, or both, probably account for the differing observations (Figure 10). Whatever the explanation, tolerance has not been shown to be an issue in humans.

Desflurane Use in the Neurosurgical Patient

As in other settings, the uptake and recovery characteristics of desflurane may offer advantages in neurosurgical patients in whom rapid differentiation of drug residua from operative sequelae is desirable at conclusion of surgery. Although rapid emergence has been demonstrated in nonneurosurgical patients (19), details of the clinical behavior of desflurane in the neurosurgical population have not yet been described.

Fleischer et al. (20) performed a retrospective review of hypertension and tachycardia during anesthetic induction in two separate randomized, open clinical studies (Figure 11). They analyzed systemic hemodynamic data for the initial 5–6 min of induction in 33 patients undergoing general anesthesia for surgery that did not include the thorax, abdomen, or central nervous system (19) and 16 patients undergoing elective craniotomy for mass lesions (9). At 5–6 min after induction (T5-6), mean arterial pressure elevated 28% from preinduction baseline was noted in nonneurosurgical desflurane patients versus 7% for the corresponding isoflurane patients ($P < 0.002$). Heart rate also increased almost uniformly (31 of 33 patients) in nonneurosurgical patients, but differences between those receiving desflurane versus isoflurane did not achieve significance ($P < 0.06$). In neurosurgical patients, the desflurane subset exhibited a 34% increase from baseline heart rate versus 11% for isoflurane. Mean arterial pressure elevation at T5-6 in neurosurgical patients was not statistically different between desflurane and isoflurane.

This study suggests that the use of desflurane as an agent in a combined intravenous and inhaled anesthetic induction without narcotic adjuvants may result in significant changes from baseline cardiovascular hemodynamics (i.e., mean arterial pressure and heart rate increases). These changes appear greater than those seen with isoflurane. Because tachycardia and hypertension may adversely impact patients with certain disease states (e.g., coronary artery disease or recently ruptured intracranial aneurysms), these findings should be borne in mind when planning anesthetic induction in such patients. The observed differences in the systemic hemodynamic effects of desflurane versus isoflurane warrant further investigation.

Summary and Conclusions

Cerebrovascular effects of desflurane appear similar to those of isoflurane in both normal subjects and in patients with intracranial mass lesions. There is dose-related depression of CBF, $CMRo_2$, and EEG activity. Desflurane may be used in a fashion similar to isoflurane to induce controlled hypotension. Use of desflurane during anesthetic induction may result in more pronounced arterial blood pressure and heart rate increases than isoflurane. These systemic hemodynamic changes are probably controllable with narcotics or other adjuvants.

Although definitive recommendations should await analysis of all available data, use of desflurane in the neurosurgical patient should be carefully considered. As is the case with isoflurane, use of desflurane may result in increases in brain volume or ICP in certain patients. Notwithstanding, if adequate hyperventilation and depth of anesthesia are maintained, it is probably safe to use desflurane in all but perhaps the most precarious cases of intracranial hypertension. Risks of increases in ICP should be weighed against the potential benefit of rapid emergence afforded by desflurane, particularly after prolonged or otherwise complicated neurosurgical procedures.

I thank Eugene Ornstein, PhD, MD, for his review of the manuscript and Joyce Ouchi for her assistance in manuscript preparation.

Addendum: Muzzi et al. have recently published their data as a full manuscript (Muzzi DA, Losasso TJ, Dietz NM, Faust RJ, Cucchiara RF, Milde LN. The effect of desflurane and isoflurane on cerebrospinal fluid pressure in humans with supratentorial mass lesions. Anesthesiology 1992;76:720–4). They added a nonrandomized and noncontemporaneous group of patients receiving equipotent isoflurane anesthesia. Desflurane CSFP became greater than the isoflurane group at 10 min after addition of the volatile anesthetic.

DISCUSSION

DR. EDMOND I. EGER II (San Francisco): Do you have any explanation for the apparently increased intracranial pressure associated with desflurane in the earlier study done by the Mayo group?

DR. WILLIAM L. YOUNG (New York): I think it is plausible that their patients did have sustained increases in cerebrospinal fluid pressure. It probably had to do with their patient selection. They did not furnish a control group. The bottom line is that both agents [isoflurane and desflurane] can cause cerebrovascular relaxation. Patients at risk should be handled carefully with any inhaled agent.

DR. RICHARD M. SMILEY (New York): This question may be for Dr. Rampil as well as for Dr. Young. Is there anything from electroencephalographic (EEG) data to suggest that the kinetic differences between the drugs might lead to qualitative differences in the development of EEG changes? In other words, is there anything in the EEG data to suggest that the different speeds of uptake between isoflurane and desflurane into the brain resulted in qualitative differences in the EEG results you see, especially during times of changing concentration?

DR. IRA RAMPIL (San Francisco): I think the major problem lies with using the EEG as a measure of anesthetic effect. The EEG really reflects electrical activity in cortical pyramidal cells. Future studies should look at subcortical sites and see what is going on at different places in the brain.

DR. YOUNG: As far as the autonomic effects and their interaction with the cerebral effects, we previously did an autoradiographic study in rats comparing isoflurane and halothane, and we happened to look at the brainstem. It appears that isoflurane activates brainstem structures much more than halothane does. So perhaps if somebody looks, he or she might see that the differential effects of desflurane may even be greater than those of isoflurane.

DR. STEVEN ROBINSON (Portland): Is there any evidence that using desflurane allowed more rapid ability to evaluate the patient postoperatively or increased the ease of evaluating the patient postoperatively for neurologic deficits compared with isoflurane?

DR. YOUNG: There are no data. I think Dr. Ornstein and I both have the clinical impression that after a very long anesthetic patients who would have in the past been a little slow on the draw are pretty wide awake after a 12-h craniotomy, even when there has been considerable brain retraction. It would be difficult but useful to design a study to see whether, in fact, neurosurgical patients wake up faster, because there is such a tremendous variation in the amount of operative trauma, brain retraction, and hyperventilation. You could control adjuvant drugs carefully, but the operative site, where the retractors were placed, and other factors would introduce a lot of variance in the analysis.

DR. ROBINSON: Is there any advantage from use of desflurane with regard to indications to initiate steps such as computed tomography scan or reoperation at an earlier point in time, or is it too early to tell?

DR. YOUNG: Anyone who handles neurosurgical cases knows that you may have a situation where a patient does not emerge from anesthesia, and the question is always whether or not this is residual drug effect, or a problem that is surgical. More often than not, it is due to something that happened intraoperatively to the brain, unless you know that you have administered too much anesthetic. I think it is a question that is probably worth looking at in a systematic fashion.

DR. RAMPIL: I think the study you might want is to examine something like brain retraction pressure during these cases and how much retraction pressure was required to achieve a specific field-of-view. You would want to consider how much pressure is under the retractor and how much ischemia you might generate from that.

DR. ROBERT G. MERIN (Houston): Do you think that we still do not know quite enough to be able to label desflurane for use in neuroanesthesia?

DR. YOUNG: Let me put it in perspective. As far as I know, there has never been a case report of someone dying during induction from increased intracranial pressure secondary to any potent volatile anesthetic. In contrast, Giannotta et al. reported a 1% incidence of aneurysm rupture during anesthetic induction of patients undergoing craniotomy for aneurysm clipping (Giannotta SL, Oppenheimer JH, Levy ML, Zelman V. Management of intraoperative rupture of aneurysm without hypotension. Neurosurgery 1991;28:531–6). Batjer and Samson have reported similar data (Batjer H, Samson D. Intraoperative aneurysmal rupture: incidence, outcome, and suggestions for surgical management. Neurosurgery 1986;18:701–7). This might be related to several things, but most people would think that major increases in arterial pressure during induction would play a role. With respect to the cerebral effects of desflurane, I do not think there is compelling evidence that indicates it to be unsafe for neurosurgical patients. I would caution clinicians who elect to use desflurane in a patient who has a recently ruptured cerebral aneurysm to be sure to monitor arterial pressure closely.

An Overview of Induction and Emergence Characteristics of Desflurane in Pediatric, Adult, and Geriatric Patients

Richard M. Smiley, MD, PhD

Department of Anesthesiology, Columbia University College of Physicians and Surgeons, New York, New York

A major advantage of desflurane over currently available agents is that the blood-gas partition coefficient of desflurane is 0.42, lower than all available volatile anesthetics, and slightly lower than nitrous oxide. This property predicts rapid induction of and recovery from general anesthesia with desflurane. This review will summarize and compare results of studies that have examined various clinical characteristics of induction and emergence with desflurane in a variety of patient populations. Studies in pediatric patients, and in adults, have confirmed that inhalation induction with desflurane is rapid. However, there has been a high incidence of airway irritation and/or reactivity, including breath holding, coughing, excessive secretions, and laryngospasm. This incidence is significantly higher than that seen with halothane, making it unlikely that desflurane will supplant halothane for inhalation inductions. The hemodynamic effects of desflurane induction and maintenance with or without intravenous adjuvants appear similar to those seen with isoflurane. Several studies have compared emergence from anesthesia with desflurane with that from isoflurane-based anesthetics, and have demonstrated that initial emergence from a given depth of anesthesia, e.g., time to eye opening or response to verbal commands, is about twice as fast with desflurane. Similar results have been obtained in pediatric patients where emergence from desflurane is faster than that seen from halothane. Emergence from desflurane anesthesia appears similar in time-course to that from propofol-based anesthetics. Psychometric testing has also confirmed more rapid emergence with desflurane than isoflurane, and the clinical impression has been that patients are more "awake" in the postanesthesia care unit, although studies have not demonstrated earlier discharge times from the postanesthesia care unit or from the hospital for ambulatory patients. Initial studies in elderly (>age 65 yr) patients have confirmed the safety of desflurane and generally confirmed the emergence and hemodynamic profiles demonstrated in younger age groups. Desflurane appears to offer some advantages over currently available anesthetics; the specific indications and potential for desflurane should become clearer over the next (first) few years of clinical use.

(Anesth Analg 1992;75:S38–46)

An ideal anesthetic should allow rapid, pleasant, and predictable induction of anesthesia, stable maintenance, and rapid, smooth emergence from the anesthetic state. Desflurane is a new polyfluorinated volatile anesthetic that has been undergoing clinical evaluation. Desflurane is synthesized from isoflurane by replacement of the chlorine atom in isoflurane by fluorine. This single change results in a molecule with a lower boiling point and considerably lower blood solubility than other available volatile anesthetics (Table 1). The low blood-gas (0.42) and brain-blood (1.3) partition coefficients of desflurane (vs 1.4 [1] and 1.6 [2] for isoflurane) predict that induction of and emergence from desflurane anesthesia should be significantly more rapid than that from isoflurane or halothane. Over the past several years, a number of clinical studies have been performed to examine whether the low partition coefficients and rapid uptake and elimination of desflurane in animals and in human volunteers are translated into rapid induction and emergence in patients undergoing surgery. This article will summarize the findings of these studies performed in a variety of surgical patients and will discuss the currently available information with regard to induction and emergence characteristics of desflurane in pediatric and adult patients, with some preliminary data on use and effects of desflurane in the elderly.

Induction

Volatile agents are used during induction either as the primary anesthetic agent, with or without nitrous

oxide (N_2O) (inhalation induction), or are administered after induction of anesthesia/amnesia with intravenous agents to deepen anesthesia, decrease airway and cardiovascular responses, and start the maintenance phase of the anesthetic. Relevant concerns about inhalation induction include the subjective nature of the experience for the patient, airway irritation and excitement, hemodynamic and respiratory characteristics, and speed of induction. When potent inhaled agents are used to supplement intravenous induction, the subjective variables (e.g., pleasant vs unpleasant smell) are removed, and speed of uptake of the agent is somewhat less critical, but issues of cardiovascular, airway, and respiratory responses are still operative. The physicochemical properties of desflurane (3) and initial reports in volunteers (4) suggested that desflurane might be useful for inhalation induction or after intravenous induction, and a number of investigations were undertaken to evaluate the effects of desflurane administration during induction of anesthesia.

Pediatric Patients

Many pediatric anesthetics are commenced via inhalation. Halothane is usually chosen over isoflurane because it is more pleasant to breathe and less irritating to the airway (5). The first report of human administration of desflurane was in adult male volunteers, who were given desflurane at inspired concentrations of 1.8% or 5.4% (~0.25 or 0.75 MAC). Jones et al. (4) reported that these subjects found the agent "not unpleasant to breathe" and that it appeared to lack irritant respiratory effects. The authors suggested that desflurane might be useful for inhalation induction in pediatric anesthesia (4). Initial reports in children indicated that rapid induction by inhalation of desflurane was possible, with loss of consciousness in 1–2 min (6,7). A fairly high incidence of airway problems were reported, including breath holding, coughing, and excessive secretions, similar to that seen with isoflurane. Taylor and Lerman (8) have recently reported on induction of anesthesia with desflurane in 66 pediatric patients aged 1 mo to 12 yr. Patients breathed desflurane in 95% oxygen, with the desflurane concentration increased rather rapidly, by 7% increments every three to four breaths, to final inspired concentrations of 20%–25% (MAC of desflurane in infants and children is ~8%–10% [9]). Eyelash reflexes were lost at 1–2 min, and intubation could be performed at 4–5 min. Cardiovascular effects were acceptable with 20%–30% decreases in blood pressure before incision, and muscle relaxation was excellent. Unfortunately, the incidence of airway problems was unacceptably high. All patients experienced a period of "excitement." Fifty percent (33 of 66) experienced breath holding, 36% had more than two instances of coughing, and laryngospasm occurred in 30% (20 of 66). Two of the latter patients required succinylcholine, although it was noted that these two patients were treated early in the authors' experience with desflurane and had suffered recent upper respiratory tract infections. Airway complications contributed to decreased arterial oxygen saturation during induction to <90% in 18% of patients. Increasing inspired desflurane concentrations more slowly during induction appeared to worsen the incidence of airway complications. In this study, there was no control group receiving halothane or isoflurane with which to compare these results. A similar high incidence of airway problems with desflurane inhalation induction has been confirmed in a multicenter U.S. trial, in which the control group received halothane for induction and had airway complication rates of only 1%–4% (J. Lerman, personal communication). It should be noted that in the Taylor and Lerman study (8), desflurane was administered without premedication or N_2O. It was considered possible that the addition of premedication or N_2O, or both, might ameliorate some of these irritant/excitatory phenomena. Despite the above, data from other centers do not support any significant amelioration by these adjuncts on airway reactivity. It appears unlikely that desflurane will supplant halothane as the agent of choice for inhalation induction in children (6).

Adults

Several investigators have reported on inhalation induction with desflurane in adults (10–12), with results similar to those seen in the pediatric population (Table 2). Loss of consciousness occurs within 1–3 min, but the incidence of airway problems is significant and is not greatly affected by concurrent use of N_2O or fentanyl (11,12). Use of N_2O during

inhalation induction does appear to speed induction; loss of eyelash reflex was reported in an average of 124 s with desflurane in O_2 and 100 s with desflurane in 60% N_2O in one study (12); and at 2.0 min with N_2O and 2.6 min with desflurane in O_2 in another (11).

The pharmacokinetics of desflurane have suggested to some that a "single-breath induction" technique might be possible. Preliminary reports have suggested rapid induction and a relatively low incidence of airway problems by administering 2 MAC desflurane after a vital capacity exhalation, particularly in premedicated patients (13,14). This is an intriguing and interesting observation, but it appears unlikely that either conventional or single-breath desflurane inhalation induction in adults has much of a future.

The most common use of desflurane during the induction period will likely be after intravenous induction, to deepen and maintain anesthesia. In our own work comparing desflurane with isoflurane, both agents were administered after induction with thiopental (15). Under these conditions, we observed an incidence of airway reactivity with desflurane that was similar to or perhaps slightly greater than with isoflurane. Increasing the inspired concentrations of desflurane more rapidly did seem to decrease these problems, as reported (8). We compared the hemodynamic effects of desflurane versus isoflurane administration after intravenous induction with thiopental. Over the first 5 min, both isoflurane and desflurane were associated with significant increases in blood pressure and heart rate over preinduction values, greater with desflurane than isoflurane (unpublished observations). This tachycardia and relative hypertension may be related to an excitement phase of anesthesia (11), and the hemodynamic or clinical significance is unclear. Future studies will need to investigate and clarify the hemodynamic effects of desflurane in common clinical settings. Premedication and anesthetic adjuvants, especially opioids, may dramatically alter many of these hemodynamic effects. In at least one report in which an induction technique similar to ours was used, no difference in the hemodynamic effects of isoflurane and desflurane was detected after thiopental induction (16).

Geriatric Patients

Little information is available about desflurane use in elderly patients. A single preliminary report has claimed little problem with airway irritation/excitement in elderly (>65 yr) patients who had anesthesia induced with small doses of fentanyl (≤ 2 μg/kg) and thiopental (70–100 mg), followed by mask ventilation with desflurane (K. Zahl, personal communication).

The future usefulness of desflurane as an induction agent appears to be limited. Despite kinetics that theoretically indicate rapid induction and excellent muscle relaxation, its pungent odor and airway irritant/excitatory effects make it inferior to halothane for inhalation induction. Some of these problems may be minimized with appropriate premedication, coadministration of N_2O, or increasing the inspired concentration of desflurane very rapidly, but none of these maneuvers are likely to make desflurane popular as an induction agent.

Maintenance

It is clear that desflurane provides a stable anesthetic state during a variety of surgical procedures (8,12,15, 17,18). The cardiovascular effects of desflurane are similar to its close relative isoflurane. Similarly, the direct muscle relaxant effects of desflurane and its potentiation of nondepolarizing muscle relaxants, are also similar to or slightly greater than isoflurane (19–21). The solubility/kinetic characteristics of desflurane suggest advantages over currently available agents during surgery, allowing more rapid alterations in anesthetic depth than are possible with currently available agents. This may allow better control during changing surgical events that require deepening or lightening of the anesthetic state. At present, details of the actual potential and use of desflurane during the operative procedure have received limited attention. Reversal of the anesthetic state is the particular alteration of anesthetic depth that has received the most attention, because it is easiest to assess.

Emergence

Pediatric Patients

Taylor and Lerman (8) reported on recovery characteristics of desflurane in children. End-tidal desflurane concentrations decreased approximately 85% in the first 2 min after the agent was discontinued, and emergence as judged by eye opening was rapid, 6.1 ± 2.2 min. There was no control group that received isoflurane or halothane, but the authors cite published studies to suggest that this is less than the expected emergence time from isoflurane or halothane anesthetics of this duration (5,22,23). In a preliminary report of a controlled study comparing desflurane with halothane, maintenance anesthesia with desflurane did result in more rapid awakening (6). Three groups were compared: halothane induction with halothane maintenance; halothane induction with desflurane maintenance; and desflurane induction with desflurane maintenance (all with N_2O). The two groups receiving desflurane for maintenance each awoke in the operating room an average of 3.7 min after the anesthetic was discontinued, compared with 8.6 min in the halothane-halothane group. Given the problems (vide supra) with inhalation induction with desflurane and the possible advantages of desflurane as a maintenance agent allowing rapid emergence, this halothane-desflurane strategy may become popular to use in pediatric patients. Initial reports from the multicenter trial of desflurane in the United States appear to confirm that the rapid emergence from desflurane anesthesia is retained when anesthesia is initially induced with halothane (J. Lerman, personal communication). None of the investigators have noted airway problems or excitement during emergence from desflurane anesthesia in the pediatric population (8; J. Lerman, personal communication).

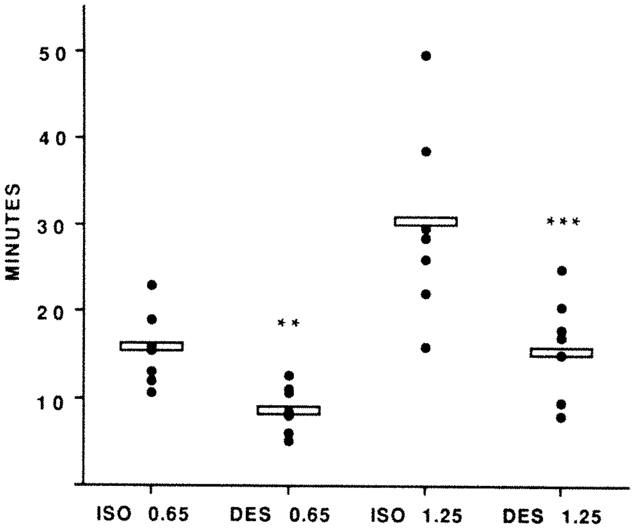

Figure 1. Individual emergence times for 28 subjects receiving desflurane (DES) or isoflurane (ISO) at 0.65 or 1.25 MAC with 60% nitrous oxide. *Rectangles*, means for each group. $^{**}P < 0.01$ versus ISO 0.65%. $^{***}P < 0.05$ versus ISO 1.25%. (Original figure from Smiley et al. [15]. Reproduced with permission of author and publisher.)

Adults

Comparison with isoflurane. We performed a controlled, randomized, prospective study to compare speed of emergence from desflurane versus isoflurane anesthesia in 28 adult patients aged 18–65 yr undergoing elective surgery (15). They were assigned to one of four groups ($n = 7$ per group) to receive isoflurane or desflurane at 0.65 or 1.25 MAC, along with 60% N_2O for maintenance of anesthesia. All patients were premedicated 5 min before induction with 0.03 mg/kg of midazolam, and anesthesia was induced with 5 mg/kg of thiopental (a few patients received additional 1–2 mg/kg of thiopental to treat excitement during induction), followed by isoflurane or desflurane in 60% N_2O-O_2 by mask to facilitate intubation without muscle relaxation. After intubation, the anesthetic concentration was adjusted to the appropriate end-tidal concentration using MAC values of 1.28% for isoflurane and 7.25% for desflurane. Subsequent to the study design, more detailed studies of desflurane MAC have revealed a 7.25% MAC value for young (18–30 yr) patients, whereas desflurane MAC in 30–65-yr-old patients has been reported to be 6.0% (10). The ages of all groups in our study were similar, so that this should have had little effect on the overall results. No opioids were administered until after emergence from anesthesia. End-tidal anesthetic concentrations were kept stable until near the end of surgery (average anesthetic exposure time was 113 min); then all anesthetic gases were discontinued. Ventilation with 100% O_2 was continued to maintain end-tidal Pco_2 at 35–40 mm Hg. The time until the patient opened his or her eyes and squeezed the investigator's hand in response to command was recorded (defined as "emergence time"). At each MAC concentration, emergence time was significantly less in the desflurane groups. At 0.65 MAC, emergence time was 15.6 ± 4.3 min (mean ± SD) for isoflurane and 8.8 ± 2.7 min for desflurane. At 1.25 MAC, the times were 30.0 ± 11.0 and 16.1 ± 6.0 min for isoflurane and desflurane, respectively. The individual patient data are illustrated in Figure 1. Of note, although we did see evidence of significant airway irritation (laryngospasm, coughing) during induction, we did not see any signs of this during emergence.

A similar study that also included preoperative and postoperative neuropsychologic testing ("psychometrics") was reported by Ghouri et al. (18). Thirty-eight outpatients undergoing relatively minor surgery (laparoscopy arthroscopy, superficial surgery) were studied. Preoperatively, psychometric testing consisted of a Trieger test (a "connect-the-dots" test of psychomotor function), visual analogue scales to assess subjective symptoms (e.g., pain, drowsiness), and the digit-symbol substitution test, in which numbers and symbols need to be matched in a given time period to assess cognitive capability.

Table 3. Emergence Time (Eye Opening) From Isoflurane-Nitrous Oxide and Desflurane-Nitrous Oxide Anesthesia

	Desflurane	Isoflurane
0.5 MAC[a]	5 ± 2	10 ± 8
0.65 MAC[b]	9 ± 3	16 ± 4
1.25 MAC[b]	16 ± 6	30 ± 11

MAC, minimum alveolar concentration.
Data are minutes ± SD.
[a] Data from Ghouri et al. (18); $n = 21$ for isoflurane, 17 for desflurane.
[b] Data from Smiley et al. (15); $n = 7$ per group.

Patients received fentanyl (3 μg/kg) and thiopental (4 mg/kg) for induction, with intubation facilitated by succinylcholine. Anesthesia was maintained with 3.0% desflurane ($n = 21$) or 0.6% isoflurane ($n = 17$) and 60% N_2O (~0.5 MAC volatile agent assuming 6% MAC for desflurane). The agent was discontinued at beginning of skin closure, N_2O was discontinued after skin closure, and ventilation was continued to maintain end-tidal Pco_2 at 35 mm Hg. Average anesthetic exposure was approximately 2 h for each anesthetic. Eye opening and hand squeeze were assessed as in our study from the time of discontinuation of the volatile agent (15). At 30, 60, and 90 min after recovery room admission, psychometric tests were repeated and compared with preoperative values and between the anesthetics. Initial emergence times were similar to the results in our study, with desflurane patients opening their eyes in 5.1 ± 2.4 min and isoflurane patients responding in 10.2 ± 7.7 min. The desflurane end-tidal concentration decreased 50% in 2.5 min, compared with 9.5 min for isoflurane. This is consistent with previous data in volunteers (24,25). In both studies, patients emerged approximately twice as fast from desflurane anesthesia as from isoflurane at each MAC concentration. The data from both studies are combined in Table 3, which reveals the expected trend toward longer emergence times with higher concentrations of anesthetics and the consistent results between the two studies. In addition to average emergence times twice as long with isoflurane, the standard deviations are correspondingly greater. Some patients do have significantly prolonged emergence from isoflurane. This could be less troublesome with desflurane.

The results of the psychometric testing also demonstrated more rapid emergence from desflurane than from isoflurane. At 30 min postoperatively, only 9 of the 21 isoflurane-group patients could perform the tests, whereas 13 of 17 desflurane-group patients could. By 60 min, the participation rates were no longer significantly different, but throughout the postoperative period, desflurane patients performed consistently better on both the subjective analogue scales and the digit-symbol substitution test, even with the higher participation rate in the desflurane group. There was no difference in performance on the Trieger (psychomotor) test, although as mentioned, fewer isoflurane-group patients were able to perform the test at 30 min. Desflurane patients rated themselves more comfortable by a linear analogue score than did isoflurane patients at all time points measured. It is possible that low residual postoperative concentrations of isoflurane are somehow "antianalgesic," or that residual sedation leads to confusion of other sensations as pain, or that the slight remaining concentrations of desflurane are analgesic. It may simply be that the more awake patients are better able to deal with pain and thus feel less subjective discomfort. There was no difference between the anesthetics in home discharge. It is unclear whether this is because there was no significant difference in recovery of psychomotor function, as suggested by similar Trieger test results, or was a result of the research protocol itself with prolonged postoperative testing or standard protocols of the particular outpatient surgery service, or both. Fletcher et al. (17) have reported findings quite similar to those of Ghouri et al. (18) and our own study, although the difference in initial emergence time between isoflurane and desflurane was 35% rather than 50%.

A preliminary report from a multicenter study further supports the previous findings (K. Zahl, personal communication). Laparoscopy patients in whom anesthesia was induced with fentanyl (1–2 μg/kg) and thiamylal until loss of eyelash reflex were randomized to receive desflurane or isoflurane at 1 MAC concentration, with or without 60% N_2O. Initial recovery was approximately 20% faster in the desflurane groups than the corresponding patients receiving isoflurane. Emergence (eye opening) after 1 MAC desflurane in O_2 occurred in 5.6 min, versus 8.5 min for isoflurane. Addition of 60% N_2O (keeping the volatile agent at 1 MAC concentration) increased these emergence times to 8.2 and 10.7 min, respectively. Other measures of initial emergence (patient's ability to state name, date of birth, etc.) followed the same pattern. Psychometric testing revealed results similar to Ghouri et al. (18), and discharge times again were not different between groups.

Comparison with propofol. For very minor, short procedures, especially outpatient procedures, the appropriate comparison for desflurane may be with propofol rather than isoflurane, because propofol has been associated with more rapid emergence than isoflurane (26). Two recent studies following similar protocols have reported comparisons between desflurane and propofol for outpatient surgery. Wrigley et al. (11) studied 60 outpatients assigned to four groups. Anesthesia was induced in group 1 with propofol (2.5 mg/kg), followed by maintenance with 6% desflurane (1 MAC) and 60% N_2O in O_2. Anesthesia was induced similarly in group 2 with propofol, followed by a maintenance infusion of propofol ($9\ mg\cdot kg^{-1}\cdot h^{-1}$ for 15 min followed by $6\ mg\cdot kg^{-1}\cdot h^{-1}$ thereafter). In group 3, anesthesia was induced by inhalation of desflurane in 60% N_2O and maintained with 6% desflurane in 60% N_2O, and group 4 received desflurane in O_2 for induction and maintenance with 6% desflurane in O_2. All groups received fentanyl ($\leq 2\ \mu g/kg$) during induction, and underwent tracheal intubation after loss of consciousness with the aid of muscle relaxants. At the end of surgery, the anesthetics were discontinued and time until emergence assessed. Patients receiving desflurane for induction and maintenance awakened numerically but not statistically significantly faster than those patients who received propofol. Patients opened their eyes to command in 6.2 min in group 4 (desflurane in O_2) compared with 9.4 min in group 2 (propofol induction and maintenance), and other measurements of awareness followed the same pattern. Psychomotor testing revealed numerical but not significantly slower recovery of preoperative function in those patients receiving propofol for induction and maintenance. There was similarly nonsignificant tendency toward an increased incidence of nausea and vomiting in patients who received desflurane. Only 1 patient in group 2, the propofol-propofol group, experienced nausea (7%), whereas a total of 16 patients in the other three groups experienced nausea (36%), with four episodes of vomiting, all in group 3, who received desflurane-N_2O for induction and maintenance. It is unclear whether these results are due to an antiemetic effect of propofol (27) or an emetic action of N_2O or desflurane, or both.

Van Hemelrijck et al. (12) reported on a study with a very similar protocol and the same four groups, except that the maintenance anesthetic was adjusted (50–$200\ \mu g\cdot kg^{-1}\cdot min^{-1}$ for propofol; 4%–7% for desflurane) according to patient responses (12). There was a trend toward more rapid initial awakening among those patients who received desflurane for maintenance compared with those who received propofol, achieving statistical significance in the desflurane in O_2 induction and maintenance group in 4.5 min versus 7.3 min in the propofol induction-propofol maintenance group. It is interesting that in this study where anesthetic depth was controlled according to patient response, patients receiving desflurane in O_2 awoke more rapidly than those receiving N_2O with desflurane. Psychometric testing did not detect significant differences between groups. There were no differences in time to sitting, standing, or discharge.

In summary, it appears that speed of emergence with desflurane is comparable to that from propofol-N_2O anesthesia. A preliminary report suggests that the same is true when comparing desflurane to alfentanil in outpatients (28). There is a higher incidence of nausea with desflurane, particularly in the presence of N_2O. A possible advantage of desflurane may be that its use could obviate the need for N_2O.

Geriatric Patients

Little has been published with regard to emergence from desflurane anesthesia in elderly patients. In general, older patients are more sensitive to sedatives, including general anesthetics, and take longer to awaken. Theoretically, desflurane might make emergence more predictable in the geriatric population. A report from the multicenter study comparing desflurane with isoflurane in elderly patients suggests results similar but less impressive than those seen in younger adults (R. L. Carpenter, personal communication). Anesthesia was induced with intravenous agents (fentanyl and thiopental), then maintained with isoflurane or desflurane, titrated to effect. Initial recovery times were 20% faster with desflurane, but the differences did not achieve statistical significance, and the times to recovery room discharge were not different. No psychometric or psychomotor testing was done, although the (nonblinded) observers suggested that desflurane patients appeared to be more "awake" at similar times after anesthesia. Incidences of complications (nausea, vomiting, intraoperative hemodynamic instability) were not different between anesthetics.

Summary

As predicted from its physicochemical properties, kinetics of induction and emergence (clinical correlates of uptake and elimination), appear to be more rapid with desflurane than with other volatile anesthetics. Owing to its somewhat unpleasant odor and propensity for causing airway reactivity, desflurane is unlikely to replace halothane as drug of choice for inhalation induction. The rapid uptake of desflurane may allow use of smaller doses of intravenous induction agents, because an anesthetic level of desflurane is likely to be more quickly attained. Decreased use of intravenous agents could lead to more rapid emergence, particularly from shorter-duration anesthetics. During maintenance, use of desflurane should allow more rapid alteration of level of anesthesia, which could prove useful for induction of deliberate hypotension or for treatment of major surgical events of short duration, without prolongation of the anesthetic. Initial emergence and postoperative recovery of mental function from desflurane anesthesia are rapid compared with isoflurane and similar to that from propofol-based anesthetics. These studies have not noted decreases in the average time spent in the recovery room or hospital. Given the variability among patients in emergence responses, it is possible that as larger numbers of patients receive desflurane they will experience fewer delayed awakenings requiring hospital admission after outpatient surgery than those patients who receive isoflurane. It will be important to investigate whether the more rapid emergence with desflurane results in fewer early airway and other complications during early recovery. Finally, it must be noted that most of the studies thus far have not been performed under normal clinical conditions; patients have been preselected, types of surgery controlled, and administration of the anesthetics has been under more or less strict guidelines. The true advantages or disadvantages of desflurane relative to current anesthetics will become more apparent after it is used in the normal clinical environment.

DISCUSSION

DR. RYAN COOK (Pittsburgh): One conclusion from your pediatric multicenter study was that incidence of laryngospasm was comparable to that with isoflurane. I submit that there were no objective data presented to document that. The incidence is nowhere near 30% or more. Also, in looking at the ideal inhaled anesthetic agent, I would envision that there are many patients who might be induced for very short surgical procedures. Despite this, it seemed as though every patient in this cohort was tracheally intubated, mostly with succinylcholine. Therefore, what is the experience, if any, of unintubated patients being given desflurane-nitrous oxide by mask, a technique used on probably one-third of my clinical practice?

DR. RICHARD M. SMILEY (New York): In my experience, none. All of our patients were adults undergoing surgery of at least 1 h duration, and they were all tracheally intubated. I do not have any information on the pediatric population.

DR. RONALD D. MILLER (San Francisco): Were such studies performed?

DR. SMILEY: Not that I have seen, no.

DR. JERROLD LERMAN (New York): What data do we have with regard to spontaneous ventilation of the tracheally intubated or unintubated pediatric, adult, or geriatric patient, depending on your age of interest? The answer was that there have been no studies defined to address those issues. In view of the impression that at >1.5 MAC, the P_{CO_2} in some adults who are healthy may approach 88 with desflurane, and considering the role for desflurane as primarily a maintenance and recovery agent, I think these two areas must be addressed in future studies.

DR. CHARLES COTÉ (Boston): We talk about single-breath induction with halothane for children. When we do that, we normally fill the circuit with 5% halothane and 60% nitrous oxide, so that is approximately 7 MAC. You cannot do that with desflurane. Perhaps that is an issue that needs to be considered. As we observed when we attempted to do mask inductions in children, the incidence of laryngospasm was very high; and it was not just laryngospasm like that with halothane, it was a "near-death" experience, as our pediatric surgeons attested.

DR. SMILEY: In Dr. Lerman's data from Canada in 66 patients, I think he reported that 18% of the patients who were induced with desflurane had arterial oxygen saturations decrease below 90% during the induction, and this is with 95% oxygen. This was not single-breath induction.

DR. COTÉ: That is the difference. In the multicenter study, ours was not either; but in the multicenter study, nitrous oxide was part of the induction technique required by the protocol, and that, I think, was one of the problems with the protocol. If we had done the study as Dr. Lerman did with 100% oxygen, we would not have had the "near-death" experiences. So I think, despite protocol difficulties, these studies point the way to appropriate labeling. The last comment I wanted to make was about the emergence. We found that emergence was so rapid with desflurane that the children were greatly confused and disoriented in the recovery room.

DR. SMILEY: Well, I think there may be some difference between pediatric outpatients and adults (either outpatients or inpatients). I was concerned about allowing people to wake up so quickly with presumably so little residual anesthesia, but very few remembered pain. They may have been amnestic, perhaps, the first few minutes.

DR. DENNIS FISHER (San Francisco): When you talked about the pediatric studies, although you gave Dr. Lerman credit, several others who were involved in the U.S. multicenter trials also deserve to be mentioned: Drs. Maurice Zwass and Dennis Fisher from UCSF; Drs. Leila Welborn and Raafat Hannallah from D.C. Children's; Drs. Charle Coté and Lydia Liu from Massachusetts General; Drs. Pete Davis and Ryan Cook from Pittsburgh Children's.

DR. SMILEY: You are absolutely right. They all wer involved and should be acknowledged.

DR. FISHER: One of the points we have been interested i is that although it is easy to make a smooth transition fron a halothane induction, followed by intubation, to a desflurane anesthetic, we really do not know what will happen i you induce anesthesia with thiopental or propofol in children and then administer desflurane. Will we see th profound laryngospasm we have seen with desfluran inductions?

DR. SMILEY: In our 52 patients, we had 28 who receive desflurane. We had two incidences of laryngospasm i adults who had been induced with thiopental. In defense o desflurane, or in defense of our studies, they were two o our first four or five patients, so it was early in ou experience. Later, in our intravenously induced patients we got better at dealing with desflurane. We still had som coughing, a little breath holding, but we had no episodes laryngospasm requiring a muscle relaxant after our first fe patients.

DR. IRA RAMPIL (San Francisco): I would like to add m perspective, having done one of these induction, maintenance, and emergence studies, with regard to hypertensio and tachycardia seen during induction. We saw fairl uniform hypertension and tachycardia, but you should tak our data with a grain of salt, as is true for many othe studies done as phase I trials. Our protocol required us t be pharmacologically pure, to assess what desfluran would do by itself, so we did not premedicate the patients I think if you were to use desflurane the way you do a inhaled induction in adults with isoflurane, the incidenc and magnitude of this excitement phenomenon would b much muted. The few times I have administered isofluran without any other drugs, I have seen similar problems With regard to laryngospasm, in the approximately 6 patients I anesthetized with desflurane, we had only tw cases of laryngospasm, both of which may have bee matters of operator technique. I would also like to mentio our patients' experience with pain after the procedures. W found after our first few anesthetics that pain returned a quickly as consciousness, and in our patients, the latte returned quite rapidly. We found we needed to add morphine at the end of the cases.

DR. SMILEY: In the first 28 patients in our group of 50, w first allowed them to awaken. Then almost all were given or 10 mg of morphine or 100 μg of fentanyl or something o that sort. After just a few minutes had passed, they ha some opiate effect.

DR. R. D. MILLER: There is difficulty in determining level of patients' pain. Blinded studies are best to solicit whethe pain is there or not. In the future, that is such a soft are that we need to be precise as to how we make determinations that somebody has had pain.

DR. SMILEY: A weakness in studies like these is the fact they were not blinded because of the nature of the anesthesia machine used to administer desflurane. We always knew what the patient was receiving. The patients did not know, generally. They all assumed they were receiving desflurane.

DR. MIRIAM LEBENBOM-MANSOUR (Detroit): There were two things I wanted to comment about. One of them was that when we did our study in Michigan, we had two patients during induction who had significant hypertension, during which diastolic blood pressures were getting up to 110 mm Hg. We had to decide what we wanted to do, whether we wanted to turn off the desflurane and do something else with those patients. The hypertension was during induction in our studies. I do not recall whether Dr. Apfelbaum's cases were during induction or during maintenance.

DR. R. D. MILLER: Did you administer fentanyl ahead of time?

DR. LEBENBOM-MANSOUR: Yes, we administered fentanyl (2 μg/kg) up front. I do not know what that really means. We had 60 patients in our study and experienced this in only two. I also wanted to comment about emergence. Most studies appear to show differences only in terms of a few minutes, particularly if you compare propofol with desflurane. Do you really care whether emergence takes 3–5 min with either drug? If you look at discharge and recovery times in other ways, even comparing them with isoflurane, they certainly look very similar to me.

DR. SMILEY: Initial wake-up was significantly faster with desflurane, and in our studies not just a few minutes, but really half time, 15 min versus 8 min and 10 min versus 5 min. Recovery room discharge times were not different. One explanation could be simply that protocols in certain recovery rooms do not permit people to leave that soon. Another possibility is that there are insufficient differences an hour later to cause a difference in discharge time. Again, a subjective comment, but all of us who were working on it could tell (and the recovery nurses could tell) that this was a patient that got the "new drug." Patients seemed much happier with their anesthetic, felt better an hour or two later, some remarking "Gee, I am more 'with it', I do not have that weird feeling I had after my last one." Those are things I think are harder to prove. I am not sure how we get at that.

DR. R. D. MILLER: I tend to agree with you. To me, what is really important is, how do they feel 24 h later?

DR. RYAN D. COOK (Pittsburgh): I will be concise. I do not think the severity of the laryngospasm should be minimized, at least not from the pediatric studies. This was not straightforward laryngospasm easily reduced with positive pressure ventilation. This was severe, intractable, associated with severe hypoxemia in many cases, and required succinylcholine. In my experience, the laryngospasm was akin to that seen with cyclopropane in the old days. On the other hand, I also agree with the observation that perhaps there is a learning curve in the administration of desflurane. Despite that learning curve, it is my recollection that we saw as much laryngospasm late in the study as we saw early. In our institution, the wizened veteran who had administered all those terrible agents in antiquity had as much laryngospasm with desflurane as did the younger physicians.

DR. RANDALL L. CARPENTER (Seattle): Future studies should prompt, "When can patients stand? When can they void?" or whatever the criteria are for discharge. Our postanesthesia care unit nurses tend to have relatively fixed expectations of how long it should take for someone to recover from a given anesthetic. They are not comfortable sending, nor are they necessarily allowed to send, a patient out until a certain time lapses after a specific operation and anesthetic technique, unless you prompt for designated criteria. Otherwise, all patients are going to come out the same. Future studies should not assess discharge time unless you are prompting for proper endpoints.

DR. SMILEY: There are protocols and there are expectations in daily practice. I think you are absolutely right.

Studies of Desflurane in Outpatient Anesthesia

Paul F. White, PhD, MD, FFARACS
Department of Anesthesiology and Pain Management, University of Texas Southwestern Medical Center, Dallas, Texas

The low solubility of desflurane contributes to rapid emergence after outpatient anesthesia. Compared with isoflurane, recovery times to eye opening, response to verbal commands, and orientation to person, place, and time have been significantly shorter. Even when compared with the rapid, short-acting intravenous anesthetic propofol for induction and maintenance of outpatient anesthesia, desflurane displayed more favorable early recovery characteristics. Although patients receiving desflurane are less sedated in the early postoperative period than those receiving propofol, times to ambulation and discharge were similar. The direct "antiemetic" activity of propofol may have contributed to a lower incidence of postoperative nausea and emesis versus desflurane. Finally, the effects of desflurane, isoflurane, and propofol on postoperative psychomotor (e.g., Trieger test, choice reaction time) and cognitive (e.g., digit-symbol substitution test, critical flicker fusion test) function are remarkably similar. Given its favorable early recovery profile, desflurane would appear to be a useful alternative to both isoflurane and propofol for maintenance of outpatient anesthesia. As desflurane is pungent and possesses respiratory irritant properties, propofol will likely remain the induction agent of choice in the outpatient setting. In conclusion, desflurane appears to have few adverse effects on recovery after ambulatory surgery, but nausea and emesis were lower with propofol. Desflurane's relative ease of administration versus propofol may be an important determinant of its future role in outpatient anesthesia.

(Anesth Analg 1992;75:S47–54)

In considering possible roles for desflurane in outpatient anesthesia, it is important first to consider factors that contribute to successful anesthesia for ambulatory surgery. An optimal anesthetic for outpatient surgery would include the following:

1. These should have a rapid and smooth onset of action. Efficiency is an important factor in the ambulatory setting.
2. Intraoperative amnesia and analgesia are quite important, as is the ability to provide for excellent operating conditions.
3. There should be rapid recovery without residual side effects or clinically significant discomfort. Degree of postoperative pain is a major limiting factor in determining whether a surgical procedure can be performed on an ambulatory basis.
4. Absence of adverse effects, such as nausea and vomiting, is extremely important after ambulatory surgery; emetic symptoms affect not only recovery times but also the incidence of unanticipated hospital admissions.

Several years ago, Gold et al. (1) evaluated factors that contributed to unanticipated hospital admissions after ambulatory surgery. Of the factors associated with increased risk of unanticipated admissions, general anesthesia was at the top of the list. Despite the availability of more rapid and shorter acting anesthetics and analgesic and muscle relaxant drugs, general anesthesia is still associated with an enhanced risk of unanticipated hospital admission (compared with local or regional anesthesia) after ambulatory surgery.

A recent survey involving U.S. anesthesiologists indicated that the predominant drug for general anesthesia maintenance in the outpatient setting was isoflurane. Although many of the recent studies involving outpatients compared desflurane with propofol, that comparison may be less relevant because isoflurane is the drug that desflurane would be likely to replace.

Most investigations involving use of desflurane in outpatients have focused on its recovery profile. Ghouri et al. (2) evaluated a group of patients undergoing outpatient procedures lasting 1–3 h (e.g., plastic, gynecologic, and orthopedic procedures). Demographically, the isoflurane and desflurane groups were similar (Table 1). The total doses of fentanyl (3 μg/kg) and thiopental (4.2–4.4 mg/kg) were representative of dosages commonly used. Emergence was

[b] Significantly different from isoflurane group; $P < 0.05$.

evaluated from equi-MAC concentrations (≈0.5 MAC). Steady-state end-tidal anesthetic gas concentrations at the end of the surgical procedures were 0.6% isoflurane and 2.9% desflurane. Both treatment groups also received the same concentration (70%) of nitrous oxide in oxygen. Compared with the isoflurane group, the time required for the end-tidal anesthetic concentration to decrease by 50% was significantly shorter in the desflurane group (Table 2). Times to emergence from anesthesia (i.e., eye opening and ability to follow commands) were also significantly shorter. There were no significant differences between the two anesthetic groups with respect to times to sitting up, to transfer from phase I to phase II recovery, and to being judged home-ready by postanesthesia care unit (PACU) staff using standardized discharge criteria. The study patients were required to complete a battery of postoperative tests, so potential differences in discharge times may have been obscured.

Intraoperative hemodynamic changes >20% above or below preinduction baseline values occurred with similar frequency in both treatment groups (Table 3).

Table 3. Adverse Intraoperative Cardiovascular Events and Side Effects in the Postanesthesia Care Unit[a]

Event	Isoflurane group	Desflurane group
Intraoperative[b]		
Tachycardia	3 (14)	0 (0)
Bradycardia	4 (19)	2 (12)
Hypertension	5 (26)	3 (18)
Hypotension	1 (5)	3 (18)
Postoperative (PACU)		
Nausea and vomiting	9 (43)	6 (35)
Pain	11 (52)	8 (47)

PACU, postanesthesia care unit.
Data presented as number (percent).
[a] Data from Ghouri et al. (2).
[b] Change in heart rate or blood pressure >20% of the preinduction baseline value.

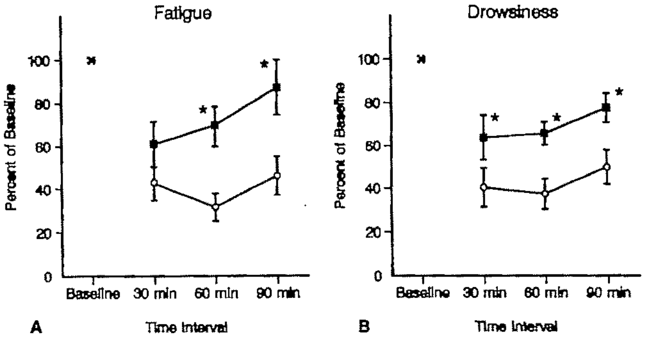

Figure 1. Visual analogue scales (-■-, desflurane; -○-, isoflurane). **A.** Fatigue; $^*P < 0.05$. **B.** Drowsiness; $^*P < 0.05$.

In the recovery room, nausea and vomiting occurred in 35% of outpatients receiving desflurane compared with 43% in the isoflurane group. Requirements for antiemetic therapy in the PACU were similar in both groups. Incidence of pain (i.e., patients who required parenteral analgesics in the PACU) was also nearly identical in the two groups.

Visual analogue scales were used to assess residual effects of the anesthetic agents to assess postoperative fatigue and drowsiness (Figure 1). At 30 min postanesthetic, there were significant decreases in both groups (compared with preoperative baseline values). There was less subjective impairment in the desflurane group compared with the isoflurane group at the 60- and 90-min time intervals. To evaluate psychomotor performance, the Trieger test was used. No differences were found between the two anesthetic groups in the early postoperative recovery period (Figure 2). Cognitive function was assessed with the digit-symbol substitution test (DSST). Postoperatively, only 43% of the isoflurane-treated patients could actually perform the test at the 30-min time point compared with 76% of the desflurane-treated patients. The desflurane group performed

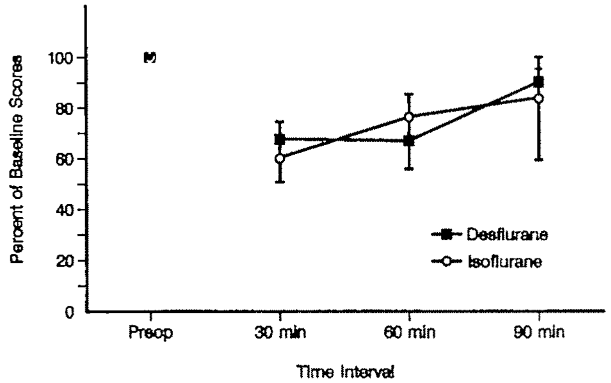

Figure 2. Trieger test.

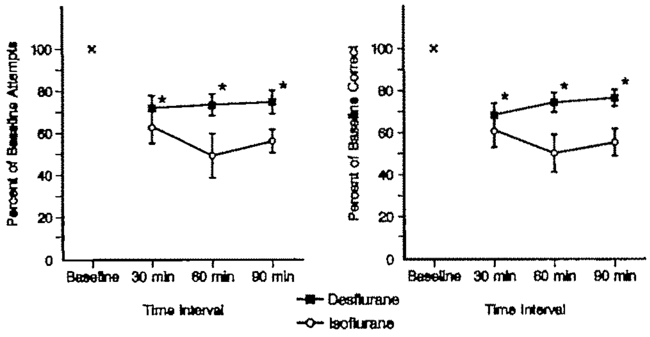

Figure 3. Digit-symbol substitution test. *$P < 0.05$.

significantly better overall on the DSST (Figure 3). Failure of test scores to return to preoperative baseline values in either group may have been related to the fact that patients in both groups were receiving parenteral analgesics for pain control and antiemetic drugs to control nausea and vomiting. These centrally active drugs can impair ability to perform cognitive function tests.

Others have evaluated inhaled agents on emergence times and psychomotor performance after outpatient procedures (3,4). Smiley et al. (3) reported shorter emergence times after desflurane versus isoflurane anesthesia. Fletcher et al. (4) evaluated early and late recovery of psychomotor performance after desflurane- and isoflurane-supplemented anesthesia. Outpatients were randomly assigned to one of four anesthetic treatment groups (Table 4). Three groups received thiopental for induction, followed by isoflurane-nitrous oxide (control), desflurane-nitrous oxide, or desflurane alone for maintenance of anesthesia. The final group received desflurane alone for induction and maintenance of anesthesia. These investigators found shorter emergence times when desflurane was used for maintenance of anesthesia compared with isoflurane (Figure 4). Use of thiopental (versus desflurane) for induction of anesthesia prolonged early recovery times after desflurane maintenance. Compared with isoflurane, the desflurane group had less residual impairment of choice reaction time (Figure 5). No differences were found between the two volatile anesthetic groups in performance on the critical flicker fusion threshold test (Figure 6). All four groups returned to baseline performance levels by 24 h.

More recent studies with desflurane have compared its recovery profile with that of propofol. Although some have suggested that propofol is an ideal anesthetic for outpatients, propofol possesses side effects, including (a) pain on injection; (b) cardiovascular depressant effects owing to direct effects on peripheral vasculature, baroreflex mechanisms, and direct myocardial depression; (c) respiratory depression as well as transient apnea and interference with central respiratory drive; and (d) excitement (euphoria) on emergence from anesthesia (5,6).

Outpatient studies comparing desflurane and propofol have been performed in the United States as well as the United Kingdom (7,8). In a group of outpatients undergoing laparoscopic procedures, desflurane was compared with propofol used for induction and maintenance of general anesthesia (7). These healthy young women were randomly assigned to one of four treatment groups (Table 5). Group I received propofol for induction, followed by propofol and nitrous oxide for maintenance. Group II received propofol for induction, followed by desflurane and nitrous oxide for maintenance. Group III received desflurane and nitrous oxide for induction and maintenance. Group IV received desflurane alone for induction and maintenance. Although the groups receiving desflurane with nitrous oxide (groups II and III) required lower end-tidal desflurane concentrations during maintenance than did the desflurane-alone group (Figure 7), emergence was significantly faster in the group receiving desflurane alone for induction and maintenance of anesthesia (Figure 8). Later recovery times (e.g., sitting up, standing, walking, discharge) were similar in all four groups (Figure 9).

In comparing the intraoperative hemodynamic changes, no significant differences were apparent between propofol and desflurane (with or without nitrous oxide) during maintenance (Figures 10 and 11). Side effects during the induction and early recovery period differed significantly among the various groups. Pain on injection was reported in 45% of the groups induced with propofol (Table 6). Respiratory irritation was more common with desflurane. Nitrous oxide did not alter the incidence of respiratory complications during induction with desflurane. Spontaneous movements during induction were noted in all four treatment groups.

Postoperatively, recovery of psychomotor function

Table 4. Demographic Characteristics of Patients in the Four Treatment Groups[a]

	Thio-Iso-N_2O group	Thio-Des-N_2O group	Thio-Des group	Desflurane group
Age (yr)	40.2 ± 2.72	39.4 ± 2.7	41.7 ± 3.0	41.7 ± 2.4
Weight (kg)	80.3 ± 2.8	78.1 ± 3.9	76.3 ± 2.7	73.3 ± 3.0
Height (cm)	169 ± 6.0	174 ± 3.2	169 ± 2.1	170 ± 11
Dose of thiopental (mg)	342 ± 15	369 ± 24	330 ± 14	—
Duration of anesthesia (min)	45.8 ± 5.1	50.4 ± 4.1	50.3 ± 6.3	53.6 ± 6.2
End-tidal anesthetic concentration at discontinuation (%)	1.1 ± 0.04	6.1 ± 0.34	8.9 ± 0.35	8.3 ± 0.41

Thio, thiopental; Iso, isoflurane; Des, desflurane.

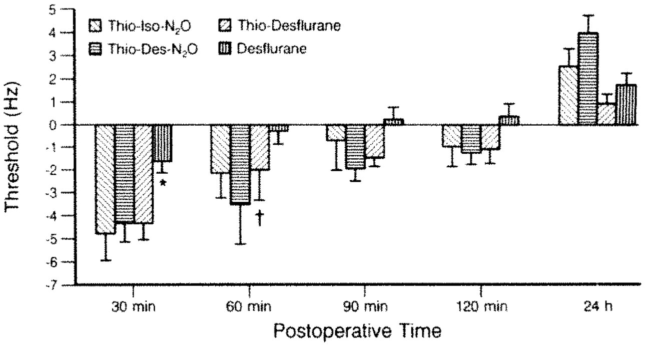

Figure 6. Critical flicker fusion thresholds. Data are mean ± SE. $^*P < 0.05$ compared with Thio-Iso-N_2O group. $^†P < 0.05$ compared with Des alone group.

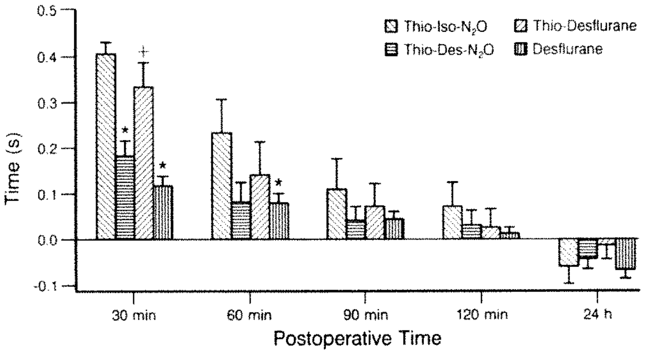

Figure 5. Choice reaction times. Data are mean ± SE. $^*P < 0.05$ compared with Thio-Iso-N_2O group. $^†P < 0.05$ compared with Des alone group.

was evaluated at 30-min intervals with the DSST. Although all four groups performed remarkably well (Figure 12), the group receiving propofol for induction followed by desflurane-nitrous oxide for maintenance (group II) recovered more slowly than those receiving propofol (group I) or desflurane (group IV) alone. Both the patients and a research nurse who was unaware of the experimental treatment evaluated residual levels of drowsiness in the PACU. At 30 min after surgery, patients who received desflurane alone tended to be more awake (and calm), compared with those assigned to group I receiving propofol alone or the propofol-desflurane-nitrous oxide group (group II) (Figure 13). Postoperative sedation scores were similar in all four groups and remained higher than the preoperative baseline values 2 h after the operation (Figure 14).

Using a similar protocol design, Wrigley et al. (8) reported that postoperative psychomotor performance (e.g., DSST, "p" deletion) in outpatients who had received propofol for induction and maintenance of anesthesia was "significantly worse compared with those who were given desflurane either for induction and maintenance or for maintenance only." Although these investigators also found a tendency for other recovery parameters to be faster in patients receiving desflurane (versus propofol), these differences were not statistically significant. Incidence of postoperative nausea and vomiting was not increased in the desflurane groups (versus propofol-nitrous oxide). In the previous study (7), a higher incidence of moderate to severe nausea was found in the desflurane treatment groups (52%–59% compared to 15% with propofol-nitrous oxide alone) (Figure 15).

Recently, Watcha et al. (9) reported that compared with a standard droperidol-halothane-nitrous oxide technique, propofol alone was associated with de-

creased emesis after strabismus surgery in pediatric outpatients. These data suggested that propofol may possess antiemetic properties.

Postoperative nausea and vomiting is a problem that importantly affects recovery after outpatient surgery (1). In reviewing the anesthetic-related causes of unexpected hospitalizations after ambulatory surgery, intractable nausea and vomiting is usually at the top of the list for both adults and children (10). Even if not intractable, nausea or vomiting clearly impacts recovery after outpatient surgery (11). Times

to ambulation and discharge were significantly prolonged with nausea alone and further prolonged when nausea was associated with vomiting. All studies involving desflurane (and propofol) have focused on emetic symptoms in the PACU. Actually, nausea and vomiting after discharge from an ambulatory surgery center may be more important from the patient's perspective. Most recent clinical reports describing the newer short-acting anesthetic, analgesic, and muscle relaxant drugs are lacking in good outcome data with regard to outpatients after discharge to their homes (i.e., when do patients resume their normal activities?).

Finally, an editorial appeared in the *Lancet* when propofol was released in Europe several years ago in which the writer suggested that the "new awakening in anesthesia [was coming] at a price" (12). Although not referring merely to the cost of propofol, the author made the astute observation that if patients awakened rapidly, they might be more aware of events in their surrounding environment, including postoperative pain. Pain control after ambulatory surgery will be increasingly important as we utilize shorter acting anesthetics and analgesics during outpatient anesthesia.

Availability of a less soluble volatile anesthetic (desflurane) will provide more rapid emergence from outpatient anesthesia than isoflurane. Cost-effectiveness and outcome studies are needed to determine the future role of desflurane in ambulatory surgery (13,14).

DISCUSSION

DR. RONALD D. MILLER (San Francisco): The presence of nausea and vomiting may well be more important than several other anesthetic-related factors in determining when people go home from ambulatory surgery. If that is the case, why use fentanyl so often at the start of anesthesia?

DR. PAUL F. WHITE (Dallas): I think most clinicians continue to use fentanyl because it appears to allow a smoother anesthetic, especially if you are performing a case with a face mask and not using muscle relaxants, a frequent occurrence in outpatients. It is very important to minimize the amount of opioid used. You are right in suggesting that even modest doses of fentanyl may increase the likelihood of nausea and vomiting in outpatients.

DR. PETER SEBEL (Atlanta): What is the essential difference among desflurane, isoflurane, and propofol, and how important is this difference?

DR. WHITE: I would suggest that studies to determine that to the fullest extent have not been conducted. For example, a study involving patients undergoing anesthesia with a face mask, which is, perhaps, 50% of our outpatient population, as far as I know, has not as yet been performed. The question is whether a less soluble agent like desflurane, with a presumed ability to improve titration, can equilibrate more rapidly and therefore provide better control. The problem with many studies, as you know, is that we are required to follow rather rigid protocols (deemed necessary to comply with FDA requirements) that do not reflect the way in which we use the drugs clinically. Th other problem is that we have not performed sufficien outcome studies needed to evaluate the impact, not only i the early recovery period, but also how patients do afte discharge, on the way home, and once they have reache home. One would wonder whether an anesthetic with much reduced solubility might offer advantages in terms o effects that occur hours later.

DR. SEBEL: Our study patients came back at 24 h to repea the battery of tests again. There were no differences note between desflurane and isoflurane, and there were n apparent differences in subjective effects in any of them regardless of whether they had been given isoflurane o desflurane, with or without an intravenous inductio agent.

DR. EDMOND I. EGER II (San Francisco): With regard t the question of differences between animal and huma rates of recovery, you have implied, and correctly I think that the animals were not the recipients of other drugs tha might tend to normalize or equalize the two groups. I thin were we to look at pure desflurane or pure isoflurane i humans, we would see similar differences in humans a those seen in the animals. We are here presented with dat indicating that recovery is faster insofar as initial recovery i concerned, but long-term recovery has not been shown t be different. I would make some other observations wit regard to long-term recovery. First, there are several factor that influence recovery quite apart from anesthetic choice. Second, in the studies comparing desflurane with agent like isoflurane, the numerical averages indicated faster recovery with desflurane than with isoflurane, although there was no statistically significant difference in several studies. I would submit that the numbers involved in each of these studies are probably too small to achieve statistical significance if, indeed, there is a real difference, and it may take hundreds of patients rather than 20–40 patients per group to do that. Also, the ideal outpatient anesthetic might be one different from anything we have yet tested. For example, the ideal outpatient anesthetic might combine ketorolac, propofol, and desflurane, without nitrous oxide. This might be better, because the other drugs often used in outpatient anesthesia, including nitrous oxide, thiopental, and narcotics, may precipitate nausea and vomiting.

DR. WHITE: I think there are dangers in combining data from multicenter studies (to assemble a larger sample) because there are other confounding factors that could influence those results. The early desflurane studies were not designed to rigorously evaluate early recovery or discharge. Also important is consideration of how patients feel postoperatively. If it turns out that desflurane-treated patients are less depressed, less lethargic, feel better in the early recovery period, and can be mobilized sooner, then we will have rapid acceptance of this as an alternative to isoflurane. One cannot lose sight of the fact that the comparator for desflurane is really isoflurane, not propofol.

DR. ROBERT G. MERIN (Houston): I have a question for Dr. Eger. In his summation about nitrous oxide a few years ago, he decided that nitrous oxide was not a causative agent in postoperative nausea and vomiting, generally speaking. Is this different now for desflurane? Do you feel that it is a causative agent with desflurane?

DR. EGER: I definitely believe that nitrous oxide causes nausea; in fact, I know it causes nausea and vomiting, because I can produce nausea in the volunteers that we study, in 80%–90% of them, just by giving them 40%–60% nitrous oxide with no other agent. They vomit, and they vomit repeatedly. In the nitrous oxide data that we published from a series of studies, we did say that it was difficult to see differences with versus without nitrous oxide, although in one group we did show differences, particularly in young patients who received nitrous oxide for a particular procedure.

DR. R. D. MILLER: Are you talking about nausea and vomiting during induction of anesthesia, or recovery, or both?

DR. EGER: Both. If you look at the desflurane studies and at the comparisons between the patients who received nitrous oxide versus those who did not (i.e., who received desflurane and oxygen), there is a rather striking difference in the incidence of nausea and vomiting.

DR. MERIN: To me, the problem is producing analgesia without increasing nausea and vomiting.

DR. CHARLES H. McLESKY (Denver): In pediatrics we seldom use narcotics. Probably 70% of our patients are outpatients. We administer an inhaled agent and a long-acting local anesthetic for postoperative analgesia. The vast majority of our children never receive a narcotic. When we participated in this multiinstitutional study, we attempted to see whether there was any difference between recovery in our patients, and we intentionally interfaced some protocols. The end result was that recovery from desflurane was faster than halothane. It was 6.7 min for eye opening versus, I think, 9.1 min for halothane. Return of corneal reflex and of conjugate gaze from disconjugate gaze was also more rapid in the desflurane group than in the halothane group. Discharge from recovery and from the hospital were not different. We called all the parents the next day to find out how the children did with nausea and vomiting, and the incidence was the same in both groups at 24 h. Many children get sick in the car on the way home. So I agree that you should look at 24 h, not just the first few hours after an anesthetic. I think more studies are needed that do look at pure techniques, where you are using just an inhaled agent and a local anesthetic, without narcotics. I think that will help clear some of the confusion about rapidity of wake-up and the nausea and vomiting issues, as well.

DR. WHITE: If you can minimize opioid administration, you can decrease nausea and vomiting. The ability to use a potent inhaled agent as the primary anesthetic may be advantageous.

DR. PETER GLASS (Durham): It would appear from a pharmacokinetic point of view that when you compare isoflurane with desflurane for 1-h procedures, you should see only a small difference in terms of recovery. As you extend procedure times—1, 3, 4 h—this difference will become more and more apparent. Do you agree?

DR. WHITE: Past comparisons between isoflurane and enflurane have demonstrated that differences only became apparent after 60 min. In fact, most of those studies indicated that unless the anesthetic is at least 90 min in duration, it was hard to show any advantage of isoflurane over enflurane. Actually, for very short cases enflurane tends to have a somewhat shorter recovery time despite its greater solubility. Whether this will hold for the isoflurane versus desflurane comparison is not known.

DR. STEPHEN ROBINSON (Portland): When you look at efficiency, what can you save in costs with an anesthetic? Discharge home is one criterion. Discharge from recovery room is often important. Ease of care in the recovery room is also a criterion to predict staffing requirements. A higher incidence of immediate postoperative nausea and vomiting will necessitate higher staffing levels. In doing brief cases, the operating room turnover rate becomes a critical step in keeping operating costs low. We (anesthesia) are usually the limiting step, and if it takes even 3–5 min longer to wake a patient up or to no longer have to attend to them in the recovery room, we are responsible for the incremental increase in time in that room. As we look toward specific cases, trying to identify what characteristics of desflurane make a difference, I think it is going to be very important to consider these elements.

A LOGICAL CHOICE

CRUCIAL PARAMETERS IN SELECTING A NEUROMUSCULAR BLOCKING AGENT

	Norcuron® (vecuronium bromide) for injection	Atracurium besylate
HEMODYNAMICS	No significant variations in blood pressure, cardiac output, or systemic vascular resistance.[1]	Statistically significant variations in blood pressure, cardiac output, and systemic vascular resistance.[1] ($P<.05$)
HISTAMINE	Available clinical experience indicates that reactions commonly associated with histamine release are unlikely to occur.[1-4]	Precautions advised for patients in whom substantial histamine release would be hazardous (eg, clinically significant cardiovascular disease, asthma).[5]
RECOVERY To 25% of control To 95% of control	 25-40 min[3] 45-65 min[3]	 35-45 min[5] 60-70 min[5]
DOSING FLEXIBILITY	The initial recommended dose is 0.08-0.1 mg/kg. Dose can be increased up to 0.28 mg/kg for long cases without significant histamine release or related cardiovascular side effects.[1,3,4]	Initial recommended dose is 0.4-0.5 mg/kg. A moderate histamine release and significant falls in blood pressure have been seen following a dose of 0.5 mg/kg ($P<.05$) and 0.6 mg/kg.[*2,5,6]
STORAGE & SHELF LIFE	2-year shelf life in lyophilized form at room temperature.[†] Can be reconstituted with various IV solutions including Lactated Ringers.[‡]	2-year shelf life under constant refrigeration.[†] Upon removal from refrigeration to room temperature storage, use within 14 days even if rerefrigerated.[5]

[*] Dose of atracurium above 0.5 mg/kg is not recommended.
[†] As originally supplied by the respective manufacturers.
[‡] Storage after reconstitution varies with solution. See package insert.

Norcuron®
(vecuronium bromide) for injection

A LOGICAL CHOICE FOR NEUROMUSCULAR BLOCKADE

WEST ORANGE
NEW JERSEY 07052

Norcuron®

(vecuronium bromide) for injection

Before prescribing, please consult complete product information, a summary of which follows:

> **THIS DRUG SHOULD BE ADMINISTERED BY ADEQUATELY TRAINED INDIVIDUALS FAMILIAR WITH ITS ACTIONS, CHARACTERISTICS, AND HAZARDS.**

CONTRAINDICATIONS: Norcuron® is contraindicated in patients known to have a hypersensitivity to it.

WARNINGS: NORCURON® SHOULD BE ADMINISTERED IN CAREFULLY ADJUSTED DOSAGE BY OR UNDER THE SUPERVISION OF EXPERIENCED CLINICIANS WHO ARE FAMILIAR WITH ITS ACTIONS AND THE POSSIBLE COMPLICATIONS THAT MIGHT OCCUR FOLLOWING ITS USE. THE DRUG SHOULD NOT BE ADMINISTERED UNLESS FACILITIES FOR INTUBATION, ARTIFICIAL RESPIRATION, OXYGEN THERAPY, AND REVERSAL AGENTS ARE IMMEDIATELY AVAILABLE. THE CLINICIAN MUST BE PREPARED TO ASSIST OR CONTROL RESPIRATION. TO REDUCE THE POSSIBILITY OF PROLONGED NEUROMUSCULAR BLOCKADE AND OTHER POSSIBLE COMPLICATIONS THAT MIGHT OCCUR FOLLOWING LONG-TERM USE IN THE ICU, NORCURON® OR ANY OTHER NEUROMUSCULAR BLOCKING AGENT SHOULD BE ADMINISTERED IN CAREFULLY ADJUSTED DOSES BY OR UNDER THE SUPERVISION OF EXPERIENCED CLINICIANS WHO ARE FAMILIAR WITH ITS ACTIONS AND WHO ARE FAMILIAR WITH APPROPRIATE PERIPHERAL NERVE STIMULATOR MUSCLE MONITORING TECHNIQUES (see PRECAUTIONS). In patients who are known to have myasthenia gravis or the myasthenic (Eaton-Lambert) syndrome, small doses of Norcuron® may have profound effects. In such patients, a peripheral nerve stimulator and use of a small test dose may be of value in monitoring the response to administration of muscle relaxants.

PRECAUTIONS:

Renal Failure: Norcuron® is well tolerated without clinically significant prolongation of neuromuscular blocking effect in patients with renal failure who have been optimally prepared for surgery by dialysis. Under emergency conditions in anephric patients some prolongation of neuromuscular blockage may occur; therefore, if anephric patients cannot be prepared for non-elective surgery, a lower initial dose of Norcuron® should be considered.

Altered Circulation Time: Conditions associated with slower circulation time in cardiovascular disease, old age, edematous states resulting in increased volume of distribution may contribute to a delay in onset time, therefore dosage should not be increased.

Hepatic Disease: Limited experience in patients with cirrhosis or cholestasis has revealed prolonged recovery time in keeping with the role the liver plays in Norcuron® metabolism and excretion. Data currently available do not permit dosage recommendations in patients with impaired liver function.

Long-term Use in I.C.U.: In the intensive care unit, in rare cases, long-term use of neuromuscular blocking drugs to facilitate mechanical ventilation may be associated with prolonged paralysis and/or skeletal muscle weakness that may be first noted during attempts to wean such patients from the ventilator. Typically, such patients receive other drugs such as broad spectrum antibiotics, narcotics and/or steroids and may have electrolyte imbalance and diseases which lead to electrolyte imbalance, hypoxic episodes of varying duration, acid-base imbalance and extreme debilitation, any of which may enhance the actions of a neuromuscular blocking agent. Additionally, patients immobilized for extended periods frequently develop symptoms consistent with disuse muscle atrophy. The recovery picture may vary from regaining movement and strength in all muscles to initial recovery of movement of the facial and small muscles of the extremities then to the remaining muscles. In rare cases recovery may be over an extended period of time and may even, on occasion, involve rehabilitation. Therefore, when there is a need for long-term mechanical ventilation, the benefits-to-risk ratio of neuromuscular blockade must be considered. Continuous infusion or intermittent bolus dosing to support mechanical ventilation has not been studied sufficiently to support dosage recommendations.

IN THE INTENSIVE CARE UNIT, APPROPRIATE MONITORING, WITH THE USE OF A PERIPHERAL NERVE STIMULATOR TO ASSESS THE DEGREE OF NEUROMUSCULAR BLOCKADE, IS RECOMMENDED TO HELP PRECLUDE POSSIBLE PROLONGATION OF THE BLOCKADE. WHENEVER THE USE OF NORCURON® OR ANY NEUROMUSCULAR BLOCKING AGENT IS CONTEMPLATED IN THE ICU, IT IS RECOMMENDED THAT NEUROMUSCULAR TRANSMISSION BE MONITORED CONTINUOUSLY DURING ADMINISTRATION AND RECOVERY WITH THE HELP OF A NERVE STIMULATOR. ADDITIONAL DOSES OF NORCURON® OR ANY OTHER NEUROMUSCULAR BLOCKING AGENT SHOULD NOT BE GIVEN BEFORE THERE IS A DEFINITE RESPONSE TO T_1 OR TO THE FIRST TWITCH. IF NO RESPONSE IS ELICITED, INFUSION ADMINISTRATION SHOULD BE DISCONTINUED UNTIL A RESPONSE RETURNS.

Severe Obesity or Neuromuscular Disease: Patients with severe obesity or neuromuscular disease may pose airway and/or ventilatory problems requiring special care before, during and after the use of neuromuscular blocking agents such as Norcuron®.

Malignant Hyperthermia: Many drugs used in anesthetic practice are suspected of being capable of triggering a potentially fatal hypermetabolism of skeletal muscle known as malignant hyperthermia. There are insufficient data derived from screening in susceptible animals (swine) to establish whether or not Norcuron® is capable of triggering malignant hyperthermia.

C.N.S.: Norcuron® has no known effect on consciousness, the pain threshold or cerebration. Administration must be accompanied by adequate anesthesia or sedation.

Drug Interactions: Prior administration of succinylcholine may enhance the neuromuscular blocking effect of Norcuron® (vecuronium bromide) for injection and its duration of action. If succinylcholine is used before Norcuron®, the administration of Norcuron® should be delayed until the succinylcholine effect shows signs of wearing off. With succinylcholine as the intubating agent, initial doses of 0.04-0.06 mg/kg of Norcuron® may be administered to produce complete neuromuscular block with clinical duration of action of 25-30 minutes. The use of Norcuron® before succinylcholine, in order to attenuate some of the side effects of succinylcholine, has not been sufficiently studied.

Other nondepolarizing neuromuscular blocking agents (pancuronium, d-tubocurarine, metocurine, and gallamine) act in the same fashion as does Norcuron®, therefore these drugs and Norcuron® may manifest an additive effect when used together. There are insufficient data to support concomitant use of Norcuron® and other competitive muscle relaxants in the same patient.

Inhalational Anesthetics: Use of volatile inhalational anesthetics such as enflurane, isoflurane, and halothane with Norcuron® will enhance neuromuscular blockade. Potentiation is most prominent with use of enflurane and isoflurane. With the above agents the initial dose of Norcuron® may be the same as with balanced anesthesia unless the inhalational anesthetic has been administered for a sufficient time at a sufficient dose to have reached clinical equilibrium.

Antibiotics: Parenteral/intraperitoneal administration of high doses of certain antibiotics may intensify or produce neuromuscular block on their own. The following antibiotics have been associated with various degrees of paralysis: aminoglycosides (such as neomycin, streptomycin, kanamycin, gentamicin, and dihydrostreptomycin); tetracyclines; bacitracin; polymyxin B; colistin; and sodium colistimethate. If these or other newly introduced antibiotics are used in conjunction with Norcuron®, unexpected prolongation of neuromuscular block should be considered a possibility.

Other: Experience concerning injection of quinidine during recovery from use of other muscle relaxants suggest that recurrent paralysis may occur. This possibility must also be considered for Norcuron®. Norcuron® induced neuromuscular blockade has been counteracted by alkalosis and enhanced by acidosis in experimental animals (cat). Electrolyte imbalance and diseases which lead to electrolyte imbalance, such as adrenal cortical insufficiency, have been shown to alter neuromuscular blockade. Depending on the nature of the imbalance, either enhancement or inhibition may be expected. Magnesium salts, administered for the management of toxemia of pregnancy, may enhance the neuromuscular blockade.

Drug/laboratory test interactions: None known.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term studies in animals have not been performed to evaluate carcinogenic or mutagenic potential or impairment of fertility.

Pregnancy: Pregnancy Category C: Animal reproduction studies have not been conducted with Norcuron®. It is also not known whether Norcuron® can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Norcuron® should be given to a pregnant woman only if clearly needed.

Pediatric Use: Infants under 1 year of age but older than 7 weeks, also tested under halothane anesthesia, are moderately more sensitive to Norcuron® on a mg/kg basis than adults and take about 1½ times as long to recover. Information presently available does not permit recommendations for usage in neonates.

ADVERSE REACTIONS: The most frequent adverse reaction to nondepolarizing blocking agents as a class consists of an extension of the drug's pharmacological action beyond the time period needed. This may vary from skeletal muscle weakness to profound and prolonged skeletal muscle paralysis resulting in respiration insufficiency or apnea.

Inadequate reversal of the neuromuscular blockade is possible with Norcuron® as with all curariform drugs. These adverse reactions are managed by manual or mechanical ventilation until recovery is judged adequate. Little or no increase in intensity of blockade or duration of action of Norcuron® is noted from the use of thiobarbiturates, narcotic analgesics, nitrous oxide, or droperidol. See OVERDOSAGE for discussion of other drugs used in anesthetic practice which also cause respiratory depression.

Prolonged to profound extensions of paralysis and/or muscle weakness as well as muscle atrophy have been reported after long-term use to support mechanical ventilation in the intensive care unit (see PRECAUTIONS).

The administration of Norcuron® has been associated with rare instances of hypersensitivity reactions (bronchospasm, hypotension and/or tachycardia, sometimes associated with acute urticaria or erythema).

OVERDOSAGE: The possibility of iatrogenic overdosage can be minimized by carefully monitoring muscle twitch response to peripheral nerve stimulation.

Excessive doses of Norcuron® produce enhanced pharmacological effects. Residual neuromuscular blockage beyond the time period needed may occur with Norcuron® as with other neuromuscular blockers. This may be manifested by skeletal muscle weakness, decreased respiratory reserve, low tidal volume, or apnea. A peripheral nerve stimulator may be used to assess the degree of residual neuromuscular blockade from other causes of decreased respiratory reserve.

Respiratory depression may be due either wholly or in part to other drugs used during the conduct of general anesthesia such as narcotics, thiobarbiturates and other central nervous system depressants. Under such circumstances, the primary treatment is maintenance of a patent airway and manual or mechanical ventilation until complete recovery of normal respiration is assured. Regonol® (pyridostigmine bromide) injection, neostigmine, or edrophonium, in conjunction with atropine or glycopyrrolate will usually antagonize the skeletal muscle relaxant action of Norcuron®. Satisfactory reversal can be judged by adequacy of skeletal muscle tone and by adequacy of respiration. A peripheral nerve stimulator may also be used to monitor restoration of twitch height. Failure of prompt reversal (within 30 minutes) may occur in the presence of extreme debilitation, carcinomatosis, and with concomitant use of certain broad spectrum antibiotics, or anesthetic agents and other drugs which enhance neuromuscular blockade or cause respiratory depression of their own. Under such circumstances the management is the same as that of prolonged neuromuscular blockade. Ventilation must be supported by artificial means until the patient has resumed control

DOSAGE AND ADMINISTRATION: Before prescribing, please consult complete product information. Norcuron® (vecuronium bromide) for injection is for intravenous use only. This drug should be administered by or under the supervision of experienced clinicians familiar with the use of neuromuscular blocking agents. Dosage must be individualized in each case. dosage information which follows is derived from studies based upon units of drug per unit of body weight and is intended t serve as a guide only, especially regarding enhancement of neuromuscular blockade of Norcuron® by volatile anesthetics an by prior use of succinylcholine (see PRECAUTIONS/Drug Interactions). Parenteral drug products should be inspected visuall for particulate matter and discoloration prior to administration whenever solution and container permit.

To obtain maximum clinical benefits of Norcuron® and to minimize the possibility of overdosage, the monitoring of musc twitch response to peripheral nerve stimulation is advised.

The recommended initial dose of Norcuron® is 0.08 to 0.10 mg/kg (1.4 to 1.75 times the ED_{90}) given as an intravenous bo injection. This dose can be expected to produce good or excellent non-emergency intubation conditions in 2.5 to 3 minutes after injection. Under balanced anesthesia, clinically required neuromuscular blockade lasts approximately 25-30 minutes. w recovery to 25% of control achieved approximately 25 to 40 minutes after injection and recovery to 95% of control achieved approximately 45-65 minutes after injection. In the presence of potent inhalation anesthetics, the neuromuscular blocking eff of Norcuron® is enhanced. If Norcuron® is first administered more than 5 minutes after the start of inhalation agent or when steady state has been achieved, the initial Norcuron® dose may be reduced by approximately 15%, i.e., 0.060 to 0.085 mg/k

Prior administration of succinylcholine may enhance the neuromuscular blocking effect and duration of action of Norcuro If intubation is performed using succinylcholine, a reduction of initial dose of Norcuron® to 0.04-0.06 mg/kg with inhalation anesthesia and 0.05-0.06 mg/kg with balanced anesthesia may be required.

During prolonged surgical procedures, maintenance doses of 0.010 to 0.015 mg/kg of Norcuron® are recommended; after initial Norcuron® injection, the first maintenance dose will generally be required within 25 to 40 minutes. However, clinical cr ria should be used to determine the need for maintenance doses. Since Norcuron® lacks clinically important cumulative effe subsequent maintenance doses, if required, may be administered at relatively regular intervals for each patient, ranging appro imately from 12 to 15 minutes under balanced anesthesia, slightly longer under inhalation agents. (If less frequent administration is desired, higher maintenance doses may be administered.)

Should there be reason for the selection of larger doses in individual patients, initial doses ranging from 0.15 mg/kg up to 0.28 mg/kg have been administered during surgery under halothane anesthesia without ill effects to the cardiovascular syste being noted as long as ventilation is properly maintained.

Use by Continuous Infusion: After an intubating dose of 80-100 µg/kg, a continuous infusion of 1 µg/kg/min can be ini ated approximately 20-40 min later. Infusion of Norcuron® should be initiated only after early evidence of spontaneous reco from the bolus dose. Long-term intravenous infusion to support mechanical ventilation in the intensive care unit has not bee studied sufficiently to support dosage recommendations (see PRECAUTIONS).

The infusion of Norcuron® should be individualized for each patient. The rate of administration should be adjusted accord to the patient's twitch response as determined by peripheral nerve stimulation. An initial rate of 1 µg/kg/min is recommende with the rate of the infusion adjusted thereafter to maintain a 90% suppression of twitch response. Average infusion rates ma range from 0.8 to 1.2 µg/kg/min.

Inhalation anesthetics, particularly enflurane and isoflurane may enhance the neuromuscular blocking action of nondepolarizing muscle relaxants. In the presence of steady-state concentrations of enflurane or isoflurane, it may be necessary reduce the rate of infusion 25-60 percent, 45-60 min after the intubating dose. Under halothane anesthesia it may not be necessary to reduce the rate of infusion.

Spontaneous recovery and reversal of neuromuscular blockade following discontinuation of Norcuron® infusion may be expected to proceed at rates comparable to that following a single bolus dose.

Infusion solutions of Norcuron® can be prepared by mixing Norcuron® with an appropriate infusion solution such as 5% glucose in water, 0.9% NaCl, 5% glucose in saline, or Lactated Ringers. Unused portions of infusion solutions should be discarded.

Infusion rates of Norcuron® can be individualized for each patient using the following table:

Drug Delivery Rate (µg/kg/min)	Infusion Delivery Rate (mL/kg/min)	
	0.1 mg/mL*	0.2 mg/mL†
0.7	0.007	0.0035
0.8	0.008	0.0040
0.9	0.009	0.0045
1.0	0.010	0.0050
1.1	0.011	0.0055
1.2	0.012	0.0060
1.3	0.013	0.0065

*10 mg of Norcuron® in 100 mL solution †20 mg of Norcuron® in 100 mL solution

The following table is a guideline for mL/min delivery for a solution of 0.1 mg/mL (10 mg in 100 mL) with an infusion pump.

NORCURON® INFUSION RATE – mL/MIN

Amount of Drug µg/kg/min	Patient Weight – kg						
	40	50	60	70	80	90	100
0.7	0.28	0.35	0.42	0.49	0.56	0.63	0.70
0.8	0.32	0.40	0.48	0.56	0.64	0.72	0.80
0.9	0.36	0.45	0.54	0.63	0.72	0.81	0.90
1.0	0.40	0.50	0.60	0.70	0.80	0.90	1.00
1.1	0.44	0.55	0.66	0.77	0.88	0.99	1.10
1.2	0.48	0.60	0.72	0.84	0.96	1.08	1.20
1.3	0.52	0.65	0.78	0.91	1.04	1.17	1.30

NOTE: If a concentration of 0.2 mg/mL is used (20 mg in 100 mL), the rate should be decreased by one-half.

Dosage in Children: Older children (10 to 17 years of age) have approximately the same dosage requirements (mg/kg) as adults and may be managed the same way. Younger children (1 to 10 years of age) may require a slightly higher initial dose a may also require supplementation slightly more often than adults. Infants under one year of age but older than 7 weeks are moderately more sensitive to Norcuron® on a mg/kg basis than adults and take about 1½ times as long to recover. See also subsection of PRECAUTIONS titled Pediatric Use. Information presently available does not permit recommendation on usage neonates (see PRECAUTIONS). There are insufficient data concerning continuous infusion of vecuronium in children, therefor no dosing recommendation can be made.

COMPATIBILITY: Norcuron® is compatible in solution with:

0.9% NaCl solution	Sterile water for injection	Lactated Ringers
5% glucose in water	5% glucose in saline	

Use within 24 hours of mixing with the above solutions.

Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration whe ever solution and container permit.

HOW SUPPLIED:

10 mL vials (10 mg vecuronium bromide) and 10 mL prefilled syringes of diluent (bacteriostatic water for injection, USP).
22 g 1¼" needle. Boxes of 10 NDC No. 0052-0441-60
10 mL vials (10 mg vecuronium bromide) and 10 mL vials of diluent (bacteriostatic water for injection, USP).
Boxes of 10 NDC No. 0052-0441-17
10 mL vials (10 mg vecuronium bromide) only; DILUENT NOT SUPPLIED. Boxes of 10 NDC No. 0052-0441-15
20 mL vials (20 mg vecuronium bromide) only; DILUENT NOT SUPPLIED. Boxes of 10 NDC No. 0052-0442-46

STORAGE: 15°-30°C (59°-86°F). Protect from light.

AFTER RECONSTITUTION:

- When reconstituted with supplied bacteriostatic water for injection: CONTAINS BENZYL ALCHOHOL, WHICH IS NOT INTENDED FOR USE IN NEWBORNS. Use within 5 days. May be stored at room temperature or refrigerated.
- When reconstituted with sterile water for injection or other compatible I.V. solutions: Refrigerate vial. Use within 24 hours. Single use only. Discard unused portion.

Caution: Federal law prohibits dispensing without prescription.

IARS 67th CONGRESS

MARCH 19 -23, 1993

San Diego Marriott Hotel & Marina

INTERNATIONAL ANESTHESIA RESEARCH SOCIETY

T. H. Seldon Memorial Lecture
Lawrence J. Saidman, M.D.
"Relationships Between Anesthesiology and Industry: A Mixed Blessing"

Program Highlights: In addition to the extensive Tutorial program, 26 Review Course Lectures will be offered on a wide variety of topics. Three Luncheon Symposia will be held, and over 425 clinical and research papers will be presented in oral, poster and poster discussion sessions. The **American Board of Anesthesiology** will conduct an informational program on the ABA examination and certification process. Detailed program information will be sent to all IARS members in December.

Achieve the power of balance.

Now more than ever, the realities of anesthesia management require providing the highest standards of patient care while controlling costs.

Ohmeda can help you achieve this delicate balance: O=(MC)^2.

Ohmeda = Maximized Care

Ohmeda offers sophisticated anesthesia delivery and monitoring systems to assist you in managing your patient during the rigors of surgery. Information systems from Ohmeda then turn case data into a key tool for quality assessment and improvement.

Ohmeda = Minimized Cost

Ohmeda products also help you manage the financial aspects of your anesthesia practice for efficiency, savings and revenue generation.

Maximized care. Minimized cost. For a new brochure that discusses how Ohmeda helps you achieve the delicate balance in anesthesia management, call 1-800-345-2700 or contact your Ohmeda representative.

Ochsner

ANESTHESIOLOGIST OPENINGS

Positions are available at the Ochsner Clinic New Orleans and Ochsner Clinic Baton Rouge for BC/BE anesthesiologists.

Ochsner Clinic New Orleans:
- Generalists
- Intensivist Medical Director for 32-bed medical surgical ICU

Ochsner Clinic Baton Rouge:
- Generalists
- Pain
- Critical Care

Ochsner offers a very competitive salary, rich fringe benefits package, two substantial retirement programs, excellent paid vacation and CME time, all malpractice insurance provided, and opportunity for partnership status. Send CV to:

Ochsner Clinic
16777 Medical Center Drive
Reference #A1ANES
Physician Recruiting Support Services
Baton Rouge, LA 70816

ANESTHESIOLOGISTS

Harvard Medical School/Brigham and Women's Hospital, Boston, MA has a limited number of faculty positions available for Board Certified or Board Eligible Anesthesiologists.

Brigham & Women's Hospital is a 726 bed Harvard Medical School academic teaching hospital. Anesthesia sub-specialty areas include obstetrical, cardiac, orthopedic, thoracic, neurosurgical, G.U. and GYN, in addition to general surgery. We serve both out-patients and in-patients and have a large Pain Treatment Service including both acute and chronic pain.

Faculty responsibility includes teaching, supervising and providing patient care, participation in clinical and/or basic research and administrative functions within the Department.

Salary is competitive with an excellent fringe benefit package. Applicants must be able to obtain a Massachusetts Medical license.

Interested individuals should send curriculum vitae to:

Simon Gelman, M.D., Ph.D.
Chairman, Department of Anesthesia
Brigham & Women's Hospital/
Harvard Medical School
75 Francis Street
Boston, MA 02115

Harvard Medical School/Brigham & Women's Hospital are Equal Opportunity employers.

INTERNATIONAL ANESTHESIA RESEARCH SOCIETY

THE B.B. SANKEY ANESTHESIA ADVANCEMENT AWARDS

1993 B.B. SANKEY ANESTHESIA ADVANCEMENT AWARDS

Applications for up to $25,000 are invited for the 1993 Awards, subject to the following basic conditions:

- Proposals must be within the general field of anesthesiology and may be for research, clinical care, education, or administration.
- Applicants must be members of the International Anesthesia Research Society.
- Applications must be received in the IARS Cleveland office no later than December 11, 1992. Where relevant, applications must include institutional approval of human studies and/or animal research.
- The official application for the Award must be used. This form, as well as the guidelines for applicants, is available on request to:

International Anesthesia Research Society
2 Summit Park Dr., #140
Cleveland, OH 44131
Telephone: (216) 642-1124

The 1993 Awards will be announced at the 67th Congress of the International Anesthesia Research Society to be held at the San Diego Marriott, March 19–23, 1993.

IARS MEMBERSHIP

FOR YOUR IN-TRAINING AND CONTINUING MEDICAL EDUCATION

The International Anesthesia Research Society is a nonprofit, scientific and educational corporation of the State of Ohio, founded in 1922 "to foster progress and research in anesthesia." To this end, the IARS

Publishes the oldest journal in the specialty, *Anesthesia & Analgesia*

Sponsors an annual scientific meeting (Congress) which is held in March

Funds projects in anesthesia-related research, clinical care, education, and administration through the B.B. Sankey Anesthesia Advancement Award, and the Ben Covino Research Award

Membership in the IARS is voluntary; it is also separate and distinct from membership in any other local, state, or national anesthesia organization. Membership is open to individuals who qualify in the various categories shown below. All memberships include a monthly subscription to *Anesthesia & Analgesia* which includes the abstract supplement and the Review Course Lectures Book. Members and Associate Members are entitled to a reduced registration fee at the IARS annual Congress, Educational Members pay no registration fee. Only IARS members may apply for the B.B. Sankey Anesthesia Advancement Award.

MEMBERSHIP CATEGORIES

MEMBERSHIP: Open to individuals with doctorate degrees who are licensed to practice in the medical, osteopathic, dental, or veterinary medicine fields (i.e., MD, MB, DO, DDS, DVM); and to individuals with doctorate degrees (PhD) in any scientific discipline who are engaged in academic, private, or commercial research.

ASSOCIATE MEMBERSHIP: Open to individuals in the allied health professions who are certified by their professional accrediting organization as nurse anesthetists (CRNA), respiratory therapists or technicians (RRT or CRTT), physician assistants (PA, MMS), and other allied health professionals in anesthesia-related practice.

Beginning with the January 1993 issue of *Anesthesia & Analgesia*, International Members will receive the Journal by Surface Air Lift (First Class to Canada) **at no additional charge**.

Annual (1992 Calendar Year) Dues for Members and Associate Members: $95 ($120 Int'l).

Annual (1993 Calendar Year) Dues for Members and Associate Members: $100.

EDUCATIONAL MEMBERSHIP: Open (with certification by program director) to doctors (interns/residents) enrolled in anesthesiology training programs; nurses enrolled in nurse anesthesia schools; students enrolled in programs leading to certification as physician assistants, respiratory therapists, or technicians.

Annual Dues for Educational Members:

2 Years beginning July 1992—$108 ($120 Int'l)	2 Years beginning January 1993—$110	NO POSTAGE SURCHARGE BEGINNING IN 1993
3 Years beginning July 1992—$163 ($175 Int'l)	3 Years beginning January 1993—$165	
4 Years beginning July 1992—$218 ($230 Int'l)	4 Years beginning January 1993—$220	

International Anesthesia Research Society
Suite 140, 2 Summit Park Drive, Cleveland, Ohio 44131-2553

ANESTHESIA & ANALGESIA

Journal of the International Anesthesia Research Society

The **International Anesthesia Research Society** is a nonprofit, scientific, and educational corporation in the state of Ohio. Members of the Board of Trustees of the Society are: David R. Bevan, MA, MB, BChir, Michael K. Cahalan, MD, Douglas B. Craig, MD, FRCPC, Bruce F. Cullen, MD, Noel W. Lawson, MD, Edward D. Miller, Jr, MD, Dean H. Morrow, MD, Joseph G. Reves, MD, Robert K. Stoelting, MD, Stephen J. Thomas, MD, John L. Waller, MD, and K. C. Wong, MD, PhD. Emeritus Trustees are: E. Paul Didier, MD, Paul R. Dumke, MD, John T. Martin, MD, Emerson A. Moffitt, MD, Morris J. Nicholson, MD, and B. B. Sankey, MD.

Anesthesia & Analgesia (ISSN 0003-2999) is issued monthly for the IARS in two indexed volumes per year by Elsevier Science Publishing Co., Inc., 655 Avenue of the Americas, New York, NY 10010. Printed in USA. © 1992 by the International Anesthesia Research Society. Second class postage paid at New York, NY and at additional mailing offices.

Subscription information for 1992 applying to IARS members: USA and possessions, $95.00 per year; in all other countries, $120.00. Membership is available to individuals with doctorate degrees in medicine, osteopathy, dentistry, veterinary medicine, or other disciplines who are engaged in active clinical practice of or research in anesthesiology. Associate Membership is available to individuals certified, licensed, or accredited by anesthesia-related professions (CRNA, CRTT, RRT, Physician Assistant). Educational Membership (at a reduced price) is available to interns, residents, and students in nurse anesthesia and related training programs, for a 2-, 3-, or 4-year period upon completion of application including certification by applicant's program director.

All membership payments and correspondence regarding IARS member subscriptions should be sent to: International Anesthesia Research Society, Suite 140, 2 Summit Park Drive, Cleveland, OH 44131-2553.

Subscription information for 1992 applying to non-IARS members: Institutions, $150.00; nonmember individuals, $110.00. Outside the USA and possessions, please add $35.00 for surface postage and handling. For airmail, add $80.00 in USA, Canada, and Mexico; $70.00 for surface airlift to Europe; $85.00 for surface airlift to Japan; and $160.00 for airmail to the rest of the world. Postmaster: Send address changes to: *Anesthesia & Analgesia*, Elsevier Science Publishing Co., Inc., 655 Avenue of the Americas, New York, NY 10010.

Orders and inquiries regarding institutional and nonmember individual subscriptions should be directed to: Journals Fulfillment, Elsevier Science Publishing Co., Inc., 655 Avenue of the Americas, New York, NY 10010.

Single issues: Single copy information is available from Elsevier Science Publishing Co., Inc., upon request. Back volume (all issues prior to 1983) information is available from the IARS.

Advertising inquiries should be addressed to: Pharmaceutical Media, Inc., 440 Park Avenue South, 14th Floor, New York, NY 10016. Although all advertising material is expected to conform to ethical (medical) standards, inclusion in this publication does not constitute a guarantee or endorsement of the quality or value of such product or of the claim made of it by its manufacturer.

Anemia, Hemodilution, and Oxygen Delivery

Bruce J. Leone, MD, and Donat R. Spahn, MD
Department of Anesthesiology, Duke University Medical Center, Durham, North Carolina

The adequacy of oxygen delivery to all regions of the body is perhaps the best indicator of sufficient red cell mass and cardiac output. In the present issue of *Anesthesia & Analgesia*, van Woerkens and colleagues (1) present the unfortunate case of a patient who succumbed to perioperative complications, refusing transfusion therapy because of religious beliefs despite severe anemia. These authors obtained informed consent from this patient to study his oxygen delivery and consumption during profound normovolemic hemodilution. We are thus given a glimpse of this patient's physiologic responses to profound normovolemic hemodilution, with the conclusion that severe normovolemic hemodilution, to hemoglobin values as low as 4 g/dL, may be well tolerated in critically ill patients.

In this era of acquired immunodeficiency syndrome, hepatitis, cytomegalovirus, and other potential complications of homologous blood transfusion, this case, considered in isolation, may suggest that more aggressive normovolemic hemodilution strategies be used (i.e., less homologous blood transfusion). Van Woerkens et al. suggest a new "magic number," an oxygen delivery rate of 184 $mL \cdot m^{-2} \cdot min^{-1}$, as the critical value of oxygen delivery. Classically, a hematocrit of 30% has been recommended as optimal for the perioperative period (2–4). These recommendations were based primarily on theoretical calculations of maximal oxygen delivery to peripheral organs. Because blood viscosity is related to hematocrit in a curvilinear manner, moderate hemodilution may increase blood fluidity by decreasing viscosity and result in greater tissue flow, which more than compensates for the decreased blood oxygen content. Oxygen delivery may actually be increased. Indeed, experimental data demonstrate that profound normovolemic hemodilution in otherwise healthy canines is well tolerated, with minimal complications and no evidence of impaired wound healing (5). Clinical studies have also observed no increased morbidity or mortality in patients with perioperative anemia (hematocrits of 20%–22%), even though limited oxygen extraction reserve may be present (6,7).

Cardiac function has had the most attention in the study of anemia. The myocardium extracts by far the largest percentage of oxygen, is virtually aerobic, has little metabolic reserve, and has a direct coupling (in most cases) between metabolism and myocardial function. It is the organ most easily studied and arguably the organ system most susceptible to anemia. Hemoglobin values <4 g/dL are associated with abnormal regional myocardial blood flow distribution in animals with normal coronary anatomy (8), yet profound perioperative hemodilution (to hemoglobin of 3 g/dL) was not associated with increased morbidity and mortality during pediatric cardiac surgery (9). There are conflicting reports on the effects of normovolemic anemia on myocardial function in the setting of experimental coronary artery disease (10–12). In general, moderate anemia may be tolerated in the setting of stable coronary disease, provided that circulating blood volume is maintained. These data were obtained in animals with normal left ventricular function. There is evidence that depressed left ventricular function may require a higher hematocrit (13). A recent report observed a higher incidence of postoperative myocardial ischemia in patients with a hematocrit <29% undergoing lower extremity revascularization (14), presumably with coexistent multisystem disease and impaired cardiac function.

Other organ systems appear to be less susceptible to the adverse effects of anemia, perhaps because their oxygen extraction is less than that of the myocardium. In fact, hemodilution may be of benefit in many disease states. Moderate hemodilution (hematocrit range 30%–35%) may ameliorate stroke damage if used within the first 6 h of cerebral insult (15,16). Moderate hemodilution also improves peripheral blood flow in occlusive vascular disease, most likely due to the improved fluid dynamics as a consequence of decreased blood viscosity (17). There is a suggestion that hemodilution may also protect against the consequences of renal ischemia (18). Tolerance to normovolemic anemia may allow more aggressive

use of perioperative autologous blood harvesting, particularly in patients with significant coincident diseases who may benefit from perioperative anemia. Some preliminary evidence suggests that autologous blood harvesting before cardiopulmonary bypass, with subsequent infusion of this blood after cardiopulmonary bypass, results in improvement in coagulation status (19). There is little information with regard to possible pulmonary effects of hemodilution or the potential adverse effects of hemodilution in the setting of chronic obstructive pulmonary disease. Thus, normovolemic hemodilution may have potential benefits, even in high-risk patients.

No data have demonstrated the effects of transfusion therapy in reversing adverse effects of anemia. Preliminary evidence from our laboratory (20) and a recent clinical report (21) suggest that anemia-induced myocardial ischemia is readily reversed by minimal transfusion. Little is known with regard to the reversal of other anemia-induced effects. Had van Woerkens et al. (1) been able to apply transfusion therapy to their patient, it would have been of great interest to observe whether recovery of the relationship between oxygen delivery and oxygen consumption followed the identical curve or whether hysteresis of the curve (presumably the consequence of ischemia and relative "oxygen debt") required additional transfusion above the "magic number" of 184 $mL \cdot m^{-2} \cdot min^{-1}$ oxygen delivery to effect complete recovery. This point is certainly not moot or of mere scientific curiosity; hysteresis of the curve suggests incomplete recovery of oxygen delivery to offset oxygen consumption, making increased use of blood products mandatory to normalize oxygen consumption and presumably completely reverse the effects of anemia. Furthermore, hysteresis of the "anemia recovery curve" would discourage aggressive hemodilution or tolerance of moderate anemia, because inadequate oxygen delivery with resultant consequences of anemia would require more transfusions than had the threshold of inadequate delivery not been attained by prophylactic transfusion therapy.

The application of a universally accepted guideline on transfusion therapy is fraught with difficulties. Susceptibility of patients may be as individual as each patient, particularly with respect to coexistent pathology. Thus, it is unlikely that one specific number or value, be it hematocrit or oxygen delivery, will be able to be universally applied to all situations. It is more likely that certain patients may tolerate marked degrees of hemodilution without evidence of ischemia, myocardial or otherwise, whereas other patients may not tolerate even mild degrees of anemia. Some generalizations can be made, however. Patients with more serious medical problems may require higher hematocrit levels; Christopherson and colleagues (14) found an increased incidence of postoperative ischemia associated with hematocrits <29% in patients with peripheral vascular disease, and thus these investigators recommended a hematocrit of at least 29% to decrease the incidence of cardiac postoperative complications. Of note is that the effects of hemodilution on other organ systems, particularly the central nervous system, are not well defined; these potential benefits or risks to other organ systems need to be elucidated and put in perspective relative to cardiac risks of hemodilution.

The whole concept of anemia may need to be redefined in the 1990s, as we enter the era of artificial blood. Several promising compounds are now undergoing extensive testing, including genetically cloned human hemoglobin, pyridoxylated hemoglobin purified from outdated banked blood, and cross-linked bovine hemoglobin. All afford the prospect of decreasing whole-blood viscosity and improving microvascular blood flow while retaining some oxygen-carrying capacity. It remains to be seen what impact these compounds will have on transfusion practice, but if these compounds prove safe and effective, certainly this impact will be a major one. Thus, characterization of the effects of hemodilution and anemia on the cardiovascular system and other organ systems is crucial to our ability to effectively use both homologous transfusion therapy and artificial blood.

Teleologically, we appear to be "built to bleed," yet how much is too much? With organ system senescence or disease, particularly coronary artery disease, prudence may dictate maintenance of a higher hematocrit. However, although the risks of hemodilution-induced ischemia will be diminished with homologous transfusion, this therapy may result in other complications, such as blood-borne infections and transfusion-related complications. The risk of transfusion-acquired infections is significant, and immunosuppression, which can result in increased infection and cancer recurrence risks, should be seriously considered before transfusion therapy (22,23). In younger patients and in patients without significant organ system disease, profound hemodilution may impose a lesser risk compared with transfusion therapy, whereas older or more infirm persons may benefit more from transfusion.

Van Woerkens and colleagues (1) have given us a number on which to base further research. This "critical value" was obtained in one patient; generalization of therapy based on a single value in one patient to the population at large may be problematic, because the relationship between oxygen consumption and delivery may be idiosyncratic. Clinical applications based on their findings must be prudent, particularly in applying a global hemodynamic variable to clinical situations in which regional disease may exist in a large number of cases. Oxygen extraction rates vary markedly in different organ systems; it is unlikely that a global measure such as total body oxygen delivery/consumption can adequately predict the responses of specific organ systems to decreased oxygen delivery. It behooves our specialty to conduct careful, controlled clinical and laboratory research not only to define a reasonable endpoint for normovolemic hemodilution, but to characterize the global and regional responses to anemia and to examine the capacity of transfusion therapy with autologous, homologous, or artificial blood to reverse the complications of anemia.

Effect of Preoperative Normovolemic Hemodilution on Left Ventricular Segmental Wall Motion During Abdominal Aortic Surgery

Patrick Catoire, MD, Michel Saada, MD, Ngai Liu, MD, Laurent Delaunay, MD, A. Rauss, and Francis Bonnet, MD

Département d'Anesthésie Réanimation, Hôpital Henri Mondor, Créteil, France

Preoperative normovolemic hemodilution (PNH) has been proposed for patients scheduled to undergo aortic surgery. Coronary artery disease is frequent in these patients. The aim of the study was to assess the effect of PNH on hemodynamics and segmental wall motion (SWM) evaluated by transesophageal echocardiography in such patients. Twenty patients with coronary artery disease were allocated randomly to either PNH or no PNH; PNH was performed after anesthetic induction using dextran 60,000. Patients were operated on under general anesthesia and monitored intraoperatively with electrocardiographic lead CM_5, radial and pulmonary artery catheters, and transesophageal echocardiography positioned to obtain a short-axis view. Hemodynamic and transesophageal echocardiographic data were collected after anesthetic induction and after PNH, before and 5 min after aortic clamping, after unclamping, and at the end of surgery. Aortic clamping induced a significant increase in systemic vascular resistance and arteriovenous difference in oxygen and a decrease in cardiac index ($P < 0.05$), but the effect of aortic clamping was inversely related to hemodilution. The SWM score (graded from 1 = normal to 5 = dyskinesia) was significantly increased after aortic clamping, mainly in the anterior segment ($P < 0.05$). Four patients in the control (no PNH) group and one in the PNH group developed new SWM abnormalities indicative of myocardial ischemia during surgery ($P =$ NS). This study suggests that PNH may improve hemodynamic tolerance to aortic clamping in patients with coronary artery disease. The observed changes in SWM indicate that PNH may not worsen myocardial ischemia in patients scheduled to undergo aortic surgery.

(Anesth Analg 1992;75:654–9)

Preoperative normovolemic hemodilution (PNH) has been proposed to avoid homologous blood transfusion in patients scheduled to undergo aortic surgery (1,2). Hemodilution decreases blood viscosity and may also improve oxygen delivery to tissues in these patients (3). However, patients who undergo abdominal aortic surgery frequently have coronary artery disease (CAD) (4), and CAD classically contraindicates PNH on the basis of results of experimental studies (5,6). Nevertheless, animal studies fail to document any significant negative effect of hemodilution on myocardial ischemia (7,8), and human studies do not in fact confirm the deleterious effect of PNH in patients with CAD. Laxenaire et al. (9) showed that in patients with CAD undergoing PNH for peripheral arterial disease, myocardial perfusion evaluated with thallium scintigraphy was not impaired. Recent studies performed during coronary artery bypass surgery showed that as much as 15% normovolemic hemodilution is well tolerated by the myocardium (10,11). Van der Linden et al. (12) showed that global myocardial function is preserved after PNH for abdominal aortic surgery (AAS). Patients undergoing AAS are likely to develop intraoperative myocardial ischemia and hemodynamic disturbances owing to clamping and unclamping of the aorta (13). Segmental wall motion (SWM) and wall-thickening abnormalities have been shown to be sensitive, early indices of myocardial ischemia, and transesophageal echocardiography (TEE) easily detects these changes (14). The current study was therefore conducted in such patients to assess the effect of PNH on hemodynamics and SWM during AAS, hypothesizing that PNH may not worsen myocardial ischemia.

Supported by a grant from the Délégation à la Recherche Clinique de l'Assistance Publique-Hopitaux de Paris, Paris, France.

Methods

After approval by our hospital ethical committee and informed consent were obtained, all patients with CAD scheduled for infrarenal AAS were eligible for the study.

The diagnosis of CAD was made if the patient met at least one of the following criteria:

1. Presence of typical angina pectoris;
2. A documented previous myocardial infarction (Q waves on the ECG and increase in creatinine phosphokinase isoenzymes at the time of occurrence);
3. Ischemic ST segments (ST segment depression of 1.0 mm or ST segment elevation of 2.0 mm at 60 ms of the J point) or Q waves on the ECG;
4. A positive exercise treadmill test;
5. Fixed or reversible defect on dipyridamole thallium-201 angioscintigraphy;
6. Significant stenosis (>75%) of at least one main coronary artery on coronary arteriography.

Exclusion criteria were the absence of CAD as previously defined, a hematocrit <36%, or a history of recent congestive heart failure.

On the morning of operation, patients were randomly allocated to two groups: control (C) and hemodilution (H). All patients received their usual cardiac medications preoperatively, and 1 mg of flunitrazepam was administered 1 h before arrival in the operating room. In the operating room, standard monitors, including ECG lead CM_5, were applied. A thoracic epidural catheter was inserted with the patient in the sitting position via the T6–7 epidural space through a 19-gauge Tuohy needle for postoperative analgesia. Radial and pulmonary artery catheters were inserted under local anesthesia.

All patients had anesthesia induced with flunitrazepam (0.05 mg/kg) and alfentanil (30 μg/kg); tracheal intubation and muscle relaxation were obtained with vecuronium (0.8 mg/kg). Anesthesia was maintained with 50% N_2O in O_2 plus alfentanil infusion (30 $\mu g \cdot kg^{-1} \cdot h^{-1}$) and alfentanil (500–1000 μg) bolus doses as needed. Ventilation was controlled to maintain end-tidal CO_2 values of 30–35 mm Hg. A TEE 5-MHz probe (Vingmed) was then inserted and positioned to obtain a short-axis view at the midpapillary muscle level of the left ventricle.

Baseline data were collected for all patients 10 min after insertion of the TEE probe. Hemodilution was performed in group H and data were recorded 5 min after PNH was completed in this group only. Data were recorded for all the patients 5 min before and after aortic cross-clamping, 5 min after aortic unclamping, and at the end of surgery.

The TEE probe was removed at the completion of surgery, and the patients were transferred to the recovery room. Postoperative epidural pain management was started on arrival in the recovery room. All patients received a 2-mg bolus dose of morphine and 6 mL of 0.25% bupivacaine, followed by a continuous infusion of 0.125% bupivacaine (6 mL/h). Additional morphine bolus doses (2 mg in 10 mL of saline) were administered every 12 h for 3 days. The ECG and creatine kinase-MB data were collected every 12 h for 3 days.

Transesophageal Echocardiographic Data Analysis

The TEE data for each patient were analyzed on-line by the anesthesiologist in charge of the patient and a posteriori by an independent observer unaware of the patient's condition and hemodynamic profile during surgery. The left ventricle was arbitrarily divided into four segments for SWM analysis: anterior, posterior, inferior, and septal. The SWM was estimated using the following grading system (14): 1 = normal thickening and >30% segment shortening; 2 = mild hypokinesia (slightly reduced thickening and 10%–30% segment shortening); 3 = severe hypokinesia (<10% segment shortening and minimal thickening); 4 = akinesia (no thickening and no segment shortening); 5 = dyskinesia (wall thinning and no shortening of the segment). An increase of more than one grade, or a change from grade 4 to 5, was considered indicative of ischemia (14). Interobserver discrepancies defined as an SWM evaluation of more than one grade difference were resolved by a third experienced echocardiographer. During the postoperative period, ischemic events were defined by new Q waves or ischemic ST segment changes on ECG, by a creatinine kinase level >350 IU/mL, with a percentage of creatine kinase-MB >6%.

The PNH was performed after anesthetic induction before surgery. Blood withdrawal and compensation were done at the same time using two antebrachial venous 16-gauge catheters each inserted in a different arm. Final expected hematocrit was 30%. To achieve this, the volume of harvested blood was determined from initial hematocrit and body weight. All the hematocrits were measured by a cooximeter (Radiometer-Copenhagen, Denmark). The final hematocrit was verified and the hemodilution continued until the hematocrit reached 30%. Compensation was achieved using dextran 60,000 (Hemodex). Allergic reaction was prevented by the administration of 3 g of dextran 1000 (Promit). Dextran 60,000 infusion was restricted to <20 mL/kg to prevent modifications in coagulation time.

Table 2. Mean Values of Homologous Transfusion and Blood Losses in the Two Study Groups

	Homologous transfusion (RBCP)	Blood loss (mL)
Group H		
Mean	0.9	1560
±SD	1.2	675
Group C		
Mean	1.4	910*
±SD	1.6	662

H, hemodilution; C, control; RBCP, red blood cell pack.
*$P < 0.05$, group C compared with group H.

The PNH lasted for 30 min. Normovolemia was controlled during PNH by the stability of pulmonary capillary wedge pressure (PCWP) and heart rate. The hematocrit and hemodynamics were recorded in the hemodilution (H) group 5 min after PNH. During the operation, if hemorrhage required transfusion, it was performed first with autologous and then with homologous blood.

Data Collection

Data collected during surgery included SWM and hemodynamics (i.e., systemic arterial pressure, pulmonary arterial pressure, PCWP, heart rate, and cardiac index [CI]). Arterial and mixed venous oxygen content, systemic vascular resistance (SVR) (normalized to the body surface area), and arteriovenous difference in oxygen were calculated from the measured variables. The volume of dextran infused and the amount of harvested blood evaluated from the number of collected red blood cell packs were noted. The TEE and hemodynamic measurements were performed 10 min after TEE insertion and anesthetic induction, at the end of PNH in group H, 5 min before and after aortic clamping, 5 min after aortic unclamping, and at the end of surgery in both study groups.

Table 3. Changes in Measured and Calculated Values of Hematocrit and Hemodynamic Variables in the Two Study Group

	Hct (%)	HR (beats/min)	PCWP (mm Hg)	SAP (mm Hg)	CI ($L \cdot min^{-1} \cdot m^{-2}$)	SVR (UI)	AVDO (vol%)
Baseline

Hct, hematocrit; HR, heart rate; PCWP, pulmonary capillary wedge pressure; SAP, systemic arterial pressure; CI, cardiac index; SVR, systemic vascu resistance; $AVDO_2$, arteriovenous difference in oxygen; H, hemodilution; C, control.

Values presented as mean ± SD.

[a] $P < 0.05$ compared with baseline data.

[b] $P < 0.05$, intergroup comparison for hematocrit.

Statistics

Results are expressed as mean ± SD. Statistical analysis used a general mixed-model analysis of variance (BMDP software). Three variables were studied in the model for hemodynamics and SWM: hemodilution, patients, and time. $P < 0.05$ was considered significant. The number of ischemic events occurring in the two groups was compared by a Fischer exact test.

Results

The clinical characteristics of the 20 male patients included in this study are reported on Table 1. Mean age, height, and weight were, respectively, 67 ± 33 and 66 ± 7 yr, 160 ± 33 and 167 ± 8 cm, and 87 ± 34 and 76 ± 11 kg in groups H and C (P = NS). Intraoperative blood losses and infusions are reported in Table 2. In group H, 875 ± 273 mL of homologous blood was harvested and replaced by 1145 ± 391 mL of dextran solution. Blood losses were significantly greater in group H. Changes in hematocrit are reported in Table 3. During surgery, the mean hematocrit was always ≤30% in group H and >36% in group C ($P < 0.05$).

Peroperative hemodynamic changes are reported in Table 3. No significant difference was documented between the two groups of patients. Aortic clamping significantly changed CI, SVR, and arteriovenous difference in oxygen ($P < 0.05$), but heart rate, systemic arterial pressure, and PCWP were not modified. The general mixed-model analysis of variance allowed us to document an inverse relation between the effects hemodilution and aortic clamping on SVR and arteri venous difference in oxygen ($P < 0.05$).

Segmental Wall Motion Analysis

Four hundred segments were recorded, of which 3 could be analyzed. No discrepancy of more than or grade was noted between the two independent ol servers. A consensus was obtained in all the patien with the help of the third observer. The SWM mea scores are reported in Table 4. Segmental wall motic was significantly increased after clamping of tl abdominal aorta in the control group ($P < 0.05$). Tab 5 reports the scores of the patients (four patients an five segments in group C; one patient and or segment in group H; P = NS) who developed ne SWM abnormalities indicative of ischemia (tw grades). Except for one patient, abnormalities i SWM occurred after aortic clamping. One patient i group C documented ST segment depression aft aortic clamping, during which time, he develope severe hypokinesia (SWM score from 1 to 3) of tl anterior segment. The ECG and TEE abnormaliti disappeared after nitroglycerin infusion in this p tient, and TEE abnormalities were also corrected b nitroglycerin in the other patients, except for one i whom SWM hypokinesia persisted until the end surgery.

Postoperatively, no patient documented EC changes or an increase in creatine kinase-MB relate

to myocardial infarction. The late postoperative course was devoid of major complications in all the patients in this study.

Discussion

This study documents that PNH with dextran changes the hemodynamic profile of patients undergoing AAS and is associated with no important changes in SWM.

The typical hemodynamic response to aortic clamping is an increase in SVR associated with a decrease in CI (15). Changes in SVR depend on the development of the collateral circulation (16). Patients with aortoocclusive disease document less hemodynamic disturbances after aortic clamping, owing to the development of collateral bypass circulation. This study shows that changes in SVR after aortic cross-clamping are inversely related to hemodilution. Hemodilution has been previously documented to improve microvascular blood flow in some patients with peripheral vascular disease (17). In addition, hemodilution increases tissue perfusion and collateral circulation, especially when critical stenoses are developed (18,19). In this study, hemodilution may have increased blood flow through collateral circulation, even before aortic clamping, which would explain the lower values of calculated SVR before and after aortic clamping in group H.

The TEE analysis documented SWM abnormalities occurring especially after aortic cross-clamping. This result is apparently at variance with the study of Roizen et al. (20) who demonstrated that the majority of episodes of SWM abnormalities occurred after aortic declamping (20). In our study, intravenous infusion with dextran was carefully adapted to maintain PCWP, in order to reduce the changes in CI and systemic arterial pressure related to aortic unclamping. Consequently, these changes appeared to be minimal, explaining the lack of important abnormalities in SWM. Changes in SWM occurring after aortic cross-clamping might be related either to changes in loading conditions or to myocardial ischemia. Changes in left ventricular loading conditions could theoretically change SWM scores. An increase in afterload could cause normal segments to appear hypokinetic, so that abnormal segments would be overgraded. In this study, abnormalities in SWM occurring after aortic clamping were mainly located in only one segment and not in the complete ventricular wall. Therefore, they may be related more to myocardial ischemia than to global ventricular dysfunction.

Aortic cross-clamping may compromise the fragile myocardial oxygen balance by increasing myocardial oxygen demand. Because hemodynamic changes were less marked in the group H patients, this could explain why myocardial ischemia might occur less frequently in this group. In addition, PNH improves coronary capillary blood flow (7,21) and thus improves myocardial oxygen supply. Transesophageal echocardiography is considered a valuable technique for evaluation of myocardial ischemia (14,22), and its accuracy is better than conventional ECG (14). In this study, only one patient developed ST segment depression and SWM abnormalities simultaneously, confirming these findings.

Detection of SWM by TEE has some limitations, one of which is that hypokinesia has been suggested to be less specific than akinesia in detecting myocardial ischemia (23). Thus, in this study overestimation of myocardial ischemia may have occurred, but the error would be comparable in both groups.

Hemodilution is associated with an increase in blood loss that may be related to the effect of dextran on platelet function (24,25). This difference in blood loss explains why no significant difference in homologous blood requirement was documented in this study between the two groups.

We conclude that PNH is well tolerated in patients with CAD undergoing infrarenal AAS. Our results further suggest that PNH improves hemodynamic tolerance to aortic clamping and may decrease the incidence of myocardial ischemia.

Splanchnic Hemodynamics and Oxygen Supply During Acute Normovolemic Hemodilution Alone and With Isoflurane-Induced Hypotension in the Anesthetized Pig

Gabriele F. E. Nöldge, MD, Hans-Joachim Priebe, MD, and Klaus Geiger, MD

Department of Anesthesia, University Hospital, Freiburg, Germany

Safety of combined hemodilution and isoflurane-induced hypotension was assessed by studying their effects on splanchnic hemodynamics and oxygenation in nine anesthetized (ketamine/flunitrazepam) pigs. Acute normovolemic hemodilution (decrease in hematocrit from 29% to 15%) with 6% hydroxyethyl starch decreased ($P < 0.05$) O_2 delivery despite increases in cardiac output and all splanchnic flows, as measured by electromagnetic flow probes. Superimposed isoflurane (1.45% end-tidal concentrations) caused marked decreases in arterial blood pressure, cardiac output, and splanchnic flows. Oxygen uptake of the liver became O_2 supply dependent. A liver surface Po_2 histogram (Clark-type electrode) showed 38% of Po_2 values between 0 and 5 mm Hg. Hepatic lactate uptake decreased by 75%. These data suggest that depression of cardiovascular function during reduced O_2-carrying capacity adversely affects hepatic perfusion, oxygenation, and function. Combined hemodilution and isoflurane-induced hypotension may not be appropriate in patients.

(Anesth Analg 1992;75:660–74)

Factors contributing to low preoperative hematocrit values in surgical patients include disease-related anemia, preoperative blood donation, and avoidance of blood transfusions for intravascular volume replacement. Transfusions are costly and carry a multitude of risks, including transfusion reactions, transmission of infection and disease, and possible immune suppression (1). Thus, alternatives to the use of homologous blood products are increasingly being sought (2,3). Preoperative acute normovolemic hemodilution (HD) and deliberate (controlled) hypotension are such alternatives (4,5).

One way of reducing arterial blood pressure during general anesthesia is the use of isoflurane. Systemic and regional hemodynamic responses to isoflurane have been studied extensively in the presence of a normal hematocrit (6–8). However, cardiovascular responses may differ substantially during underlying HD. In addition, coexistence of reduced O_2 content and perfusion pressure may well lead to tissue hypoxia. Thus, examination of the effects of combined HD and deliberately induced hypotension on regional organ perfusion and function are required before such a technique can be recommended for clinical practice.

Accordingly, the goal of this study was to evaluate first the effects of severe HD and, subsequently, of superimposed isoflurane-induced hypotension on systemic and, predominantly, hepatic perfusion, oxygenation, and metabolism. Although certain strains of pigs have baseline hematocrit values less than those of humans, the pig was chosen because of its anatomic and physiologic similarity to humans with respect to the cardiovascular and digestive systems (9).

Methods

Instrumentation

The experimental protocol was approved by the local Committee on Animal Research. The study was performed in nine 4–5-mo-old domestic male and female pigs, weighing 28–37 kg. After overnight fasting and intramuscular azoperon (5 mg/kg), anesthesia was induced with methomidate (6 mg/kg IV) administered via ear vein, and the trachea was intubated. Anesthesia was maintained by continuous intravenous infusions of ketamine ($4\ mg \cdot kg^{-1} \cdot h^{-1}$) and

flunitrazepam (0.0125 $mg \cdot kg^{-1} \cdot h^{-1}$). Mechanical ventilation was provided by a constant-volume ventilator (Siemens, SV 900 B, Stockholm, Sweden) and facilitated by a continuous intravenous infusion of pancuronium (0.12 $mg \cdot kg^{-1} \cdot h^{-1}$). Respiratory rates and inspired O_2 concentration were adjusted to maintain arterial CO_2 tension between 38 and 42 mm Hg and arterial O_2 tension between 95 and 115 mm Hg. All animals were in the supine horizontal position. Body temperature was continuously monitored by a thermistor of a flow-directed thermodilution catheter (model 93A-131-7F, Edwards Laboratory) and was kept constant by placing the animals on a heating pad and by warming the inspired gases. Catheters were inserted into the abdominal aorta, pulmonary artery, and superior vena cava, as previously described (8). All animals received Ringer's solution at an amount (10–15 $mL \cdot kg^{-1} \cdot h^{-1}$) that maintained right and left cardiac filling pressures. After median laparotomy, the left hepatic and portal vein were cannulated, as previously described (8).

Precalibrated electromagnetic flow probes (Stölzer Messtechnik, Waldkirch, Germany) of appropriate sizes to ensure a snug fit were placed around the hepatic artery, portal vein, and superior mesenteric artery. Care was taken to preserve the periarterial nerve plexus. Zero flow readings were checked repeatedly during the experiment by transiently occluding the respective vessels.

Hemodynamic Measurements

Intravascular catheters were connected to pressure transducers (Senso Nor, type 840, Horten, Norway). A multichannel recorder (Hellige) was used for recording signals. Cardiac output was determined by thermodilution technique (Siemens, CO Computer model 404-1, Erlangen, Germany). The mean value of triplicate injections of 5 mL of ice-cold, temperature-monitored saline was considered to reflect actual cardiac output if the measurements were within a range of ±5% from the calculated mean.

Total hepatic blood flow was calculated as the sum of hepatic arterial and portal venous blood flow. Vascular resistances (systemic, hepatic arterial, portal venous, and superior mesenteric arterial) were calculated using the formulas listed in the Appendix. Heart rate was derived from the R-R intervals of an extremity electrocardiogram.

Determination of Oxygen Supply/Uptake

Blood gas tension and pH values were determined using an ABL 3 autoanalyzer (Radiometer, Copenhagen, Denmark). Hemoglobin O_2 saturation was measured by an OSM 3 hemoximeter (Radiometer). Hematocrit was measured from centrifuged (Bayer AG, Compur Microspin, Leverkusen, Germany) arterial blood sampled in capillary tubes. Hemoglobin concentration was determined by the cyan methemoglobin method. Oxygen content, delivery, uptake, and extraction ratios were derived from the formulas listed in the Appendix.

Preliminary studies had shown that there were no differences between portal and mesenteric venous O_2 content. Thus, portal venous O_2 content was used for the calculation of small intestine O_2 uptake (see Appendix).

Determination of Surface Po_2 of Liver and Small Intestine

Surface Po_2 of liver and small intestine were measured simultaneously using a multiwire platinum electrode, as described previously (10,11). Preliminary studies had shown that placement of the electrodes at different areas of the liver and small intestine surfaces produced comparable results. At each stage, a total of approximately 100 individual Po_2 measurements were obtained at 10–15 different electrode locations. The distribution of these values, illustrated as summary surface Po_2 histograms, reflects tissue oxygenation, which is the net result of nutritive blood flow and tissue O_2 consumption (12).

Determination of Hepatic Metabolic Function

Arterial, portal venous, and hepatic venous blood samples were collected for determination of lactate and pyruvate concentrations. These substances were determined enzymatically, as previously described (13). Hepatic uptake of lactate and pyruvate were calculated using formulas listed in the Appendix.

Experimental Protocol

At the end of the surgical preparation, at least 30 min was allowed before baseline readings during ketamine/flunitrazepam anesthesia were obtained. Hemodilution (with a mean hematocrit of 15%) was then induced by simultaneously replacing blood (withdrawn via right femoral artery) with roughly equal amounts of 6% hydroxyethyl starch (mol wt 450,000; Plasmasteril, Fresenius, Homburg, Germany) administered at body temperature via the left jugular vein. As indices of normovolemia, central venous and pulmonary capillary wedge pressures were maintained constant during the HD procedure. After the hematocrit had been decreased to the required level of 15%, measurements were performed after at least 15 min of stable hemodynamics.

Table 1. Variables for Systemic and Regional Hemodynamics During Baseline, Hemodilution, and Combined Hemodilution and Isoflurane in Anesthetized Pigs

Variable	Baseline	HD	HD + Iso
Intravascular pressure (mm Hg)			
Central venous	2.8 ± 0.4	2.8 ± 0.3	2.9 ± 0.5
Pulmonary capillary wedge	6.8 ± 0.4	6.7 ± 0.5	6.8 ± 0.5
Portal venous	6.9 ± 0.6	7.4 ± 0.6	7.1 ± 0.8
Hepatic venous	2.7 ± 0.4	2.9 ± 0.4	3.2 ± 0.6
Splanchnic blood flow (mL/min)			
Total hepatic	634 ± 24	864 ± 36^a	672 ± 56^b
Hepatic arterial	83 ± 6	149 ± 14^a	64 ± 9^{a,b}
Portal venous	561 ± 33	732 ± 45^a	616 ± 55^b
Superior mesenteric arterial	410 ± 31	492 ± 27^a	422 ± 32^b
Vascular resistance (U)			
Hepatic arterial	1142 ± 126	568 ± 55^a	618 ± 84^a
Portal venous	8 ± 2	6 ± 1^a	6 ± 1^a
Superior mesenteric arterial	220 ± 24	172 ± 31^a	74 ± 9^{a,b}

HD, hemodilution; Iso, isoflurane.
Values are mean ± SEM.
[a] $P < 0.05$, compared with baseline.
[b] $P < 0.05$, compared with HD.

Subsequently, isoflurane was introduced and maintained at an end-tidal concentration of 1.45% for 30–40 min. During administration of isoflurane, the infusion of ketamine was continued unchanged. Measurements were repeated during stable hemodynamics.

In four additional animals, after the surgical preparation, isoflurane (at an end-tidal concentration of 1.45%) was administered first, followed by HD (to a mean hematocrit of 15%). Data obtained after surgical preparation were compared with those obtained after HD during isoflurane. This was done to assess the likelihood of the sequence of experimental interventions (i.e., isoflurane always after HD) modifying the results.

In three additional animals, the effects of time on stability of surgical preparation during HD were evaluated. After surgical preparation and HD had been performed as described, measurements were obtained. Without any further intervention, repeat measurements were made 2 h later. None of the seven additional animals were studied in random order.

Statistical Analysis

The data were statistically analyzed by Friedman's statistic, followed by the Wilcoxon signed-rank test (for comparison between experimental periods), and by Kruskal-Wallis one-way analysis of variance, followed by the Mann-Whitney test (for comparisons within experimental periods). A P value of <0.05 was considered statistically significant. Values are presented as mean ± SEM.

Results

To reduce the hematocrit from an initial value of 29% ± 1% to 15% ± 1%, 33 ± 2 mL/kg of blood was withdrawn and replaced by 36 ± 2 mL/kg of 6% hydroxyethyl starch. At this exchange ratio, central venous and capillary wedge pressures remained unchanged (Table 1).

Systemic and Splanchnic Hemodynamics

Hemodilution resulted in increases in cardiac output and heart rate of approximately 20% and 30%, respectively (Figure 1). Stroke volume remained unchanged, mean arterial pressure decreased slightly (10%) but significantly, and systemic vascular resistance decreased by 35%.

Hemodilution caused increases in all splanchnic flows and decreases in regional vascular resistances (Table 1). When expressed as percent changes from baseline values, hepatic arterial blood flow increased (80%) more than twice as much as cardiac output and all other splanchnic flows (Figure 2). Correspondingly, hepatic arterial blood flow increased when expressed as a fraction of total hepatic blood flow (from 12% ± 1% to 17% ± 1%). The alterations in flows were reflected by quantitatively respective changes in vascular resistances (i.e., hepatic arterial greater than portal venous and superior mesenteric arterial) (Table 1).

During superimposed isoflurane, there were further decreases in mean arterial pressure (50%) and systemic vascular resistance (30%) and newly occur-

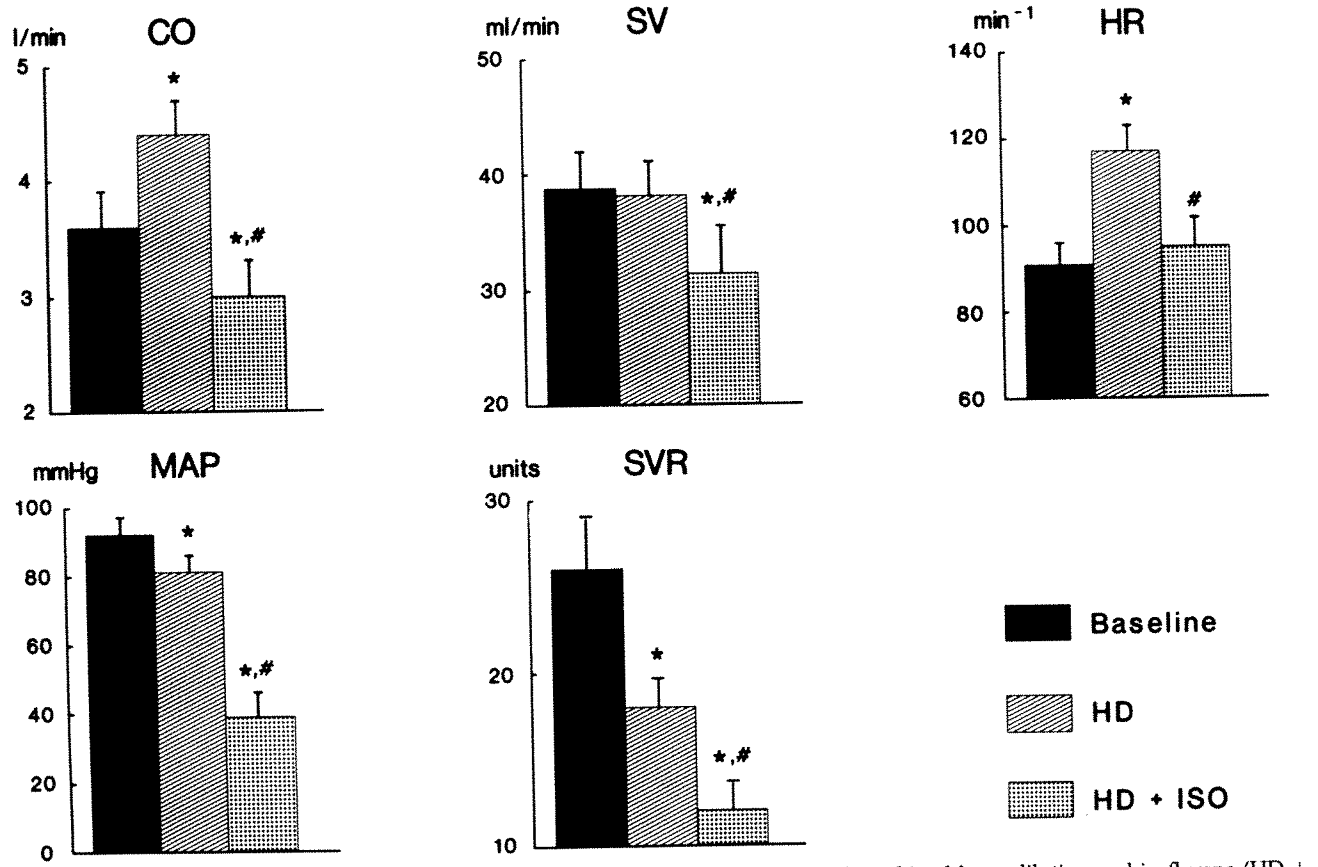

Figure 1. *Bars* represent mean values and SEM during baseline, hemodilution (HD), and combined hemodilution and isoflurane (HD + ISO). ring decreases in cardiac output (30%), stroke volume (15%), and heart rate (20%) (Figure 1).

Isoflurane-induced hypotension was associated with decreases in all splanchnic flows (Table 1). Compared with baseline values, the decreases in cardiac output and hepatic arterial blood flow were significant and of similar magnitude (Figure 2). Consequently, hepatic arterial blood flow decreased when expressed as a fraction of either total hepatic blood flow (from 17% ± 1% to 10% ± 1%) or cardiac output (from 3.5% ± 0.2% to 2.1% ± 0.2%). Although hepatic arterial and portal venous vascular resistances did not change significantly, there was a (further) decrease (55%) in superior mesenteric arterial vascular resistance (Table 1).

Systemic and Splanchnic O_2 Supply/Uptake Relationships

Normovolemic HD resulted in decreases in hepatic arterial, portal and hepatic venous (Figure 3), and mixed venous (Table 2) O_2 contents. This was due to both reduction in hematocrit and (except for arterial hemoglobin O_2 saturation, which remained unchanged) decreases in O_2 saturation. Consequently, except for hepatic arterial O_2 delivery, all O_2 delivery decreased (Table 2, Figure 3). Whole-body, liver, and small intestine O_2 uptake remained unchanged and were independent of O_2 delivery (Figure 4). All O_2 extraction ratios increased (Table 2).

Isoflurane-induced hypotension caused (further) decreases in portal and hepatic venous (Figure 3) and mixed venous (Table 2) O_2 contents owing to (further) reductions in the respective O_2 saturation. Because there was a uniform decrease in flows, all O_2 delivery decreased (Table 2, Figure 3).

Although systemic and small intestine O_2 extraction increased further, hepatic O_2 extraction did not change significantly (Table 2). Oxygen uptake of whole body and liver decreased, because the decrease in systemic and total hepatic O_2 delivery outweighed the respective increase in O_2 extraction, therefore becoming dependent on O_2 delivery (Figure 4). In contrast, small intestine O_2 uptake remained independent of O_2 delivery.

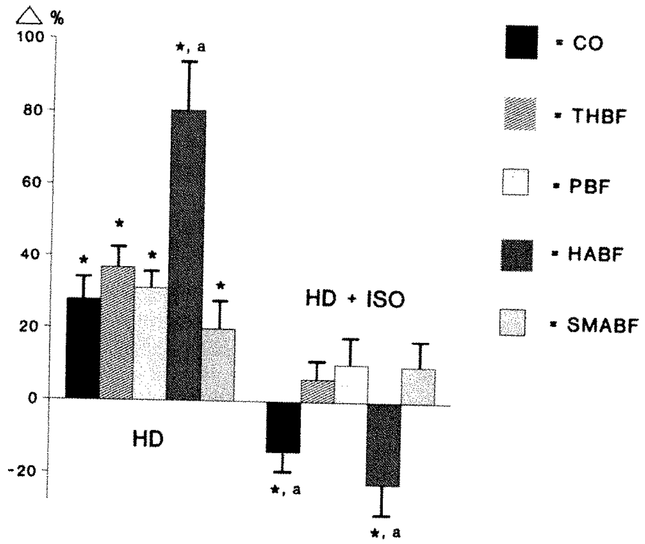

Figure 2. *Bars* represent percent changes (△) (mean and SEM) from baseline values during hemodilution (HD) and combined hemodilution and isoflurane (HD + ISO). Tissue Oxygenation of Liver and Small Intestine

Hemodilution resulted in decreases in mean liver and small intestine surface Po_2 values of approximately 35% and 20%, respectively (Table 2). In addition, the liver surface Po_2 histogram was broadened at the base and shifted to the left, with some Po_2 values in the hypoxic range (0–5 mm Hg) (Figure 5). In contrast, the small intestine surface Po_2 histogram retained its bell-shaped form, with no Po_2 values in the hypoxic range (Figure 6).

Isoflurane-induced hypotension caused a further 60% decrease in mean liver surface Po_2 (Table 2). In contrast, the 10% decrease in mean small intestine surface Po_2 was not significant. The liver surface Po_2 histogram was shifted even further to the left, with 38% of Po_2 values in the hypoxic range (0–5 mm Hg) (Figure 5). In contrast, the leftward shift of the small ntestine surface Po_2 histogram was minimal, with no Po_2 values <20 mm Hg (Figure 6).

epatic Metabolic Function

fter HD, hepatic lactate and pyruvate uptake renained unchanged (Table 2). Systemic arterial and ortal and hepatic venous pH values decreased (Tale 2).

Although hepatic pyruvate uptake continued to emain unchanged during superimposed isoflurane, lactate uptake decreased by 75% (Table 2). Portal and hepatic venous pH values decreased further.

Effects of Change in Experimental Sequence

In the four animals in which isoflurane was administered before HD, the changes between baseline on the one hand and combined isoflurane and HD on the other were quantitatively as well as qualitatively comparable to those observed during the reverse experimental sequence (Table 3). Mean percent changes of approximately 45 variables did not differ by >15% from those reported in the present study.

Effects of Time on Stability of Surgical Preparation During Maintained Hemodilution

In the three animals studied, changes in approximately 45 variables of hemodynamics, oxygenation, and metabolism did not exceed 15% over the 2-h period (Table 4).

Discussion

The principal findings of this study can be summarized as follows:

1. During severe HD (decrease in mean hematocrit from 29% to 15%), (a) cardiac output and splanchnic flows increased (with hepatic arterial blood flow increasing twice as much as all other flows); (b) hepatic arterial buffer response was not observed; (c) mean surface Po_2 of liver and small intestine decreased with a leftward shift of predominantly the hepatic surface Po_2 histogram; and (d) liver and small intestine O_2 uptake remained independent of O_2 delivery.
2. During superimposed isoflurane (1.45% end-tidal concentration), (a) mean arterial blood pressure, cardiac output, and splanchnic flows decreased; (b) a further decrease in mean hepatic surface Po_2 and a further (pronounced) leftward shift of the surface Po_2 histogram of the liver (38% of Po_2 values 0–5 mm Hg) were observed; and (c) hepatic O_2 uptake became O_2-delivery dependent.

These studies were conducted in anesthetized and ventilated pigs during laparotomy. The pig was chosen because of its anatomic and physiologic similarities to humans, particularly with respect to liver enzyme systems (9,14). Both laparotomy and mechanical ventilation are known to interfere with splanchnic perfusion (15,16). In contrast to barbiturates (15,17) and opiates (15,18), ketamine has no or little effect on liver and preportal circulation (19). The same is true for pancuronium (20). The effects of

flunitrazepam on the splanchnic circulation are unknown. It should therefore be realized that the effects associated with HD and isoflurane occurred during a baseline anesthesia with ketamine and flunitrazepam and during surgery. This, however, mimics the clinical situation in which patients receive baseline anesthesia during laparotomy, to which an inhaled anesthetic may subsequently be added to induce hypotension.

Six-percent hydroxyethyl starch was chosen as replacement fluid. It is a macromolecular polymer consisting of hydroxyethylated glucose molecules linked by α-1.4 bonds. The intravascular half-life is approximately 12 h. Owing to its physicochemical characteristics and minimal adverse effects, it is as suitable as 6% dextran 70 to induce HD (21).

If potentially adverse effects of acute HD are to be kept at a minimum, maintenance of normovolemia becomes essential. Although we did not determine actual blood volume, circumstantial evidence suggested that normovolemia was maintained. First, the amount of hydroxyethyl starch administered was slightly in excess of the amount of blood withdrawn. Second, right and left cardiac filling pressures remained unchanged throughout. Third, cardiac output could increase by 30%.

The concentration of 1.45% end-tidal isoflurane was chosen for two reasons. First, it had previously been used in the identical experimental model but without concomitant HD (8). Using the same concentration again enabled us to assess the modifying effects of underlying HD on subsequent isoflurane administration. Under conditions of preexisting HD, 1.45% isoflurane caused pronounced hypotension. It thus needs to be emphasized that animals with a presumably normal circulation were studied. Translation of this data to patients with diseased circulation (e.g., long-standing hypertension or atherosclerosis) is therefore unwarranted.

Second, the concentration of 1.45% isoflurane corresponds to 1 MAC in pigs (7). On the basis of recently revised MAC values for isoflurane in pigs (2.04%) (22), it is possible that the end-tidal concentration used in this study may be somewhat <1 MAC.

The transparenchymatous cannulation of the left hepatic vein was performed as previously described (8,23). Correct position of the catheter tip in the

region where the four hepatic veins merge was verified at autopsy. This technique allows collection of mixed venous hepatic blood while avoiding the ventilation-related changes in catheter position and partial occlusion of hepatic venous outflow sometimes associated with hepatic vein catheterization via internal jugular vein (23).

The portal vein was catheterized using Seldinger's technique. Preliminary studies had shown identical portal venous flows before and after portal vein catheterization, thus excluding vascular obstruction by the catheter.

The technique of measuring surface Po_2 using O_2-sensitive multiwire surface electrodes has been well established (10,11). This technique allows determination of tissue Po_2 without causing tissue trauma or interference with the microcirculation (11). However, that liver surface Po_2 values are not entirely representative of whole-organ oxygenation cannot entirely be ruled out. Owing to species-related distributions of hepatic arterial and portal blood flow, surface Po_2 values may reflect primarily hepatic arterial blood flow (24). In addition, in pigs the liver capsule contains a dense arterial network (25). Relatively high mean surface Po_2 values and a rightward localization of the Po_2 histograms during baseline conditions would support such possibilities. Al-

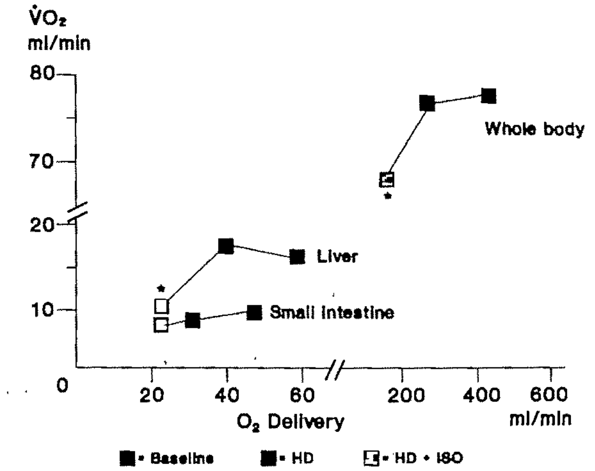

Figure 4. Relationship between O_2 uptake ($\dot{V}O_2$) and O_2 delivery of whole body, liver, and small intestine during baseline, hemodilution (HD), and combined hemodilution and isoflurane (HD + ISO). For reasons of clarity, only mean values are depicted (see Table 2 for SEM). $^*P < 0.05$, compared with both preceding values.

though polarographic reduction of halothane at the Po_2 electrode yields artificially elevated Po_2 values (26), isoflurane does not interfere with this technique (11).

The protocol required baseline anesthesia and extensive surgical preparation. In addition, isoflurane was always administered after established HD. These factors may have influenced the results. However, the data obtained in three animals with 2 h of maintained HD and in those four with a reverse sequence of interventions (i.e., HD after isoflurane) would rule out significant spontaneous deterioration of the preparation or major modification of the results by the experimental sequence.

In agreement with previous work (27–30), HD caused an increase in cardiac output. In contrast to previous findings, this increase was due to an increase in heart rate rather than in stroke volume. This response in heart rate is likely to vary with baseline heart rate. Heart rate is unlikely to increase (even further) if it is markedly elevated during baseline conditions (31). If hypovolemia would have been the reason for the development of tachycardia, stroke volume would have decreased, cardiac output would not have increased by 30%, and cardiac filling pressures would not have remained unchanged. In agreement with previous work (28,29), there was a marked reduction in systemic vascular resistance and a small (10%) but significant decrease in mean arterial pressure.

Compared with HD alone, addition of approximately 1 MAC isoflurane caused a pronounced decrease in cardiac output to values below baseline related to decreases in stroke volume and heart rate. The decrease in stroke volume despite unchanged indices of preload (right and left cardiac filling pressures) and lowered indices of afterload (mean arterial pressure, systemic vascular resistance) reflects the well-known negative inotropic properties of isoflurane (32,33).

The cardiovascular depression elicited by isoflurane during underlying severe HD was more pronounced than previously observed in the identical experimental model but without preexisting HD (8).

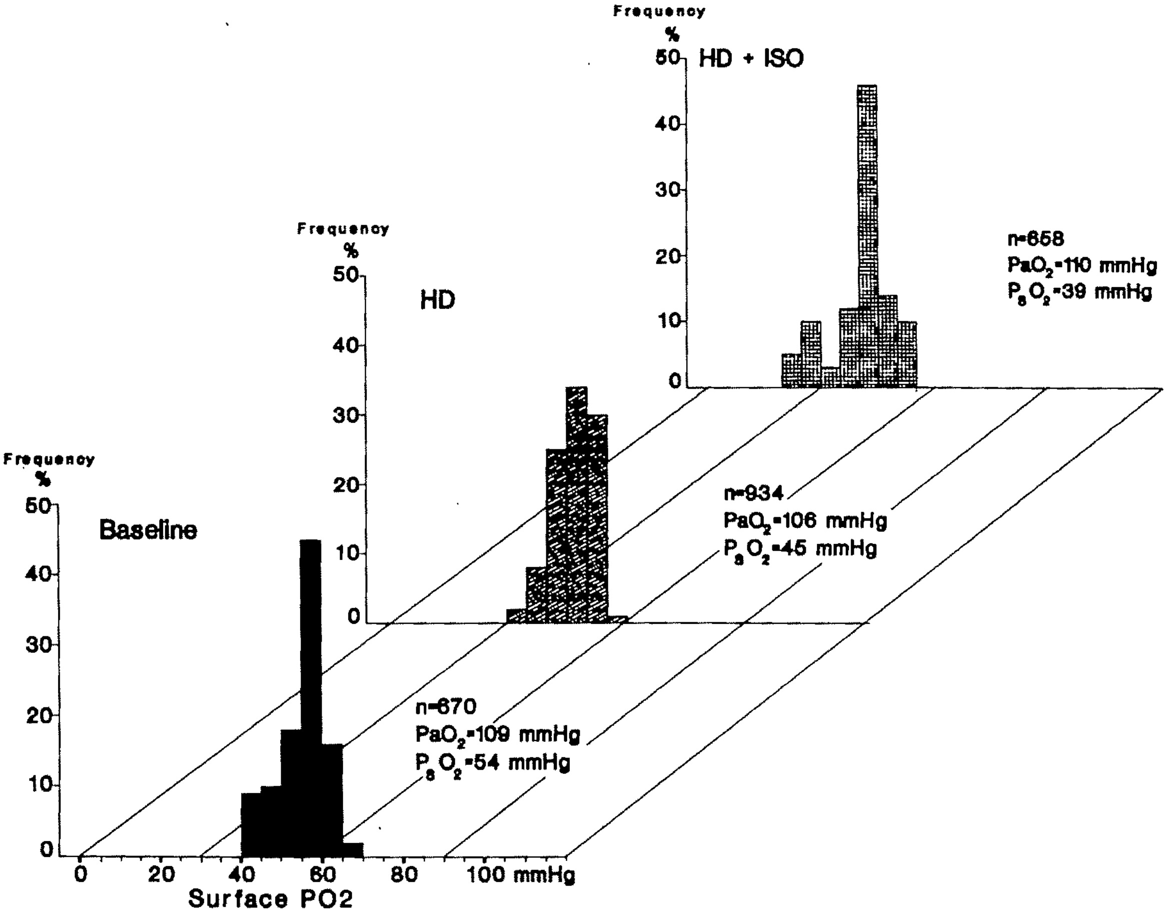

Figure 6. Summary histograms of small intestinal surface Po_2 during baseline, hemodilution (HD), and combined hemodilution and isoflurane (HD + ISO). Abbreviations as in Figure 5.

Specifically, the decrease in mean arterial pressure was significantly greater (50% vs 30%). It is conceivable that this was in part related to both the difference in underlying vascular motor tone and reactivity associated with the decrease in viscosity and the decrease in myocardial contractility as a consequence of inadequate oxygen transport to the myocardium during HD and isoflurane. Hemodilution had already caused a 30% reduction in systemic vascular resistance, which, however, was compensated by increases in heart rate and cardiac output. When these compensatory mechanisms were eliminated by isoflurane, the further 25% reduction in systemic vascular resistance now provoked an unopposed decrease in perfusion pressure. Cardiovascular depression is also reflected by the decrease in arterial pH.

There are few data on the effects of induced hypotension during HD available for direct comparison. During nitroprusside-induced (30) or adenosine-induced (29) hypotension, cardiac output decreased when compared with HD alone, but it either remained unchanged (30) or was even elevated (29) when compared with baseline status. Differences in results can easily be explained on the basis of differences in species (pigs vs dogs), baseline anesthesia (flunitrazepam/ketamine vs halothane and pentobarbital), degree of HD (hematocrit values of 14% vs 22%), baseline heart rates (90 vs 130–160 beats/min), and drugs used to induce hypotension (combined cardiodepressant and vasodilator vs pure vasodilators).

Hemodilution caused all splanchnic flows to increase proportionally with cardiac output, except for hepatic arterial blood flow, which increased twice as much (Figure 2). This finding would suggest active dilation of the hepatic vascular bed in addition to increases in flow related to changes in cardiac output and viscosity. It can only be speculated that the decreases in hepatic venous Po_2, O_2 saturation, and pH provided additional stimuli for active hepatic arterial vasodilation to compensate for the decrease in O_2 delivery.

Although such reasoning might seem intuitively obvious, the hepatic arterial buffer response (34) would predict a decrease in hepatic arterial blood flow in response to an increase in portal blood flow

Values are mean ± SEM.

(as observed during HD). This buffer response suggests that total hepatic perfusion is flow regulated rather than demand dependent. It is postulated that the rate of intrahepatic adenosine washout forms the basis for the hepatic arterial buffer response (35).

Our findings either provide evidence against the adenosine-washout hypothesis (i.e., total hepatic perfusion is not simply flow regulated), or they indicate that factors associated with HD overcome or at least modulate the hepatic arterial buffer response. Such factors may be related to changes in cardiac output, blood viscosity, hepatic oxygenation, or hepatic venous pH. However, this does not explain entirely why hepatic arterial vascular resistance declined almost twice as much as did the resistances of other vascular beds. It is conceivable that the hepatic arterial buffer response is not as effective in pigs as it is in cats (35) or dogs (36). It also is possible that the degree of the response varies with the baseline anesthesia and with the initial value for the relative contribution of hepatic arterial blood flow to total hepatic blood flow.

Most previous studies found insignificant changes in hepatic arterial blood flow in response to HD (27,29,37,38). Only one study (39) in addition to ours, showed a significant increase in hepatic arterial blood flow. Total hepatic blood flow was found to be unchanged (37) or to increase (39); portal blood flow also was found to increase (37).

Direct comparison of these results with ours is difficult because of differences in species (pigs vs cats vs dogs vs rats), in baseline anesthesia (ketamine/flunitrazepam vs pentobarbital vs neuroleptic vs conscious), in degree of HD, in means of achieving HD, and in methods of determining hepatic blood flow (electromagnetic flow probes vs microspheres vs bromsulphalein vs reservoir). Furthermore, in most of these studies, portal blood flow was not determined (27,29,38,39). Such lack of flow measurement will render determination of total hepatic blood flow and, consequently, any evaluation of a potential hepatic arterial buffer response impossible.

Isoflurane-induced hypotension was associated with decreases in all splanchnic flows (Figure 2). There were, however, quantitative differences among flows. Although superior mesenteric arterial, portal venous, and total hepatic blood flow returned to baseline values, hepatic arterial blood flow decreased to below (≈25%) baseline. Of note, unlike during HD, the change in hepatic arterial blood flow was now proportional to that of cardiac output. Further decreases in systemic and superior mesenteric arterial vascular resistances but not in hepatic arterial vascular resistance in response to administration of isoflurane would suggest that HD had resulted in near maximal vasodilation of only the hepatic arterial vascular bed, with flow now becoming pressure dependent. In this case, hepatic arterial blood flow would be expected to decrease in parallel with the reduction in perfusion pressure. Apparently, further decreases in portal and hepatic venous Po_2 saturation and in pH did not provide (potent enough?) stimuli for additional vasodilation.

These findings are in marked contrast to those previously observed in the identical experimental model but without preexisting HD (8). The same concentration of isoflurane had resulted in a 40% increase in hepatic arterial blood flow on the one hand and in a 15%–25% decrease in portal, superior mesenteric arterial, and total hepatic blood flow on the other. The increase in hepatic arterial blood flow (in contrast to the decrease observed in the present study) might be explained on the basis of either preserved hepatic arterial buffer response (i.e., increase in hepatic arterial blood flow in response to the decrease in portal blood flow), selective isoflurane-induced vasodilation of the hepatic arterial vascular bed (not previously dilated by HD), or by a less pronounced reduction in systemic arterial pressure (mean arterial pressure of 65 vs 40 mm Hg). On the other hand, it is difficult to explain why, in the present study, splanchnic flows were maintained (compared with baseline values) rather than decreased (as in the previous study) despite a profound decrease in perfusion pressure. It can only be postulated that the underlying HD modified (by mechanisms unidentified by this study) vascular reactivity.

In other studies of nonhemodiluted animals, isoflurane caused decreases in total hepatic and portal blood flows (15,40) and an increase in hepatic arterial blood flow in nonlaparotomized animals (7,41,42) but not in laparotomized miniature pigs (43).

Owing to decreases in hematocrit and O_2 saturation (portal and hepatic venous), O_2 contents of all vascular beds decreased (Figure 3). Because these decreases in O_2 content mostly outweighed the increases in flows, O_2 delivery decreased (except for hepatic arterial). Because of its unchanged O_2 saturation and the disproportional increase in flow, the hepatic artery was the only vascular bed that maintained O_2 delivery. In this model, hepatic arterial blood flow contributes just between 12% (baseline) and 17% (HD) to total hepatic blood flow; therefore, unchanged hepatic arterial O_2 delivery could not compensate for the marked decrease in portal venous O_2 delivery (as reflected by the decrease in total hepatic O_2 delivery). The pig compensated for reduced O_2 contents by progressively increasing flows (by lowering vascular resistances) and O_2 extraction ratios.

Both portal and hepatic venous pH values and hepatic and small intestine surface Po_2 decreased. In addition, the summary Po_2 histogram of the liver broadened at the base and shifted leftward, with 20% of Po_2 values <20 mm Hg. This is suggestive evidence of disturbed microcirculation. Although a tendency for a leftward shift also was observed in the surface Po_2 histogram of the small intestine, these changes were less pronounced: no Po_2 values were <25 mm Hg. Combined evidence thus suggests that during severe HD, compensatory mechanisms (i.e., increases in flows and O_2 extraction ratios) were no longer able to fully compensate for the decreases in O_2 delivery.

Despite decreases in O_2 delivery between 30% and 40%, O_2 uptake of liver and small intestine did not decrease significantly. This implies that the point at which tissue O_2 uptake becomes limited by delivery in a supply-dependent manner (i.e., critical O_2 delivery) had not yet been reached.

During superimposed isoflurane-induced hypotension, portal and hepatic venous O_2 content decreased even further, related to decreases in the respective O_2 saturation. In contrast, hepatic arterial O_2 content was maintained, owing to unchanged O_2 saturation. Because there was a uniform decrease in flow, all O_2 delivery decreased.

There were also further decreases in portal and hepatic venous pH and in hepatic surface Po_2. The leftward shift of the summary Po_2 histogram became pronounced, with 80% of Po_2 values <20 mm Hg and with almost 40% of Po_2 values in the hypoxic range (i.e., 0–5 mm Hg). All factors taken together, this would suggest severely impaired hepatic microcirculation. This would correlate with evidence of impaired hepatic function, as suggested by the decrease in hepatic lactate uptake.

As with HD alone, the effects on the surface Po_2 of the small intestine were less pronounced. The 10% decrease in mean surface Po_2 was statistically not significant, and the leftward shift of the summary histogram was relatively small, with no Po_2 values <20 mm Hg. Two findings might help to explain why the small intestinal microcirculation was apparently somewhat less disturbed than the hepatic circulation. First, the decrease in superior mesenteric arterial O_2 delivery was relatively less than that in total hepatic delivery (20% vs 35% compared with HD alone). Second, whereas hepatic O_2 extraction did not increase further, there was an additional increase in small intestinal O_2 extraction.

Overall evidence clearly suggests that during combined HD and isoflurane-induced hypotension, adaptive mechanisms (i.e., increases in flows and O_2 extraction) are almost completely exhausted and no longer compensate for decreases in O_2 content to maintain tissue oxygenation. In accordance with these findings, O_2 uptake of liver (and of whole body) decreased (Figure 4). Thus, the point of critical O_2 delivery had been reached. In contrast, small intestinal O_2 uptake remained supply independent.

Data for direct comparison are limited. When isoflurane was administered at the same concentration in the identical experimental model but without underlying HD, there were also decreases in O_2 delivery to liver and small intestine, in hepatic and small intestine surface Po_2, and a leftward shift of the surface summary Po_2 histograms (8). However, in contrast to the present findings, extraction ratios of liver and small intestine, portal and hepatic venous O_2 contents, and hepatic O_2 and lactate uptake remained unchanged. In addition, despite the leftward shift of the surface Po_2 histograms, hypoxic Po_2 values (0–5 mm Hg) were not observed. This would suggest that in the absence of HD, the increases in O_2 extraction sufficiently compensated for the decreases in O_2 delivery. Other investigators have made similar observations (37). In contrast, and in agreement with species-related differences in liver blood flow distribution, in a dog model, hypoxic (0–5 mm Hg) surface Po_2 values were observed in 8% of all Po_2 measurements during piritramid baseline anesthesia and in 20% of all measurements during 1 MAC isoflurane (11).

In conclusion, we have shown that in anesthetized and laparotomized pigs, even severe, acute normovolemic HD (from an initial hematocrit of 29% down to 14%) with 6% hydroxyethyl starch does not necessarily have grossly adverse effects on liver and small intestine (as suggested by statistically insignificant changes in splanchnic O_2 and hepatic lactate uptake). However, decreases in mean surface Po_2 of liver and small intestine, broadening and leftward shift of the liver surface Po_2 histogram, and decreases in portal and hepatic venous pH and O_2 content values provide evidence that compensatory mechanisms were becoming exhausted.

When isoflurane-induced hypotension was superimposed on HD, splanchnic hemodynamics and oxygenation became severely impaired (as suggested by decreases in hepatic O_2 and lactate uptake, a marked reduction in mean liver surface Po_2, and a pronounced leftward shift of the liver surface Po_2 histogram). This clearly indicates that mechanisms usually compensating for decreases in O_2 content (i.e., decreases in vascular resistance, increases in flows and O_2 extraction) were no longer effective. It is conceivable that the cardiodepressant effect of isoflurane accentuated the potentially adverse effects of combined reductions in O_2 content and perfusion pressure on regional perfusion and oxygenation. These data would thus suggest that combined HD and deliberate hypotension should be used with extreme caution in patients, especially when a mixed cardiodepressant and vasodilator (e.g., isoflurane) drug is chosen for inducing hypotension during underlying normovolemic anemia.

It remains to be determined whether the human splanchnic circulation responds to acute HD in a manner similar to that of the pig. Normal hematocrit values in humans are approximately 45% (rather than 30% as in the pig). We are therefore unable to define the human correlate to a hematocrit of 15% in the pig. In the human, comparably low values may reflect a much greater degree of HD. If only the percent changes in hematocrit after HD (50%) were applied, this would correspond to absolute hematocrit values of approximately 20% in humans.

Appendix: Formulas Applied

Vascular Resistance

$$\text{SVR (U)} = \frac{\text{MAP (mm Hg)} - \text{CVP (mm Hg)}}{\text{CO (L/min)}},$$

$$\text{HAVR (U)} = \frac{\text{MAP (mm Hg)} - \text{HVP (mm Hg)}}{\text{HABF (mL/min)}} \times 10^3,$$

$$\text{PVVR (U)} = \frac{\text{PVP (mm Hg)} - \text{HVP (mm Hg)}}{\text{PBF (mL/min)}} \times 10^3,$$

$$\text{SMAVR (U)} = \frac{\text{MAP (mm Hg)} - \text{PVP (mm Hg)}}{\text{SMABF (mL/min)}} \times 10^3,$$

where SVR, HAVR, PVVR, and SMAVR are systemic, hepatic arterial, portal venous, and superior mesenteric arterial vascular resistances, respectively; MAP, CVP, PVP, and HVP are mean arterial, central venous, portal venous, and hepatic venous pressures, respectively; CO is cardiac output; HABF, PBF, and SMABF are hepatic arterial, portal venous, and superior mesenteric arterial blood flows.

Oxygen Supply/Uptake

$$O_2 \text{ content} = \text{Hb} \times O_2 \text{ saturation} \times 1.34 + P_{O_2} \times 0.0031,$$

$$O_2 \text{ delivery} = O_2 \text{ content} \times \text{flow},$$

$$DO_2TH = DO_2HA + DO_2PV,$$

$$DO_2HA = CO_2A \times HABF \times 10^{-2},$$

$$DO_2PV = CO_2PV \times PVF \times 10^{-2},$$

$$DO_2SMA = CO_2A \times SMABF \times 10^{-2},$$

$$VO_2TH = (CO_2PV - CO_2HV) \times PBF \times 10^{-2} + (CO_2A - CO_2HV) \times HABF \times 10^{-2},$$

$$VO_2SI = (CO_2A - CO_2PV) \times SMABF \times 10^{-2},$$

$$EO_2TH = VO_2TH/DO_2TH,$$

$$EO_2SI = VO_2SI/DO_2SMA,$$

where DO_2TH, DO_2HA, DO_2PV, and DO_2SMA are total hepatic, hepatic arterial, portal venous, and superior mesenteric arterial O_2 deliveries; CO_2A, CO_2PV, and CO_2HV are systemic arterial, portal venous, and hepatic venous O_2 contents; VO_2TH and VO_2SI are total hepatic and small intestinal O_2 uptake; EO_2TH and EO_2SI are total hepatic and small intestinal O_2 extraction ratios.

Hepatic Metabolism

$$\text{Hepatic lactate uptake} = (\text{CLACPV} - \text{CLACHV}) \times \text{PBF} + (\text{CLACHA} - \text{CLACHV}) \times \text{HABF},$$

$$\text{Hepatic pyruvate uptake} = (\text{CPYRPV} - \text{CPYRHV}) \times \text{PBF} + (\text{CPYRHA} - \text{CPYRHV}) \times \text{HABF},$$

where CLAC and CPYR are lactate and pyruvate concentrations in hepatic arterial (HA), portal venous (PV), and hepatic venous (HV) blood.

Greater Neuromuscular Blocking Potency of Atracurium During Hypothermic Than During Normothermic Cardiopulmonary Bypass

Christoph Diefenbach, MD, Manfred Abel, MD, and Walter Buzello, MD

University Department of Anesthesiology, Koeln, Germany

Previous studies drew attention to the greater neuromuscular blocking potency of atracurium during, than before or after, hypothermic cardiopulmonary bypass (CPB) while disregarding the periods of normothermic perfusion. We recorded the evoked twitch tension in 15 patients during nitrous oxide/narcotic anesthesia who were undergoing open heart surgery. Atracurium was injected as an initial bolus dose of 460 μg/kg. Waning neuromuscular blockade was enhanced by repeat injections of 138 μg/kg whenever the twitch tension attained 25% of control. During hypothermic (<32°C) and normothermic (>34°C) CPB, the times of onset of the maintenance doses were 57% and 18% longer, respectively, than before CPB ($P < 0.05$). Maintenance doses of atracurium were required every 24 ± 4 min (mean ± SD) before CPB, every 45 ± 8 min ($P < 0.05$) during hypothermia, every 22 ± 3 min during normothermic perfusion, and every 23 ± 3 min after CPB. In conclusion, the patients' changing demand of atracurium paralleled the changes of temperature rather than the institution and cessation of CPB.

(Anesth Analg 1992;75:675–8)

Hypothermic cardiopulmonary bypass (CPB) causes a 35% reduction in the rate of atracurium infusion necessary to maintain a 95% neuromuscular blockade (1,2). In one study, an average of 80% of the prebypass rate of infusion had to be resumed after cessation of CPB (1). In the other study, after the end of CPB, the time from the end of infusion to recovery to 95% of control neuromuscular transmission averaged 85 min (2) (i.e., approximately three times as long as in continuously normothermic patients [3]). Because both studies (1,2) disregarded the period of normothermic perfusion, the present study was designed to quantitate the impact of normothermic versus hypothermic CPB on atracurium-induced neuromuscular blockade.

Methods

After approval of the study by the hospital ethical committee, 15 adult patients, ASA physical status III and IV, undergoing open heart surgery gave their informed consent to participate in the study. Patients with neuromuscular, kidney, or liver disease and those taking medication known to interact with muscle relaxants were excluded from the study. All patients were premedicated with flunitrazepam (2 mg) administered orally 90 min before the induction of anesthesia. Anesthesia was induced with midazolam (10–15 mg IV) and fentanyl (0.75–1.5 mg IV). After losing consciousness, the patients received 100% oxygen via face mask over 10 min. Anesthesia was maintained with an infusion of fentanyl (0.8–1.2 mg/h) and midazolam (10–15 mg/h) during mechanical ventilation with 50% oxygen in air, adjusted for 35–45 mm Hg end-tidal carbon dioxide concentration. The pump was primed with lactated Ringer's solution (2200 mL) including heparin (2000 U) and aprotinin (2×10^{-6} U). Capillary oxygenators were used. The pump flow was 2.4 L/m^2. Neuromuscular transmission was monitored by the evoked twitch tension (boomerang force displacement transducer [4]) in response to supramaximal train-of-four stimuli (2 Hz/2 s every 15 s) administered to the ulnar nerve at the wrist via surface electrodes. Neuromuscular monitoring was instituted after the loss of consciousness, and the recording system was allowed to stabilize for 10 min until a bolus dose of atracurium (460 μg/kg, equal to twice the effective dose for 95% depression of twitch tension) was injected intrave-

nously over 60 s. The trachea was intubated when the twitch response was completely abolished. Waning neuromuscular blockade was enhanced by intravenous injection of constant maintenance doses of atracurium (138 μg/kg, equal to 0.6 times the effective dose for 95% depression of twitch tension) whenever the first twitch response of a train-of-four (T1) had attained 25% of its control. Spontaneous recovery of neuromuscular transmission to at least 75% of control twitch tension was allowed to occur after the last maintenance dose of atracurium. The twitch recordings were evaluated for the following variables: time from end of injection of the initial dose to recovery of 25% of control twitch tension; time from end of injection of the maintenance doses to recovery of 25% of control twitch tension (DUR25%$_{maint}$); time from end of injection of the maintenance doses to maximal twitch suppression (time of onset); and time from 25% to 75% twitch recovery (recovery index) after injection of the last maintenance dose. The results were calculated as mean ± SD and range. Intragroup comparison was performed by paired Student's *t*-test. Both the DUR25%$_{maint}$ values and the corresponding times of onset were related to particular events of CPB and to nasopharyngeal temperature. In those patients where more than one maintenance dose of atracurium had to be injected before or after CPB or during hypothermia, only the time of onset and the DUR25%$_{maint}$ of the last maintenance dose before the new event were used for statistical evaluation.

Results

Patient characteristics as to age, body weight, and height were 63 ± 6 yr (range 54–71), 72 ± 12 kg (range 55–86), and 168 ± 8 cm (range 152–177), respectively (10 men, 5 women). Surgical procedures were coronary artery bypass grafting ($n = 11$), aortic valve replacement ($n = 3$), and mitral valve replacement ($n = 1$). The CPB data are listed in Table 1. The intravenous injection of both the initial bolus dose and the maintenance doses of atracurium resulted in complete suppression of the twitch response in all patients. The number of maintenance doses administered before the institution of CPB was 2.5 ± 1 (1–4). The changes in time of onset of the atracurium injections and in their DUR25%$_{maint}$ in relation to specific events of CPB are shown in Table 2. The time of onset of the maintenance doses averaged 57% longer during hypothermia (<32°C) than before the institution of CPB ($P < 0.05$). Correspondingly, hypothermia almost doubled the DUR25%$_{maint}$ ($P < 0.05$). The delayed onset of the maintenance doses persisted during normothermic perfusion when the DUR25%$_{maint}$ had already returned to normal. No further change in DUR25%$_{maint}$ occurred after cessation of CPB, when the time of onset of the maintenance doses was no longer significantly different from its prebypass values. At the end of surgery, neuromuscular transmission had attained 75% of control twitch tension in all patients.

Table 1. Cardiopulmonary Bypass Data

Injection of initial dose of atracurium to start CPB (min)	92 ± 29 (50–130)
Time of start of CPB to lowest temperature (min)	19 ± 5 (15–30)
Lowest temperature (°C)	27.9 ± 2.1 (22.0–30.0)
Duration of hypothermic CPB <32°C (min)	64 ± 17 (40–95)
Start rewarming to 34°C (min)	15 ± 7 (10–22)
Duration of normothermic CPB >34°C (min)	28 ± 7 (20–45)
End of CPB to end of surgery (min)	58 ± 13 (40–80)
Total duration of CPB (min)	122 ± 30 (90–200)

CPB, cardiopulmonary bypass.
Values are mean ± SD (range); $n = 15$.

Discussion

In an attempt to quantitate the impact of hypothermic CPB on the intensity or duration of nondepolarizing neuromuscular blockade, previous workers basically resorted to one of the following three variables: (a) rate of infusion of a muscle relaxant required to maintain a predetermined constant intensity of neuromuscular blockade (1,2); (b) intensity of neuromuscular blockade in response to a preset constant rate of muscle relaxant infusion (5); and (c) intervals between repeated injection of a predetermined constant dose of a muscle relaxant administered whenever the evoked twitch tension returns to 25% of its control value (6). We adhered to the repeat injection technique to obtain data comparable to those of both a concomitantly conducted study on atracurium in noncardiac surgery patients (7) and previous communications on vecuronium in patients with CPB (6) or with neuromuscular disease (5,8).

Possible mechanisms by which hypothermic CPB interferes with nondepolarizing neuromuscular blockade include increased volume of distribution, reduced muscle perfusion, reduced biodegradation of the muscle relaxant, and functional alterations of the neuromuscular junction. The relative significance of each of these factors has been extensively discussed (5,6,9). It was concluded that the modifications of neuromuscular blockade by hypothermic CPB may be attributed to low body temperature rather than to other factors of the bypass (6) and that hypothermia may act at the level of the neuromuscular junction and the contractile apparatus of the muscle cells

Table 2. Time of Onset and Duration of Action of Maintenance Doses of Atracurium (0.6 × ED_{95} = 138 μg/kg) Injected Intravenously on 25% Recovery of the Evoked Twitch Tension After an Initial Dose of 2 × ED_{95} (460 μg/kg) During Cardiopulmonary Bypass With Hypothermia

	Time of onset (min)	$DUR25\%_{maint}$ (min)	No. of patients
Before CPB	2.1 ± 0.6 (1.0–3.5)	24 ± 4 (17–30)	15
Start of CPB to lowest temperature	2.7 ± 0.9 (2.0–4.0)	—[a]	10[b]
During hypothermic CPB (<32°C)	2.9 ± 0.9[c] (2.0–5.0)	45 ± 8[c] (35–60)	15
During rewarming	3.3 ± 0.9[c] (2.0–4.8)	—[a]	13[b]
During normothermic CPB (>34°C)	2.8 ± 1.1[c] (2.0–5.0)	22 ± 3[d] (15–26)	15
After CPB	2.3 ± 0.4[d] (1.8–3.0)	23 ± 3[d] (19–34)	15
Recovery index		17 ± 7 (8–27)	15

CPB, cardiopulmonary bypass; $DUR25\%_{maint}$, time from end of injection of the maintenance doses to recovery of 25% of control twitch tension; ED_{95}, effective dose for 95% depression of twitch tension.

[a] Not applicable, because times of cooling and rewarming are shorter than $DUR25\%_{maint}$.

[b] Injection of a maintenance dose during the process of cooling or rewarming was not required in all patients.

[c] $P < 0.05$ versus corresponding value before CPB.

[d] NS versus corresponding value before CPB.

rather than at the level of drug metabolism (9). Yet, owing to the lack of information on both pharmacokinetic and possible ultrastructural effects of hypothermic CPB, these views remain to be proved. Although our method was confined to twitch recording, the discrimination between distinct periods of the CPB may contribute to a better understanding of its effects on neuromuscular blockade.

The prolongation of the time of onset of the maintenance doses observed promptly on the institution of CPB suggests an increased volume of distribution as its causative factor. However, the onset of the maintenance doses was further retarded by cooling but was accelerated again during subsequent normothermic perfusion (>34°C). Thus, besides an increased volume of distribution, low body temperature appears to be an additional factor affecting neuromuscular blockade. Reduced temperature may interfere with neuromuscular transmission by reduced muscle perfusion or by functional impairment of the neuromuscular junction. Our present knowledge does not allow a precise understanding of the role of each of these factors. Yet, the delayed onset of action of the maintenance doses at low body temperature is not compatible with an increased bioavailability of atracurium, which previous reports (1,2) proposed to account for the increased neuromuscular blocking potency of atracurium during hypothermic CPB. The alleged significance of reduced biodegradation of atracurium was also doubted when a hypothermia-related prolongation of the $DUR25\%_{maint}$ was recorded with both pancuronium and vecuronium (6), which are known not to undergo significant biodegradation (10).

Like all previous studies on muscle relaxants and CPB, our study does not confer a reference value for the recovery index, nor can a true control group of hypothermic patients without CPB be studied in cardiac surgery. The recovery index may therefore be compared with corresponding data of a concomitantly conducted study on repeated atracurium injection in 10 noncardiac surgery patients (7). Relative to this reference value of 12 ± 5 min, the recovery index after hypothermic CPB was 42% longer, indicating some impairment of neuromuscular transmission extending beyond the duration of the bypass. In contrast to atracurium, the prolongation of the $DUR25\%_{maint}$ of pancuronium was reported to be only poorly attenuated by rewarming, with only 2 of 10 patients having attained 75% of the control electromyogram amplitudes (6). With vecuronium, the prolongation of the $DUR25\%_{maint}$ was found to be more efficiently attenuated by rewarming than with pancuronium, and at the end of surgery, only 5 of 10 patients had failed to attain 75% of control neuromuscular transmission (6). Thus, when comparing our results with previous findings (6), the impact of hypothermic CPB on neuromuscular blockade appears to be reversible in the following order: atracurium, vecuronium, pancuronium. As in neuromuscular disease (8,11), the recovery index would then be a more sensitive indicator of impaired neuromuscular transmission than $DUR25\%_{maint}$.

In conclusion, when atracurium was administered by repeated injection before, during, and after CPB, both the time of onset and the DUR25% of the maintenance doses were significantly longer during hypothermic than normothermic CPB. The $DUR25\%_{maint}$ and the time of onset of the maintenance doses returned to normal during normothermic perfusion and after cessation of CPB, respectively, whereas the recovery index remained significantly longer after CPB than reported in noncardiac surgery patients. The joint effects of an increased volume of distribution, reduced muscle perfusion, and functional impairment of the neuromuscular junction secondary to hypothermia most likely explain our results.

Effects of Surgical Stress and Volatile Anesthetics on Left Ventricular Global and Regional Function in Patients With Coronary Artery Disease

Evaluation by Computer-Assisted Two-Dimensional Quantitative Transesophageal Echocardiography

---

We investigated the effects of halothane, enflurane, and isoflurane on central hemodynamics and left ventricular global and regional function when used to control intraoperative hypertension in 39 patients with coronary artery disease. Left ventricular short-axis, midpapillary images were obtained by transesophageal echocardiography. Using a centerline algorithm, we analyzed left ventricular images for global area ejection fraction (GAEF) and segmental area ejection fraction (SAEF). The SAEF/GAEF ratio was calculated for each of eight segments. Measurements were performed after induction of anesthesia but before skin incision; 1 min after sternotomy; and during administration of the inhaled anesthetic. The increase in arterial blood pressure during sternotomy was due to an increase in vascular resistance accompanied by increases in heart rate and filling pressures while GAEF decreased. No changes in the SAEF/GAEF ratio appeared during sternotomy. The inhaled anesthetics restored arterial blood pressure by a similar decrease in vascular resistance. Isoflurane caused an increase in cardiac index that was not seen with halothane or enflurane (halothane vs isoflurane, $P < 0.05$). The GAEF was decreased by halothane but unaffected by isoflurane and enflurane (halothane vs enflurane; $P < 0.05$). Isoflurane induced a decrease in the SAEF/GAEF ratios of two segments corresponding to the inferolateral wall of the left ventricle that was, in one of these segments, significantly more pronounced compared with both halothane and enflurane. Halothane or enflurane did not cause any change in regional wall motion. We conclude that isoflurane is more likely to cause regional wall motion changes than halothane or enflurane in patients with coronary artery disease.

(Anesth Analg 1992;75:679–87)

Patients undergoing coronary artery surgery during low- or high-dose opioid anesthesia may experience systemic vasoconstriction, tachycardia, and intraoperative hypertension in response to sternotomy that will increase myocardial oxygen demand (1–7). Surgical stress in these patients has also been shown to increase myocardial oxygen extraction, indicating that the autoregulatory myocardial blood flow response does not meet the increased metabolic demand (4–7). This unfavorable effect on the myocardial oxygen supply/demand ratio by intraoperative hypertension may induce myocardial ischemia irrespective of the opioid dose used (1,2,4,5,7,8).

One approach to control intraoperative hypertension and to decrease myocardial oxygen demand is to use inhaled anesthetics to increase the depth of anesthesia. Roizen et al. (9) found that halothane and enflurane both effectively decreased pulmonary capillary wedge pressure (PCWP) and systemic vascular resistance (SVR) when used to treat intraoperative hypertension. Hess et al. (3), however, demonstrated that halothane-induced restoration of arterial blood

pressure during surgical stress in patients with coronary artery disease was accompanied by a further increase in PCWP and found no change in SVR, in striking contrast to isoflurane, which acted as an afterload-reducing agent. Cardiometabolic and coronary hemodynamic measurements were not performed in these two studies.

O'Young et al. (6) and Sahlman et al. (7) studied the myocardial circulatory and metabolic effects of isoflurane as an adjunct to opioid/nitrous oxide anesthesia used to treat intraoperative hypertension in patients with coronary artery disease. The former group demonstrated that isoflurane was safe and caused no electrocardiographic (ECG) signs or metabolic evidence of myocardial ischemia. Sahlman et al. (7), however, using higher concentrations of isoflurane, showed that a normalization of intraoperative hypertension with isoflurane was associated with a significant heart rate (HR) increase and lactate production in some patients. Halothane has also been studied in this situation and was found to induce myocardial ischemia in some patients but to improve regional myocardial lactate metabolism in others (10). To our knowledge, there is no study on the cardiometabolic and coronary hemodynamic effects of enflurane when used to treat intraoperative hypertension in patients with coronary artery disease.

Thus, data are lacking, and there is also some controversy concerning the effects of the different volatile anesthetics on central hemodynamics, myocardial oxygenation, and the development of myocardial ischemia when these anesthetics are used to decrease myocardial oxygen demand during surgical stress in patients with coronary artery disease. This is probably due to the fact that these anesthetics have not been compared in one randomized study. We have therefore conducted a prospective, randomized study on the effects of halothane, enflurane, and isoflurane on central hemodynamics and global and regional left ventricular function using two-dimensional transesophageal echocardiography. The three different volatile anesthetics were used to normalize intraoperative high blood pressure caused by sternotomy in patients undergoing coronary artery bypass grafting, and our aim was to evaluate whether any of the anesthetics was preferable to the others with respect to regional left ventricular wall motion.

Methods

The study was approved by the Human Ethics Committee of the University of Gothenburg. After informed consent was obtained, 39 patients scheduled to undergo elective coronary artery bypass grafting were included in the study. All patients had two- or three-vessel coronary artery disease and an ejection fraction >0.5, determined on preoperative cardioangiography. Patients with known mitral or aortic valve insufficiency were excluded from the study. All patients were being treated with β-adrenergic receptor blockers. The patient's cardiac medication, including β-blockers, was continued up to the morning of surgery.

The patients were randomly assigned to one of three groups to receive halothane ($n = 13$), enflurane ($n = 13$), or isoflurane ($n = 13$) to control intraoperative hypertension during sternotomy. The mean age in the halothane, enflurane, and isoflurane groups was 63.1 yr (range 41–76), 58.5 yr (range 36–70), and 63.1 yr (range 44–84), respectively.

The patients were premedicated with flunitrazepam (1 mg), morphine (10 mg), and scopolamine (0.4 mg). Anesthesia was induced with thiopental (4 mg/kg), followed by fentanyl. Pancuronium (0.1 mg/kg) was used as muscle relaxant. Fentanyl was administered in incremental doses during induction of anesthesia and after intubation (i.e., before the first hemodynamic measurement, up to a total amount of 15 μg/kg). Thereafter, no central nervous system depressant was administered. The patients were ventilated with 60% nitrous oxide in oxygen during the course of the study. Ventilation was controlled with $P_{CO_2} = 4.5–5.0$ kPa and $P_{O_2} > 12$ kPa.

Central Hemodynamic Measurements

An arterial cannula was placed in the left radial artery and a central venous catheter in the left subclavian vein. A Swan-Ganz thermodilution catheter (USCI, C. R. Bard Inc., Billerica, Mass.) was inserted through the right internal jugular vein and, under fluoroscopy, guided into the pulmonary artery. Continuous recordings of systolic, diastolic, and mean arterial pressure, together with systolic, diastolic, and mean pulmonary artery pressure, central venous pressure, PCWP, and ECG leads II and V_5 were obtained with a Siemens Sirecust monitoring system (Siemens AG, Erlangen, Germany) and saved on a paper strip. Thermodilution cardiac output (L/min) measurements were performed in triplicate at each measuring point. Cardiac index ($L \cdot min^{-1} \cdot m^{-2}$), stroke volume (mL), stroke volume index (mL/m^2), SVR ($mm\ Hg \cdot min \cdot L^{-1}$), and systemic vascular resistance index (SVRI) ($mm\ Hg \cdot min \cdot m^{-2} \cdot L^{-1}$) were also calculated.

Measurements of Global and Regional Left Ventricular Function by Transesophageal Echocardiography

A single-plane transesophageal echocardiographic transducer (ALOKA, 5 MHz, phased array; ALOKA

Co., Tokyo, Japan) was positioned approximately 40 cm into the esophagus and adjusted until good short-axis images of the left ventricle at the midpapillary level were obtained with an ALOKA SSD 870 echocardiography system. Images were stored on VHS videotape and later transferred to a computer system by means of a video digitizer (11) at a rate of 25 images/s. Three cardiac cycles were selected for each measurement and saved on a floppy disk. Using a digitizing tablet, the endocardial border was outlined in systole and diastole, starting at the anterior papillary muscle. Papillary muscles were not included in the outline. Systole was defined as the smallest area during the cardiac cycle and diastole as the area at the R wave on ECG. The image sequence was displayed in real time and in slow motion, with the endocardial outline superimposed on the image to certify that the endocardial border was correctly outlined. The systolic and diastolic outlines were then projected over each other and corrected for rotational movement of the heart. No correction for translational movement was made (12). Mean values of the three cardiac cycles were used for calculations. The fractional area change between diastolic and systolic areas was calculated and was called the global area ejection fraction (GAEF). Ninety-six radii were constructed using the centerline method (13), and the areas of the 96 "slices" between the systolic and diastolic contours were calculated. These slice areas were then added together to obtain eight segments representing, approximately, anterior wall (segments 1 and 2), septal wall (segments 3 and 4), inferior wall (segments 5 and 6), and lateral wall (segments 7 and 8). The area change of each segment was divided by the corresponding diastolic area to obtain an area ejection fraction for the segment, called segmental area ejection fraction (SAEF). The SAEF/GAEF ratio was then calculated for each segment.

Each digitized and stored beat was analyzed on two different occasions by the same observer who at the second attempt was unaware of the result of his previous analysis. A correlation analysis was performed on the values of GAEFs obtained on the two occasions ($r = 0.86$).

Experimental Protocol

Hemodynamic measurements, echocardiographic images, and ECG recordings were obtained at three occasions: (a) after induction of anesthesia and tracheal intubation but before skin incision (preincision); (b) 1 min after sternotomy; and (c) during addition of a volatile anesthetic in concentrations adequate to decrease mean arterial pressure to preincision levels. High inspiratory concentrations of the volatile anesthetics were used initially to induce a rapid decrease of arterial blood pressure to presternotomy levels. The inspiratory concentrations of the different anesthetics were then gradually reduced as arterial blood pressure approached and finally stabilized around the presternotomy level. Inspiratory and end-tidal concentrations of halothane, enflurane, or isoflurane were monitored using a Siemens-Elema Servo Gas Analyzer (Siemens AG). The ECG signs of myocardial ischemia were defined as ST-segment elevation >0.2 mV or ST-segment depression >0.1 mV, 80 ms beyond the J point. Mean rectal body temperature at the start of the experimental procedure was 35.8° ± 0.1°C (mean ± SEM).

Coronary Anatomy

Without knowledge of administered anesthetic, occurrence of ischemia, or intraoperative course, one of the investigators reviewed the coronary angiogram of each patient for the characteristics of steal-prone coronary anatomy: total occlusion of at least one major epicardial artery (right or left anterior descending or proximal circumflex coronary artery), collateral flow into the bed distal to the occluded artery, and a proximal stenosis (>50% diameter reduction) of the artery supplying the collateral vessels (14). The incidence of steal-prone coronary anatomy for each of the three groups was calculated.

Statistical Analysis

Values of the various hemodynamic and echocardiographic variables were subjected to a repeated-measures two-way analysis of variance (SuperAnova, Abacus Concepts Inc., Berkeley, Calif.). A means comparison contrast analysis was performed to test the interaction between experimental stage and experimental group. To evaluate the influence of the coronary artery anatomy on the results, a repeated-measures three-way analysis of variance was performed, and interactions between data were tested by a means comparison contrast analysis. Values are presented as mean ± SEM.

Results

The incidence of steal-prone coronary artery anatomy was 46% in the halothane group, 46% in the enflurane group, and 61% in the isoflurane group (differences not significant).

Effects of Surgical Stress on Central Hemodynamics, GAEF, SAEF, and the SAEF/GAEF Ratio

and PCWP increased significantly, whereas no significant changes were found in cardiac index or stroke volume index (Table 1).

Sternotomy induced a decrease in the GAEF from 0.45 ± 0.02 to 0.39 ± 0.02 ($P < 0.01$); SAEF decreased significantly in five of the eight segments during sternotomy (Figure 1). The SAEF/GAEF ratio was not significantly affected by sternotomy (Figure 2).

Effects of Inhaled Anesthetics on Central Hemodynamics

When arterial blood pressure was restored to presternotomy levels, percent end-expiratory concentrations of halothane, enflurane, and isoflurane were 0.61% ± 0.14%, 0.86% ± 0.14%, and 1.03% ± 0.10% after 4.4 ± 0.48, 5.0 ± 0.87, and 4.1 ± 0.56 min, respectively. The three anesthetics reduced arterial

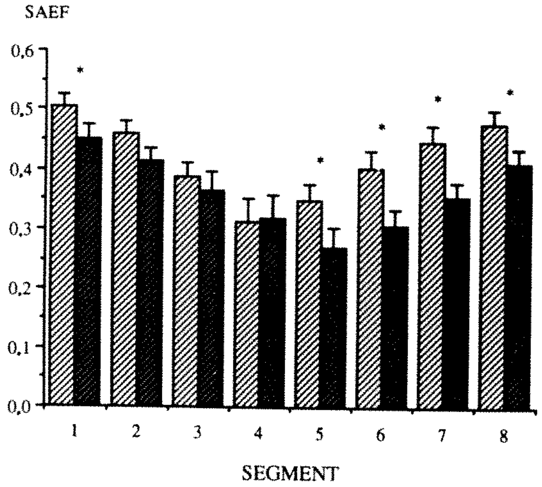

Figure 1. Effects of sternotomy on left ventricular regional wall motion. SAEF, segmental area ejection fraction. *Significant difference between preincision (▨) and sternotomy (■) ($P < 0.05$).

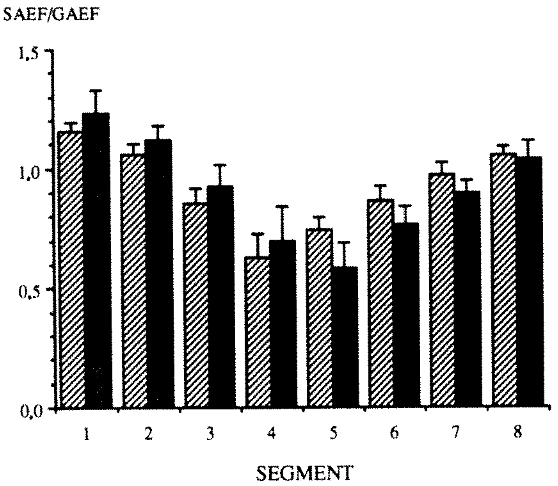

Figure 2. Effects of sternotomy on left ventricular regional wall motion. Values corrected for changes in global area ejection fraction (GAEF). SAEF, segmental area ejection fraction. Preincision (▨); sternotomy (■).

blood pressure to approximately the same extent. The restoration of arterial blood pressure to preincision levels was accompanied by a similar decrease in SVRI in the three groups. The cardiac index increased with isoflurane but did not change with halothane or enflurane (halothane vs isoflurane; $P < 0.05$). The stroke volume index was unaffected by the anesthetics. Both isoflurane and enflurane induced a small increase in HR that was significantly different from the likewise small decrease in HR caused by halothane. There were no significant differences among the groups with respect to changes in mean pulmonary artery pressure and PCWP. Changes in central venous pressure were significantly different when halothane and enflurane were compared.

Effects of Inhaled Anesthetics on GAEF and the SAEF/GAEF Ratio

Halothane caused a significant decrease in GAEF, from 0.46 ± 0.03 to 0.41 ± 0.02 ($P < 0.05$), which was not seen with isoflurane or enflurane (halothane vs enflurane; $P < 0.05$). Isoflurane induced a significant decrease in the SAEF/GAEF ratio of segments 6 and 7 ($P < 0.01$) that was significantly different when compared with halothane and enflurane ($P < 0.05$; segment 6) (Table 2, Figure 3). Halothane and enflurane did not cause any changes in the SAEF/GAEF ratio in any of the segments. There was no statistically significant interaction among type of volatile anesthetic and coronary anatomy in the halothane or enflurane groups. In the isoflurane group, however, the SAEF/GAEF ratio differed significantly between patients with steal-prone coronary anatomy ($n = 8$) and patients with other varieties of coronary anatomy ($n = 5$). Among the patients with no evidence of steal-prone coronary anatomy, isoflurane decreased regional wall motion in several segments, whereas among the patients with steal-prone coronary anatomy, regional wall motion, if anything, improved in some segments.

One patient had ECG signs of myocardial ischemia before sternotomy. In this patient, neither sternotomy nor the addition of the volatile anesthetic affected the ST segment. None of the other patients had ECG signs of ischemia during the experimental procedure.

Discussion

The baseline anesthetic in the present study was fentanyl (15 μg/kg), with the addition of nitrous oxide. A substantial hypertensive response was therefore expected, because it is known that even doses of 50–100 μg/kg are insufficient in preventing a pronounced stress-induced activation of the sympathetic nervous system and myocardial ischemia during sternotomy (2,4,5,8). In clinical practice, inhaled anesthetics are therefore used in many institutions as adjuvants to fentanyl/nitrous oxide anesthesia whenever a surgical stress response is encountered in patients with coronary artery disease. The aim of the anesthesiologist is of course to prevent or minimize the hypertensive stress response by the aid of volatile anesthetics. However, to understand the actions of these anesthetics on the cardiovascular system in this situation it is important to delineate the myocardial and circulatory effects of the inhaled anesthetics and to separate them from the effects of the surgical stress itself.

An increase in the afterload of the left ventricle during surgical stress will decrease GAEF (15). Furthermore, a general depression of myocardial contractility by (e.g., volatile anesthetics) also decreases global left ventricular function (16). Changes in SAEF during sternotomy and after the addition of volatile anesthetics could therefore to some extent be explained by changes in afterload conditions or in the contractile state of the myocardium. We have therefore used the SAEF/GAEF ratio for quantitative evaluation of regional wall motion in the present study. A decrease in this ratio during sternotomy or during the addition of volatile anesthetics would indicate a newly developed regional wall motion abnormality not necessarily caused by changes in afterload or inotropism per se. This is demonstrated in Figures 1 and 2. Sternotomy induced a significant decrease in SAEF in five of the eight segments that most likely was caused by an increase in afterload, not by re-

gional ischemia in any of the segments, because the SAEF/GAEF ratios did not change during sternotomy.

Surgical Stress, Hemodynamics, and Myocardial Function

Sternotomy caused a pronounced increase in arterial blood pressure (46%), SVR (43%), and PCWP (52%), these data confirming previous findings using an identical protocol (7,10). This was associated with a small (13%) but significant decrease in GAEF, most likely caused by an increase in the left ventricular outflow impedance. Roizen et al. (15) studied patients of advanced age and with severe signs of left ventricular dysfunction undergoing abdominal aortic aneurysm repair. Aortic cross-clamping at the supraceliac level caused an increase in aortic pressure (54%) and PCWP (38%), whereas area ejection fraction decreased by 38%. This was accompanied by frequent wall motion abnormalities not detected by conventional monitoring devices. Although the increase in loading conditions during sternotomy in the present study were comparable to that in the study by Roizen et al. (15), the decrease in GAEF was less pronounced, probably due to the fact that the preoperative left ventricular function of our patients was good. None of the patients developed ECG signs of myocardial ischemia during sternotomy, and there was no change in the SAEF/GAEF ratio, possibly due to the protective effect of the β-blockade that prevented large increases in HR and contractility.

Inhaled Anesthetics and Central Hemodynamics

The blood pressure-reducing effect of the three anesthetics was caused by comparable decreases in SVR. Hess et al. (3) could not demonstrate a halothane-

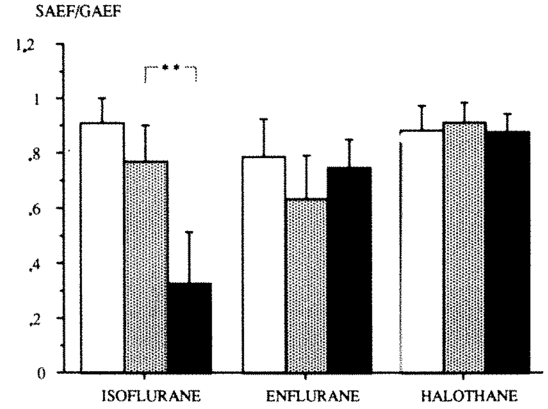

Figure 3. Regional wall motion in segment 6 (approximately inferolateral wall of the left ventricle) for the three inhaled anesthetics at the three experimental stages: preincision (□); sternotomy (▨); inhaled anesthetic (■). **Significant difference between sternotomy and inhaled anesthetic ($P < 0.01$). Halothane versus enflurane, no significant interaction between anesthetic and experimental stage. Isoflurane versus enflurane and isoflurane versus halothane, significant interaction ($P < 0.05$) between anesthetic and experimental stage. SAEF/GAEF, segmental area ejection fraction/global area ejection fraction.

induced decrease in SVR in this situation, which, however, was described by Roizen et al. (9) for both halothane and enflurane and recently by Sahlman et al. (10) for halothane. The restoration of arterial blood pressure by the inhaled anesthetics was accompanied by a significant increase in cardiac output with isoflurane, whereas no changes were seen with halothane or enflurane. These findings are in accordance with data from O'Young et al. (6) and Sahlman et al. (7,10). To our knowledge, there is no report on the effects of enflurane on systemic hemodynamics when used to treat intraoperative hypertension in patients with coronary artery disease.

Inhaled Anesthetics and Left Ventricular Wall Motion

The GAEF was only marginally affected by the volatile anesthetics, probably due to the combination of a decrease in myocardial contractility, which would decrease GAEF, and a decrease in SVR, which would increase GAEF. In the halothane group, GAEF was slightly but significantly decreased, which could be ascribed to the more marked negative inotropic effect compared with enflurane and isoflurane (17). The effects of the volatile anesthetics on regional left ventricular function were, however, clearly different. A significant decrease in the SAEF/GAEF ratio by isoflurane was seen in segments 6 and 7 but was not seen with halothane and enflurane. This was not accompanied by an overall change in stroke volume or PCWP compared with halothane or enflurane (Table 1), because dysfunction in some myocardial segments may lead to an increase in function in other segments (18).

In previous studies on myocardial, circulatory, and metabolic effects of volatile anesthetics, net lactate production has been used as "the gold standard" for diagnosing myocardial ischemia (19). It has been shown, however, that myocardial lactate metabolism is heterogenous in patients with coronary artery disease and that a significant amount of lactate can be released by the myocardium at a time when there is a net global myocardial lactate extraction (20). Net myocardial lactate production is therefore an insensitive indicator for myocardial ischemia. This was recently demonstrated by Häggmark et al. (21) who showed that only 15% of myocardial ischemic episodes were associated with net lactate production, whereas abnormal regional wall motion and ECG abnormalities were present in 83% and 44% of ischemic episodes, respectively.

Isoflurane and Myocardial Ischemia

Induction of anesthesia with isoflurane during nonsurgical conditions alone or in combination with nitrous oxide may cause ECG or metabolic evidence (net lactate production), or both, of myocardial ischemia (22–25). This has been attributed to a redistribution of coronary blood flow, coronary steal (caused by isoflurane-induced coronary vasodilatation), or isoflurane-induced hypotension in combination with tachycardia (26–29). The prerequisites for isoflurane-induced coronary steal is a steal-prone coronary artery anatomy (14). In the present study, isoflurane-induced regional wall motion abnormalities were, if anything, less pronounced in patients with steal-prone coronary anatomy and more pronounced in patients with other varieties of coronary anatomy. Although our patient population is far too small to compare the effects of different anesthetics on left ventricular regional wall motion in patients with different forms of coronary anatomy, which was not the primary aim of the study, our data do not support the hypothesis that isoflurane-induced regional wall motion abnormalities are caused by a coronary steal mechanism. Using the same protocol as in the present study, Sahlman et al. (7) showed that treatment of intraoperative hypertension with isoflurane was not associated with myocardial redistribution of flow. Instead, isoflurane-induced lactate production was associated with a combination of decreased supply and increased demand (HR increase).

Limitations

It is widely accepted that development of perioperative regional wall motion abnormalities is a sensitive and specific indicator of myocardial ischemia (30–32). It has also been demonstrated that detection of newly developed perioperative regional wall motion abnormalities is a more sensitive method than ST-segment analysis for diagnosing myocardial ischemia (30). However, all such observed changes in regional wall motion may not be entirely due to ischemia but could be ascribed to, for example, myocardial stunning or tethering of nonischemic myocardium adjacent to ischemic or infarcted myocardium (32). These nonischemic causes of regional wall motion changes would, however, tend to be evenly distributed among the three groups. Furthermore, it is theoretically possible that the isoflurane-induced hypokinesia in some of the segments, as demonstrated in the present study, was caused not only by ischemia, but by a temporal change in the ventricular wall motion pattern such that end-systole was reached earlier in one region than in another. This would be interpreted by our method as reduced wall motion in one or more segments. It is, however, not immediately obvious why this induction of temporal motion heterogeneity should be more pronounced for isoflurane compared with halothane or enflurane. Other limitations of the present study were that the clinician was aware of the study anesthetics; that the various segments were treated as independent variables, whereas these segments are physically and functionally coupled; and finally that only a single-plane, one-position transesophageal echocardiography image was used for quantification of regional wall motion.

In summary, we have studied the effects of surgical stress (sternotomy) and the inhaled anesthetics halothane, enflurane, and isoflurane on central hemodynamics and global and regional left ventricular function in patients with coronary artery disease. The sternotomy-induced increase in left ventricular outflow impedance caused a 13% decrease in GAEF, no changes in regional wall motion, and no ECG signs of myocardial ischemia. Restoration of intraoperative hypertension by the anesthetics was caused by a decrease in SVR. Isoflurane-induced control of intraoperative hypertension was accompanied by an increase in cardiac output. Isoflurane induced a depression in regional wall motion that was not seen with halothane and enflurane. These isoflurane-induced regional wall motion changes were, if anything, more pronounced in patients with other varieties of coronary anatomy than steal-prone coronary anatomy.

Effects of Halothane and Quinidine on Intracardiac Conduction and QTc Interval in Pentobarbital-Anesthetized Dogs

John D. Gallagher, MD

Department of Anesthesiology, Dartmouth Medical School, Hanover, New Hampshire

---

To confirm in vitro data that halothane and quinidine depressed cardiac conduction and prolonged action potential (AP) duration, the electrocardiogram and His bundle electrogram were recorded in dogs during basal pentobarbital anesthesia, after 1% halothane or quinidine (2.38 ± 0.22 μg/mL serum concentration [mean ± SEM]), or both. Purkinje fibers from a second dog were superfused with blood from the intact (support) dog, and APs were recorded. In the intact dogs, 1% halothane caused no changes in the electrocardiogram or His bundle electrogram. Quinidine prolonged QRS duration, QT interval, and rate-corrected QT ($P < 0.05$). Ventricular conduction (HS interval) slowed, and atrial effective refractory period increased ($P < 0.05$). Quinidine combined with halothane widened QRS, QT, and rate-corrected QT, prolonged the HS interval, and increased the vulnerability of the atrioventricular node to conduction block. Three of 20 dogs developed torsades de pointes-type ventricular tachycardia during simultaneous quinidine and halothane administration. In cross-superfused Purkinje fibers, the AP duration to 50% repolarization was shortened, and conduction time was prolonged by 1% halothane (both $P < 0.05$). Quinidine decreased AP amplitude, prolonged AP duration to 90% repolarization, and slowed conduction ($P < 0.05$). Quinidine combined with halothane decreased AP amplitude, and prolonged both AP duration to 90% repolarization and conduction ($P < 0.05$). When 1% halothane and therapeutic concentrations of quinidine are administered in dogs, depressed conduction and an acquired long QT syndrome with malignant ventricular arrhythmias may develop.

(Anesth Analg 1992;75:688–95)

Simultaneous administration of halothane and quinidine to isolated canine Purkinje fibers prolonged action potential duration (APD) and decreased conduction velocity (1). Depressed conduction can cause heart block (2), and prolongation of APD may induce arrhythmias by producing an acquired long QT interval syndrome (3,4). To confirm earlier results and test speculation concerning QT interval prolongation (1), this investigation determined the effects of halothane and quinidine on the surface electrocardiogram (ECG) and His bundle electrogram in intact dogs. Additionally, the blood cross-superfusion technique was used to correlate ECG and His bundle electrogram changes with changes in the action potentials (APs) of Purkinje fibers obtained from a second dog (5).

Blood cross-superfusion uses blood from an anticoagulated support dog to superfuse Purkinje fibers excised from another dog. A bypass circuit from the femoral artery to femoral vein of the support dog includes the tissue bath containing the Purkinje fiber. Drugs administered to the support dog subsequently bathe the excised Purkinje fiber as blood from the support dog superfuses the Purkinje fiber. Published uses of the technique include effects of both short- and long-term administration of a variety of drugs (5–7).

Methods

The local Institutional Animal Care and Use Committee approved this study, and procedures conformed to the standards described in Guide for Care and Use of Laboratory Animals (NIH publication No. (PHS) 85-23 [Rev. 1985]).

Electrocardiogram and His Bundle Electrogram Recording

Twenty (support) dogs were anesthetized with pentobarbital (30 mg/kg IV). In each experiment, the

trachea was intubated, and the lungs were ventilated mechanically with 100% O_2 to maintain arterial CO_2 tension between 35 and 40 mm Hg. Arterial blood gases were obtained at 30-min intervals, and bicarbonate administered as needed for metabolic acidosis. The temperature of the support dog was maintained between 37° and 37.5°C with the aid of a heating lamp and heating blankets. Femoral arterial pressure was transduced and recorded.

Fluoroscopic guidance assisted the placement of 5F bipolar pacing catheters. One catheter was passed through a femoral vein into the right atrial appendage for pacing. A second catheter was placed through a femoral artery into the noncoronary cusp of the aortic valve for recording His bundle electrograms (8). The ECG (leads 1, 2, and V_1) and His bundle electrogram were recorded during sinus rhythm and at a normalized atrially paced cycle length (CL) of 400 ms (rate 150 beats/min). His bundle electrograms were filtered at 30–500 Hz and the ECGs at 0.1–100 Hz and were recorded with a Gould eight-channel recorder (Gould, Inc., Cleveland, Ohio) at paper speeds of 100 mm/s. Variables measured from the ECG included RR and PR intervals, QRS duration, and QT interval. The QT interval was corrected (QTc) for heart rate by dividing by the square root of the RR interval (9): $QTc = QT/\sqrt{RR}$.

Standard measurements were obtained from His bundle electrograms (10). The AH interval represents conduction delay within the atrioventricular node and surrounding junctional tissues (10). The AH interval was measured from the onset of the first high-frequency component of low atrial depolarization to the onset of the first high-frequency component of the His bundle spike (10–12). The HV interval, measured from the onset of the His bundle spike to the earliest point of ventricular depolarization on the His bundle electrogram (11,12), represents conduction time from the proximal His bundle to ventricular septal tissue (10). The HS interval, the time from the onset of the His bundle deflection to the latest point of ventricular depolarization on the surface ECG, represents conduction through the His-Purkinje system, the Purkinje-myocardial junction, and then through the myocardial wall itself (12,13).

The atrial effective refractory period (AERP) was determined during atrial pacing. After an eight-beat paced train at a 400-ms CL, a single extrastimulus was introduced at coupling intervals that decreased from the basic CL by 5 ms per paced train until the extrastimulus failed to capture the atrium. The longest coupling interval that failed to capture the atrium was defined as the AERP (13). Atrioventricular Wenkebach CL, the CL at which atrioventricular nodal conduction fails as a result of rate stress, was also measured (14). A slowly accelerating ramp of atrial pacing started at the underlying sinus CL, with successively decreased CLs (increased paced rates) until atrioventricular nodal conduction failed and second-degree atrioventricular block occurred. The CL at which conduction failed defined the Wenkebach CL and was determined as the average of three measurements for each experiment. Triplicate measurements were always within 10 ms.

Blood Cross-Superfusion Studies

The Purkinje fiber donor dog ($n = 20$) was anesthetized with pentobarbital (30 mg/kg IV). The trachea was intubated, and the lungs were ventilated mechanically with room air. The heart was removed rapidly through a left thoracotomy and placed in cold, oxygenated Tyrode's solution. Free-running Purkinje fibers were excised from either ventricle and placed in a Plexiglas tissue bath with a 4-mL internal volume similar to that described by Rosen et al. (5). The surface on which the Purkinje fiber rested was slanted to prevent stagnation of blood during later cross-superfusion. Multiple perfusate inlets were present to allow continuous superfusion while minimizing turbulence that could dislodge intracellular microelectrodes.

Before starting blood cross-superfusion, a peristaltic pump provided a 25-mL/min flow of Tyrode's solution through a heat exchanger into the tissue bath. The Tyrode's solution contained 137 mM NaCl, 4.0 mM KCl, 18 mM $NaHCO_3$, 1.8 mM NaH_2PO_4, 0.5 mM $MgCl_2$, 2.7 mM $CaCl_2$, and 5.5 mM dextrose. Tyrode's solution was equilibrated with a gas mixture of 95% O_2 and 5% CO_2, heated to 37°C, and had a pH of 7.40 ± 0.05.

Fibers were stimulated from one end with a bipolar Teflon-coated silver wire electrode at a CL of 500 ms (rate 120 beats/min). A stimulator pulse duration of 1 ms and a current of twice threshold were applied. Standard microelectrode techniques were used to record intracellular APs. False tendons were impaled in their midportions with glass microelectrodes filled with 3 M KCl (resistance 10–30 MΩ) and connected through a silver/silver chloride junction to the input of a WPI KS-700 dual microprobe amplifier (World Precision Instruments, New Haven, Conn.). The first derivative of the transmembrane potential was obtained with the use of an electronic differentiator that was linear between 50 and 1000 V/s.

After obtaining a stable implement, Tyrode's solution was discontinued, and blood cross-superfusion was instituted. The remaining femoral artery and vein of the support dog were cannulated, and the support dog received heparin (300 U/kg IV), before the institution of blood cross-superfusion. Blood was pumped from the femoral artery through the heat

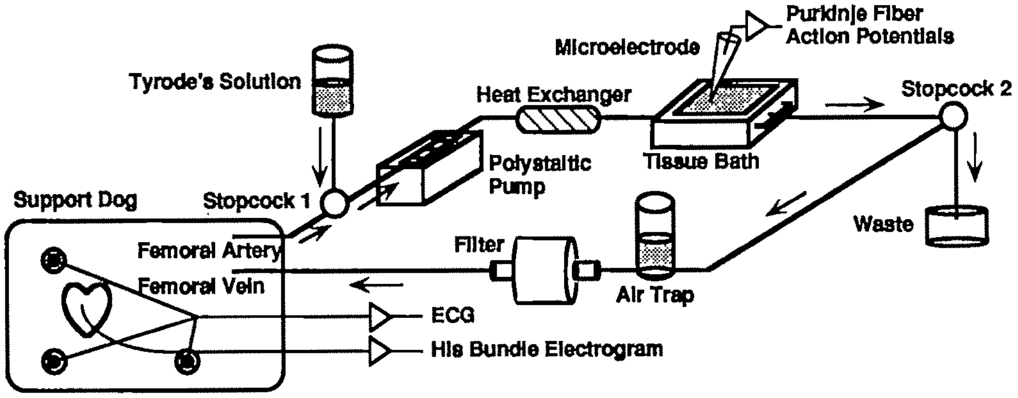

Figure 1. Diagram of blood cross-superfusion circuit. Stopcock 1 controls the selection of Tyrode's solution or femoral arterial blood from the support dog. The blood or Tyrode's solution is pumped through a heat exchanger into the tissue bath containing the excised Purkinje fiber. Stopcock 2 routes the effluent either to a discard chamber (Tyrode's solution) or through an air trap and particle filter for return to the support dog through a femoral vein cannula. The ECG and His bundle electrogram are recorded from the support dog. Action potentials are recorded from the excised Purkinje fiber in the tissue bath.

exchanger, to maintain a 37°C bath temperature, and into the bath, thus superfusing the Purkinje fiber. The effluent from the bath was collected, passed through an air trap and particle filter, and returned to the support dog. Circuit volume was 50 mL. Figure 1 shows the superfusion circuit.

Previous studies demonstrated that the change of superfusate from Tyrode's solution to blood has little effect on AP characteristics. The AP amplitude (APamp) may increase (7), as may conduction velocity (5).

The APs were photographed from an oscilloscope display, and the following measurements were performed: resting membrane potential, transmembrane potential at the onset of phase 0; APamp; APD at 50% and 90% repolarization (APD_{50} and APD_{90}, respectively); and $\dot{V}$max, maximal rate of rise of phase 0 of the AP. Conduction time (CT) was calculated as the time between the appearance of the pacer stimulus artifact and the onset of $\dot{V}$max. Data were used when a single-cell impalement was maintained for the entire experiment.

Experimental Protocol

After 1 h of stable blood cross-superfusion, control recordings of the ECG, His bundle electrogram, and AP were obtained. Halothane (1% in 100% O_2) was then administered to the support dog by inhalation. The vaporizer used was calibrated with a mass spectrogram. Through the arteriovenous bypass circuit, blood with an equivalent halothane concentration superfused the Purkinje fiber. After 1 h, measurements were repeated, and after another 1 h was allowed for halothane washout, 10 mg/kg of intravenous quinidine, followed by an infusion at 0.2 $mg \cdot kg^{-1} \cdot min^{-1}$, was administered to the support dog (15), and electrophysiologic measurements were repeated. Quinidine dosage was based on pharmacokinetic data reported by Clohisy and Gibson (15) and was intended to produce quinidine serum concentrations of 3 μg/mL. The 1% halothane was administered for 1 h while the quinidine infusion was continued and the measurements repeated. The final two data collection points, quinidine and quinidine with halothane, were alternated. Blood was withdrawn for measurement of serum quinidine (TDX Analyzer; Abbott, Inc., Irving, Tex.) and potassium (IL443 flame photometer; Instrument Laboratories, Lexington, Mass.) concentrations.

The effects of halothane and quinidine on ECG, His bundle, and Purkinje fiber data were analyzed by two-way analysis of variance for repeated measures. Significant F ratios were evaluated with Bonferroni's modification of the *t*-test (PRODAS, Conceptual Software, Houston, Tex.). A value of $P < 0.05$ was considered significant. All results are reported as mean ± SEM.

Results

Experiments involved 20 Purkinje fiber donors and 20 support dogs. Quinidine serum concentration was 2.38 ± 0.22 μg/mL; serum potassium concentration was 4.0 ± 0.3 mM. Table 1 summarizes femoral arterial pressure changes produced by halothane and quinidine administration. The combination of 1% halothane and clinically therapeutic quinidine concentrations caused significant decreases in systolic, diastolic, and mean arterial blood pressures relative to the control and 1% halothane conditions. Only the decrease in systolic pressure caused by simultaneous

Table 1. Hemodynamic Effects of Halothane and Quinidine in Dogs Anesthetized With Pentobarbital

	Control	1% Halothane	Quinidine	Quinidine + 1% halothane

AERP, atrial effective refractory period; CL, cycle length; ECG, electrocardiogram; QTc, QT interval corrected for RR (9); Wenkebach CL is the point of atrioventricular nodal conduction failure during rate stress.

Results are mean ± SEM; $n = 20$.

[a] PR, QRS, QT were measured from the surface ECG; AH, HV, HS intervals were measured from His bundle recordings.

[b] $P < 0.05$ versus control and 1% halothane.

[c] $P < 0.05$ versus 1% halothane.

[d] $P < 0.05$ versus all other conditions.

halothane and quinidine administration achieved significance versus the quinidine without halothane state.

Table 2 describes the effects of halothane and quinidine on the ECG and His bundle recordings during spontaneous sinus rhythm. The 1% halothane produced no significant changes in measured variables, whereas quinidine significantly prolonged only the QTc interval versus control. In contrast, the combination of quinidine and halothane prolonged QRS duration (vs control and 1% halothane administration) and QT and QTc intervals (both vs control).

Table 3 presents data at a paced CL of 400 ms. Just as during spontaneous CL, 1% halothane had no effect on the measured variables. Quinidine prolonged QRS duration and QTc and HS intervals. Additionally, quinidine increased AERP relative to the control or 1% halothane conditions. The combination of halothane and quinidine prolonged QRS duration and QT, QTc, and HS intervals versus control and 1% halothane. The AERP during halothane and quinidine only was prolonged relative to 1% halothane (203 ± 20 vs 136 ± 15 ms). Wenkebach CL increased relative to all other conditions during the simultaneous administration of halothane and quinidine, making the atrioventricular node more vulnerable to block. Changes in HS, QT, and QTc intervals and Wenkebach CL demonstrated significant interactions ($P < 0.05$) between halothane and quinidine.

Table 4 details the effects of halothane and quinidine on Purkinje fiber APs during blood cross-superfusion. Halothane 1% significantly prolonged CT, and the reduction of APD_{50} approached statistical significance ($P = 0.06$). Addition of quinidine in the absence of halothane reduced APamp and prolonged APD_{90} versus control; $\dot{V}$max decreased, although the reduction in $\dot{V}$max did not reach statistical significance; CT also increased. Combination of 1% halothane and quinidine superfusion further prolonged APD, with a significant prolongation of APD_{90} compared with control; $\dot{V}$max was further reduced, but as before, decrements were not statistically significant; CT was prolonged further during administration of halothane and quinidine ($P < 0.05$ vs control).

Figure 2 shows APs recorded from a single cell during superfusion with quinidine and halothane. Inhalation of 1% halothane shortened APD_{50} (Figure 2B) and, after superfusion with quinidine, loss of

Table 4. Effects of Halothane and Quinidine on Canine Purkinje Fibers During Blood Cross-Superfusion in Pentobarbital-Anesthetized Dogs

Variable[a]	Control	1% Halothane	Quinidine	Quinidine + 1% halothane
RMP (mV)	93.1 ± 2.3	92 ± 2.8	87.8 ± 2.7	85.8 ± 2.2
APamp (mV)	122 ± 2	121 ± 1	115 ± 2[b]	112 ± 3[b]
APD_{50} (ms)	141 ± 9	135 ± 7[c]	136 ± 8	145 ± 8
APD_{90} (ms)	213 ± 11	207 ± 8	230 ± 9[b]	246 ± 4[b]
$\dot{V}$max (V/s)	491 ± 63	482 ± 53	396 ± 44	386 ± 49
CT (ms)	3.98 ± 0.4	4.46 ± 0.39[b]	5.17 ± 0.43[b]	5.55 ± 0.45[b]

RMP, resting membrane potential; AP, action potential; APamp, AP amplitude; APD_{50}, AP duration at 50% repolarization; APD_{90}, AP duration at 90% repolarization; $\dot{V}$max, maximal rate of rise of phase 0 of the AP; CT, conduction time.

Results are mean ± SEM; $n = 20$.

[a] Paced cycle length 500 ms.

[b] $P < 0.05$ versus control.

[c] $P = 0.06$ versus control.

plateau potential, coupled with a prolongation of the terminal phase of repolarization, produced a "triangular" AP (Figure 2C). Combination of 1% halothane and quinidine (Figure 2D) further prolonged the APD and slowed conduction.

During administration of halothane and quinidine, 3 of the 20 support dogs developed torsades des pointes, and one of the three died.

Discussion

In vitro study of excised cardiac tissue to determine the electropharmacologic effects of drugs allows precise control of experimental variables such as temperature and drug concentration. However, extrapolation from such studies to the intact animal or clinical situation poses considerable problems. Blood is a heterogeneous suspension that contains epinephrine (16), thyroid hormone (17), and other electrophysiologically active components (5). Because isolated tissue is devoid of autonomic innervation, significant direct autonomic or indirect baroreceptor effects of the drugs under study may not be observed. Halothane causes significant depression of autonomic outflow at central and peripheral sites and alters baroreflex control of the cardiovascular system (18,19). Quinidine also has significant parasympathetic and α-adrenergic blocking effects (20,21). These cardiodepressant and vasodilator effects combined to produce the hypotension noted in the intact dogs in this study.

In a previous study of isolated Purkinje fibers superfused with Tyrode's solution, quinidine depressed $\dot{V}$max, prolonged APD, and depressed conduction (1). When halothane was added, resting membrane potential and APamp decreased, $\dot{V}$max decreased further, and both APD and conduction were markedly prolonged (1). Conduction block and inexcitability occurred often during the simultaneous administration of quinidine and halothane (1).

This investigation sought to confirm these observations in the more clinically relevant model of intact dogs. Inclusion of Purkinje fiber data during blood cross-superfusion allowed validation of previous work and comparison with findings in the intact animal. The objective was not reexamination of the effects of halothane/pentobarbital anesthesia on cardiac conduction. In fact, at paper speeds of 100 mm/s, the minimal expected resolution of 2.5 ms for intracardiac intervals was insufficient to differentiate the 2-ms halothane-induced increase in HV interval reported by Atlee et al. (22).

Purkinje Fiber Action Potentials

The present study estimated CT as the interval from the onset of the pacer artifact to the upstroke of the AP. This interval depends not only on conduction, but also on the excitability of the tissue depolarized by the pacing stimulus and the "liminal length" (i.e., the length of tissue that must be depolarized beyond threshold to allow propagation) (23). The effects of halothane on these properties are unknown and could complicate the interpretation of CT in the present study. Still, 1% halothane prolonged CT, consonant with previous studies (1,24,25). Both halothane-induced inhibition of the fast Na^+ channel responsible for the rapid phase 0 upstroke of the AP (24,26) and increased resistance at the gap junctions between cardiac cells may contribute (27). Depression of either $\dot{V}$max or cell-to-cell communication slows conduction in myocardium (28).

In this study, halothane shortened APD_{50} from 141 ± 9 to 135 ± 7 ms ($P = 0.06$). Previously published data concur that APD_{50} is the AP variable most affected by halothane (1,29,30). Turner et al. (31) suggested that halothane shortened the AP plateau phase by inhibition of a persistent Na^+ "window" current, although the prominent effects of halothane on slow inward Ca^{2+} current (32–34) and myocardial Ca^{2+} handling (35,36) may also contribute.

The effects of quinidine on AP variables agreed with existing data (20,37). Quinidine reduced Purkinje fiber APamp and increased CT, consistent with Na^+ channel block and shift of reactivation to more positive membrane potentials (37). The reduction in $\dot{V}$max, from 491 ± 63 to 396 ± 44 V/s (19%), did not achieve statistical significance. Prolongation of APD appears to be due to block of the delayed rectifier K^+ channel responsible for repolarization (38).

Simultaneous administration of halothane and quinidine to Purkinje fibers by blood cross-superfu-

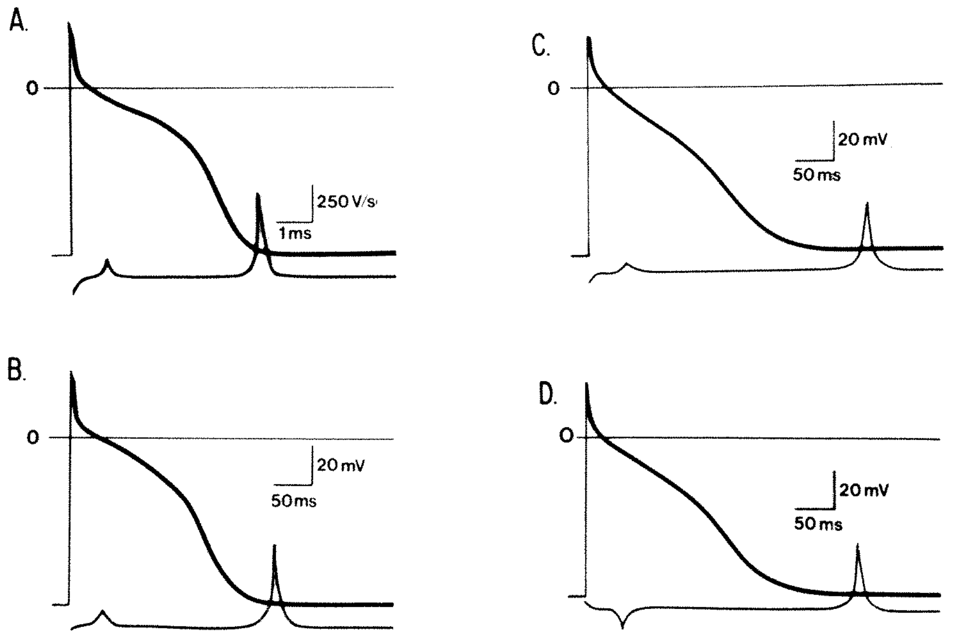

Figure 2. Effects of halothane and quinidine on canine Purkinje fiber APs during blood cross-superfusion. The *upper trace* in each panel shows a canine Purkinje fiber AP at a paced CL of 500 ms. The *lower trace* shows $\dot{V}$max for each AP at a different oscilloscope sweep speed. The amplitude of the spike is proportional to $\dot{V}$max of phase 0. The 0-mV potential line is shown in each panel. (**A**) Time and amplitude calibrations for $\dot{V}$max; (**B–D**) time and amplitude calibrations for the AP. (**A**) Normal AP during blood cross-superfusion. (**B**) 1% Halothane has been added and the plateau shortened. (**C**) Quinidine produced triangulation of the AP with prolongation of APD$_{90}$; $\dot{V}$max decreased and conduction slowed. (**D**) Effects of 1% halothane and quinidine during blood cross-superfusion; loss of APamp and further prolongation of APD$_{90}$ are evident.

sion confirmed previous observations (1). Quinidine and halothane decreased APamp, and prolonged both APD$_{90}$ and CT. However, the present data did not evince the synergistic interaction between halothane and quinidine previously reported (1).

Electrocardiogram

In the current study, halothane had no significant effect on the ECG or His bundle electrogram. Previous investigators concluded that halothane prolongs the QT interval in dogs and humans (39,40). In dogs, Riley et al. (39) found that 2% halothane prolonged the QT interval relative to the awake state. The QT interval prolongation in the presence or absence of autonomic block demonstrated a direct effect of halothane on repolarization independent of changes in autonomic tone (39).

Differences between the current study and previous investigations (39,40) may reflect the use of 1% halothane or the presence of basal barbiturate anesthesia in the current study. Thiopental prolongs the QT interval (41,42), and pentobarbital prolongs repolarization during blood cross-superfusion (5). McConachie et al. (41) demonstrated in patients that preexisting barbiturate-induced QT interval prolongation abolished the expected incremental increase in repolarization produced by enflurane or isoflurane. However, Hart et al. (43) showed that 1.13% halothane prolonged QT interval in dogs despite basal pentobarbital anesthesia.

Although quinidine significantly increased only QTc during spontaneous sinus rhythm (Table 2), during rate-normalized pacing, prolongation of QRS duration and HS interval reflected slowed conduction. Increased QT and QTc intervals demonstrated prolonged repolarization (20,37).

Intracardiac Electrogram

Elegant work by Atlee et al. (22) showed that 1.2 MAC halothane increased the AH, HV, and HS intervals compared with the awake state in chronically instrumented dogs. Abolition of AH interval prolongation by autonomic blockade demonstrated an indirect sympatholytic effect of halothane on the AV node (22). However, in an otherwise similar study, the same group reported no change in heart rate or AH interval when anesthesia was induced with halothane (14). The authors speculated that differences in intrinsic sympathetic tone, indicated by different baseline heart rates in the two studies, may have been responsible (14). In an isolated guinea pig heart preparation, Gallenberg et al. (44) demonstrated no prolongation of atrioventricular conduction time by 1% halothane.

Basal pentobarbital anesthesia in the present study contrasts with previous studies (14,22,44). Pentobarbital anesthesia increased heart rate and HV interval in chronically instrumented dogs (45). Addition of 1% halothane to basal pentobarbital anesthesia in dogs increased AH interval (61 ± 3 to 67 ± 5 ms), whereas heart rate decreased from 167 ± 7 to 147 ± 7 beats/min (46); HV interval did not change (46). After vagotomy, halothane produced no change in heart rate or AH interval (46). Morrow et al. (46) concluded that the slowed heart rate prolonged the AH interval. Ammendrup and Atlee (47) described a slowed heart rate, increased AH and HV intervals, and no change in HS interval when dogs anesthetized with pentobarbital breathed 1% halothane. However, Turner et al. (48) showed that basal pentobarbital anesthesia abolished halothane-induced depression of epicardial activation time, a variable analogous to the HV interval. Hart et al. (43) found prolonged AH intervals and slowed heart rates without changes in HV interval during inhalation of halothane by pentobarbital-anesthetized dogs. Blood pressure was maintained by phenylephrine infusion (43). Thus, prolongation of HV interval by halothane during pentobarbital anesthesia is controversial. Prolongation of AH interval occurs when heart rate slows (46) and probably represents sympatholytic effects of halothane. In the present study, heart rate and arterial pressure were unchanged after halothane administration. This indicated minimal reduction in sympathetic tone and suggested that little change in AH interval or arterial pressure could be expected.

Effects of halothane on Wenkebach CL and AERP have been reported previously. At a paced CL of 500 ms, increasing doses of halothane did not alter AERP in dogs but shortened AERP at faster paced rates (300 ms CL) (49). Atlee and Yeager (14) found no change in Wenkebach CL or AERP in autonomically intact dogs after administration of halothane and an increased Wenkebach CL after autonomic block. Gallenberg et al. (44) found no halothane-induced increase in Wenkebach CL in isolated guinea pig heart. Hart et al. (43) added further confusion by showing that Wenkebach CL decreased from 280 ± 7.6 to 241 ± 6.3 ms when halothane was inhaled by pentobarbital-anesthetized dogs. The absence of effect in the present study is not surprising.

As anticipated (20,37), quinidine significantly prolonged AERP and Wenkebach CL. Prolongation of HS interval was noted above.

Halothane and Quinidine

The combined effects of halothane and quinidine confirmed previous in vitro results (1) and demonstrated a potential for conduction abnormalities in both the atrioventricular node, indicated by the synergistically increased Wenkebach CL, and the ventricle, suggested by the synergistically increased HS interval.

The occurrence of torsades des pointes in three dogs receiving halothane and quinidine illustrated the arrhythmogenicity of prolonged repolarization (4). Prolongation of the QT interval actuates oscillatory inward currents during the protracted plateau phase of the AP (50). These result in membrane potential oscillations called early afterdepolarizations and typically produce torsades des pointes-type ventricular tachycardia (3). In addition, drug-induced slowing of conduction, as observed in this study, may produce a critical area of myocardium that acts as a substrate for reentrant ventricular tachycardia (3). Prolongation of repolarization and slowing of conduction by halothane and quinidine could exacerbate arrhythmias by either mechanism.

Published clinical reports describe life-threatening arrhythmias and death during anesthesia in patients with congenital prolongation of the QT interval (51). Riley et al. (39), on the basis of their observation of QT interval prolongation by volatile anesthetics in dogs, advised caution during the administration of volatile anesthetics to patients with QT interval prolongation. The present data suggest that patients with pharmacologically induced QT interval prolongation may also be at increased risk during anesthesia, especially if halothane is used.

Differences in pH Management and Pulsatile/Nonpulsatile Perfusion During Cardiopulmonary Bypass Do Not Influence Renal Function

Neal H. Badner, MD, John M. Murkin, MD, and Peter Lok, RRT

Department of Anaesthesia, University Hospital, University of Western Ontario, London, Ontario, Canada

The renal effects of pulsatile (pulse pressure 18.0 ± 1.5 mm Hg [mean ± SEM]) or nonpulsatile perfusion (mean pulse pressure 1.9 ± 0.4 mm Hg) during either α-stat (mean Pa_{CO_2} 41.2 ± 0.9 mm Hg measured at 37°C) or pH-stat (mean Pa_{CO_2} 60.6 ± 1.7 mm Hg measured at 37°C) pH management of hypothermic cardiopulmonary bypass (CPB) were studied in 100 patients undergoing elective coronary artery bypass surgery. Mean urine output, fractional excretion of sodium and potassium, and renal failure index all increased during the study period; however, there was no difference among the four different CPB management groups. Mean postoperative creatinine and blood urea nitrogen values decreased compared with preoperative values, again without differences among treatment groups. Three patients developed acute renal insufficiency; of these, two had received nonpulsatile perfusion and pH-stat management, and the other had been managed with pulsatile perfusion and pH-stat management. These three patients all had undergone prolonged CPB and required at least two vasoactive drugs and the use of an intraaortic balloon pump to be weaned from CPB. In patients with normal preoperative renal function undergoing hypothermic CPB, neither the mode of perfusion, pulsatile or nonpulsatile, nor the method of pH management, pH-stat or α-stat, influences perioperative renal function.

(Anesth Analg 1992;75:696–701)

Recent debate (1) concerning optimal pH management during cardiopulmonary bypass (CPB) has centered on the resulting cerebral perfusion (2) and the implications for postoperative neurologic outcome (3,4). Similar controversy with respect to the use of pulsatile or nonpulsatile perfusion has focused on the function of other organs such as the kidney. In this regard, conflicting results as to the benefit of the use of the more physiologic pulsatile perfusion were obtained in the 1970s, with both improved (5,6) and unchanged renal function being observed (7,8). Kastl-Killinger et al. (9) have renewed interest in this issue after demonstrating increased urine output (U/O) when using pulsatile perfusion in seven patients undergoing CPB for coronary artery bypass (CAB) surgery. The effect of pH management on renal function has not been investigated as extensively, although two recent studies have suggested improved renal function with α-stat, as opposed to pH-stat, pH management during nonpulsatile CPB (10,11). However, in all of these studies, the renal effects of either pulsatile or nonpulsatile perfusion, or pH-stat or α-stat pH management, were investigated independently of each other.

The purpose of this study was therefore to investigate the renal effects of pulsatile or nonpulsatile perfusion during either α-stat or pH-stat pH management in patients undergoing hypothermic CPB for CAB surgery.

Methods

The study was begun after institutional approval and written, informed consent were obtained. As part of an ongoing study evaluating neuropsychologic outcomes, patients undergoing elective CAB surgery were randomly assigned to one of four treatment groups to receive either pulsatile or nonpulsatile perfusion and either pH-stat or α-stat pH management during hypothermic CPB. This randomization was stratified according to surgeon ($n = 4$), to account for differences in technique. Patients were included in this portion of the study if they had not received a diuretic on the operative day (either preoperatively or intraoperatively) or if they had abnormal renal func-

tion, defined as blood urea nitrogen (BUN) >10.7 (women) or >12.1 (men) mmol/L, or creatinine >124 (women) or >168 (men) μmol/L (the upper ranges of normal in our laboratory, where 1 mmol/L BUN = 2.8 mg%, and 1 μmol/L creatinine = 0.011 mg%).

Patients received an opioid or benzodiazepine, or both, as premedication. Anesthesia consisted of a high-dose opioid (fentanyl [50–100 μg/kg] or sufentanil [10–20 μg/kg]), benzodiazepine (midazolam), nondepolarizing muscle relaxant (vecuronium or pancuronium), and air/oxygen. A five-lead electrocardiogram, radial artery blood pressure, pulmonary artery blood pressure, and U/O were continuously monitored. Arterial blood gas analysis was performed using a Radiometer ABL2 analyzer. For α-stat management during CPB, arterial blood gas was measured at 37°C and CO_2 was adjusted to maintain a $Paco_2$ of 40 mm Hg. For pH-stat management, arterial blood gas was measured at 37°C and corrected to the patient's nasopharyngeal temperature using the Kelman-Newman nomogram, and exogenous CO_2 was adjusted to maintain a temperature-corrected $Paco_2$ of 40 mm Hg. Simultaneous blood and urine samples were collected intraoperatively before CPB, during hypothermic CPB, during normothermic CPB, and after discontinuation of CPB. To obtain appropriate samples, the urine was collected after emptying the existing urine from the urometer. This allowed determinations to be made of the fractional excretion (Fe) of sodium ($Fe_{Na} = U/P_{Na} \div U/P_{Cr} \times 100$) or potassium ($Fe_K = U/P_K \div U/P_{Cr} \times 100$), as well as renal failure index (RFI $= U_{Na} \div U/P_{Cr}$), where U is urine concentration, P is plasma concentration, and Cr is creatinine (12). Measurements of BUN and creatinine were also made preoperatively as well as on the first and second mornings postoperatively.

All operations were performed through a median sternotomy. Anticoagulation was produced using 300–400 U/kg of heparin before aortic cannulation. Additional heparin was added as necessary to maintain the activated clotting time >400 s. Cold crystalloid cardioplegia without mannitol was used for myocardial preservation by two of the surgeons, whereas cold blood cardioplegia without mannitol was used by the other two. A Cobe Stockert roller pump and a Bard hollow-fiber membrane oxygenator were used for CPB. The circuit was primed with 2.3 L of lactated Ringer's solution to which 100 mEq of sodium bicarbonate and 5000 U of heparin were added. Pump flows of 2.0–2.5 $L \cdot min^{-1} \cdot m^{-2}$ were used, with mean arterial pressure maintained between 50 and 80 mm Hg using isoflurane or phenylephrine as necessary. Pulsatile perfusion was produced using a Cobe Flow Controller II at a rate of 65 pulses/min, by maintaining systole approximately equal to 65% of the cycle time, adjusted as necessary to produce maximal pulse pressures (PP). The PP was measured via a radial arterial line and recorded on a Hewlett Packard Merlin monitor, which uses a five-beat averaging program. Pulsatile perfusion was limited to the period during which the aortic cross-clamp was in situ (hypothermic CPB). This was necessary because cross-clamp removal and the institution of rewarming frequently led to the resumption of cardiac ejection, which could not be effectively synchronized with the pump pulsations. After discontinuation of CPB, heparinization was reversed using protamine in a dose of 1 mg per active unit of heparin.

Demographic data were compared using one-way analysis of variance with χ^2 analysis for comparison of gender distribution. Intraoperative variables were analyzed with one-way analysis of variance, whereas measurements of renal function were analyzed using repeated measures analysis of variance with Student-Newman-Keuls post hoc testing when differences were found. A P value <0.05 was considered statistically significant.

Results

One hundred six patients undergoing elective CAB surgery were enrolled in the study. Six patients received diuretics intraoperatively and were excluded from data analysis, leaving 100 patients. Their demographic data are listed in Table 1. There were no statistically significant differences among the four groups with respect to patient age, height, weight, gender distribution, number of vessels grafted, or duration of CPB. There was also no difference in the intraoperative use of dopamine among the four groups.

The CPB values obtained during aortic cross-clamping (hypothermic CPB) are listed in Table 2. It can be seen that in the pulsatile groups, an average PP of approximately 20 mm Hg, at a rate of approximately 67 pulses/min, was achieved. This was significantly different from the nonpulsatile groups ($P < 0.001$). The pH and $Paco_2$ values are shown as measured at 37°C; those for the α-stat groups were approximately 7.42 and 37 mm Hg, respectively, and were significantly different ($P < 0.001$) from those same indices in the pH-stat groups. Four significantly different treatment groups were therefore produced.

The U/O before CPB and that during CPB for the four groups are shown in Figure 1. Although there was a statistically significant increase in U/O during CPB, there were no differences among the groups separately or when pulsatile was compared with nonpulsatile perfusion or α-stat with pH-stat management. Figures 2–4 show the fractional excretion of

sodium and potassium and the RFI as a function of time for each of the four groups. Although there was a statistically significant and progressive increase of these variables during the study period, again, there were no differences among the four groups or between the two treatment options when compared independently. Comparisons between preoperative and postoperative BUN and creatinine are shown in Figures 5 and 6. Again, there was no difference between treatments, although both variables decreased significantly in the postoperative period. There was a slight but statistically significant difference in postoperative creatinine when α-stat-group and pH-stat-group patients were compared (85 ± 20 [mean ± SEM] vs 89 ± 24 μmol/L; $P < 0.05$). Three patients developed acute renal insufficiency (ARI)

within the first 48 h postoperatively, defined as BUN or creatinine outside the upper range of normal in our laboratory (see earlier text). Two of these patients underwent nonpulsatile perfusion and pH-stat management; the other underwent pulsatile perfusion and pH-stat management. By χ^2 analysis, pH-stat management was not statistically worse than α-stat management ($P = 0.06$). These three patients were older than the average, having a mean age of 65.7 ± 4.0 yr. Their mean cross-clamp times of 61.7 ± 6.5 min and total duration of CPB of 167.7 ± 11.9 min were also longer than average. These patients all required inotropic support and the use of an intraaortic balloon pump to allow weaning from CPB. Use of an intraaortic balloon pump was significant ($P < 0.001$) as a marker for developing ARI, because three of five patients in this study requiring an intraaortic balloon pump developed ARI.

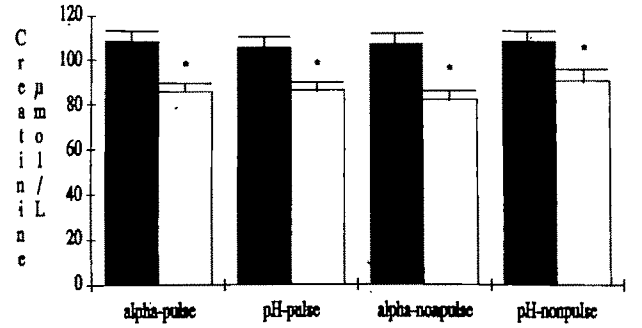

Figure 6. Preoperative (*filled bars*) and postoperative (*open bars*) creatinine. Values are mean ± SEM. *Preoperative versus postoperative; $P < 0.001$; no significant differences between groups. Other abbreviations as in Figure 1.

Discussion

The demographics of our patients are representative of those undergoing elective CAB surgery. Our incidence of ARI of 3% is also consistent with that reported by other groups (13,14). Although we were able to produce the four possible treatment options of pH management and pulsatile/nonpulsatile perfusion, we were unable to show clear superiority of one combination over the others with respect to renal function. However, it was shown that α-stat management did result in a slightly lower mean postoperative creatinine value compared with pH-stat management and that the three patients who developed ARI had all received pH-stat management, although this was not statistically significant ($P = 0.06$).

The influence of pH management, either α-stat or pH-stat, on renal function has also been examined in two previous studies. Michielon et al. (10) studied 201 patients, and although they noted increased U/O in the α-stat group, they found no differences in fractional excretion of sodium and RFI and believed that they could not claim superiority for α-stat management. The second study, by Tuppurainen et al. (11), found no difference in inulin clearance between their α-stat and pH-stat groups. Inulin clearance did, however, correlate with systemic oxygen uptake, which in turn was correlated with arterial pH. Because the higher pH during α-stat management yielded increased oxygen uptake, they therefore concluded that inulin clearance and thus renal function was better preserved with α-stat management. These subtle differences in renal function are clinically inconclusive but are similar to our findings. In contrast to these findings is an animal study in which no differences in renal blood flow, as measured using microsphere injections, were observed when α-stat and pH-stat management were compared (15).

The pulsatile/nonpulsatile debate during the 1970s ended without a clear resolution with respect to the effects on renal function, because various studies showed improvements as well as no effect (16). The recent report by Kastl-Killinger et al. (9), in which atrial natriuretic peptide levels were measured, again reported improved renal function with pulsatile perfusion. This was defined as increased atrial natriuretic peptide and U/O that resulted from a PP of 25 mm Hg. Their conclusions, however, were based on a total of only 14 patients, 7 of whom received pulsatile perfusion, and all of whom were normotensive and not receiving β-adrenergic blocker therapy. Our findings are, however, based on 100 patients, most of whom were receiving β-blockers and are therefore likely to be more representative of the current CAB surgery population.

Which, if any, of the characteristics of the pulse wave are important for end-organ perfusion is unclear. The mean PP of 20 mm Hg achieved in our study is low but clinically representative of PP achieved using a noninvasive pulsator with a hollow-fiber membrane oxygenator. Additionally, PP amplitude itself may not be a primary factor. In several studies, mean PP values of 30 and 34 mm Hg did not improve renal function (7,8), whereas in other studies, PP values of 25, 30, and 36 mm Hg were reported as beneficial (5,6,9). What may be of more importance is the actual rate of rise of pressure, or dP/dt, which can be partially implied from the contour of the arterial pressure waveform. At least some of the purported benefits of pulsatile perfusion appear to be associated with the increased kinetic energy that results from a higher dP/dt (17). In our pulsatile perfusion group, dP/dt was probably low, because the arterial waveform during CPB was generally more sinusoidal in appearance compared with that generated by the normal heart, as shown in Figure 7. Finally, the pump flow rate to which pulsatile perfusion is added may be important. A recent study in dogs undergoing normothermic CPB found increased renal blood flow and decreased renal lactate production with a PP of 40 mm Hg when flows were 80 and 100 $mL \cdot kg^{-1} \cdot min^{-2}$ (1.7 and 2.1 $mL \cdot min^{-1} \cdot m^{-2}$) but not at flows of 40, 60, or 120 $mL \cdot kg^{-1} \cdot min^{-2}$ (1.0, 1.3, and 2.4 $mL \cdot min^{-1} \cdot m^{-2}$) (18). Because our patients received pump flows of 2.0–2.5 $mL \cdot min^{-1} \cdot m^{-2}$, they may have received too high a flow to show the maximal benefit.

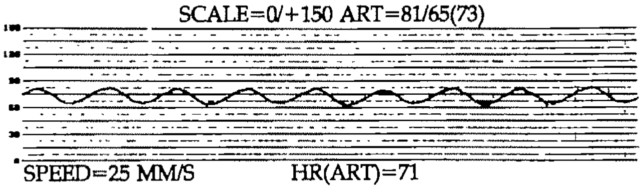

Figure 7. Sample tracing of arterial (ART) blood pressure (mm Hg) during pulsatile cardiopulmonary bypass. Note slow upstroke and almost sinusoidal appearance. HR, heart rate (beats/min).

The variables that we measured are not as sensitive markers of renal function as are inulin or creatinine clearance, both of which measure glomerular filtration rate. However, the latter measurements require at least 1 h of steady-state conditions for each determination (19). Because the cross-clamp time and resultant pulsatile period was less than 1 h, these steady-state conditions would not have been achieved. Urine output, although a crude measure of renal function, is the most routinely used clinical variable. Our results, showing an increase in U/O during CPB in all groups, have been observed elsewhere and are thought to be due to the hemodilution that these patients experience (20). Measures such as fractional excretion of sodium and potassium and RFI, which assess renal tubular function, have been used by others (10,21,22). A similar rise in these variables during and after CPB was also noted in these studies and was believed to reflect clearance of the increased solute load that CAB patients receive (21).

Our inability to clearly show better preservation of renal function with any of the treatment options may have been because these parameters do not in fact influence renal function. It may also have occurred because the majority of patients that we studied had normal preoperative renal function. Two studies have recently shown that preoperative renal insufficiency and postoperative circulatory dysfunction are the best predictors of postoperative renal failure, as opposed to circulatory variables obtained during CPB (23,24). The fact that all three of our patients who developed ARI postoperatively were hemodynamically unstable, requiring vasopressors and intraaortic balloon counterpulsation, supports this observation.

In summary, using a randomized, prospective study design, we were unable to show any clinically relevant differences in intraoperative or postoperative renal function when comparing pulsatile/nonpulsatile perfusion simultaneously with α-stat/

pH-stat management during hypothermic CPB in CAB patients with normal preoperative renal function.

Effects of Sodium L-Lactate and Sodium Racemic Lactate on Intraoperative Acid-Base Status

Shougo Kuze, MD, Takanori Naruse, MD, Mitsuaki Yamazaki, MD, Kouki Hirota, MD, Yusuke Ito, MD, and Tatsuro Miyahara, PhD

Department of Anesthesiology, Faculty of Medicine, and Department of Toxicology, Faculty of Pharmaceutical Science, Toyama Medical and Pharmaceutical University, Toyama, Japan

Lactated Ringer's solution is frequently used to avoid metabolic acidosis during fluid resuscitation. The standard lactated Ringer's solution contains racemic lactate, an equal mixture of the D- and L-stereoisomers. We investigated whether sodium L-lactate or sodium racemic lactate (DL-lactate) is more effective for increasing buffering capacity in body fluids. For the purpose of this comparison, Ringer's solutions containing no lactate, sodium L-lactate, or racemic lactate at a concentration of 84 mEq/L (three times more than the ordinary level) were infused in patients under general anesthesia during tympanoplasty. Although differences occurred among the three groups in blood concentrations of L-lactate, D-lactate, and the L-lactate/pyruvate ratio, no differences occurred between the two lactate groups in either bicarbonate ion concentration or base excess. The amount of buffering capacity increased significantly in both lactate groups, compared with preinfusion levels, and was more than the values in the nonlactated Ringer's solution group. We conclude that sodium racemic lactate is metabolized at nearly the same rate as that of sodium L-lactate.

(Anesth Analg 1992;75:702–7)

There are two stereoisomers of lactate. The physiologic lactate produced by cellular metabolism is L-lactate, and D-lactate is normally present in only trace concentrations in vivo (1). It has been proposed that the metabolic rate and utilization of D-lactate are inferior to those of L-lactate (2,3). Lactated Ringer's solution containing racemic lactate is commonly used as an intraoperative fluid for several reasons. Lactated Ringer's solution has an electrolyte composition similar to that of extracellular fluids, except that lactate replaces bicarbonate. Metabolism of sodium lactate produces an equimolar sodium bicarbonate that is intimately involved with maintenance of the acid-base balance (4). Since Hartmann and Senn (5) introduced lactated Ringer's solution in the 1930s, it has been a racemic mixture of equal amounts of L- and D-lactate. Lactated Ringer's solution containing only L-lactate is now commercially available in Japan. There are no data on the relative rates of metabolism of D- and L-lactate in humans. The purpose of this study was to determine whether or not there is any difference between sodium L-lactate and sodium racemic lactate with regard to their rate of conversion to bicarbonate.

Methods

This study was approved by the Institutional Review Board in our hospital, and consent was obtained from each patient at the time of a preanesthetic visit. Forty adult patients undergoing tympanoplasty under general anesthesia were assigned randomly to three groups by drawing envelopes: a nonlactate group ($n = 10$), an L-lactate group ($n = 15$), and a DL-lactate group ($n = 15$) (Table 1). Subjects with liver or renal disease or metabolic disorders such as diabetes were excluded from the study.

The nonlactate group received plain Ringer's solution (Otsuka Pharmaceutical Co., Ltd.) without lactate. Standard lactated Ringer's solution contains 28 mEq/L of DL-lactate; however, in the L-lactate and DL-lactate groups, we used sodium lactate at a concentration of 84 mEq/L, three times higher than usual (Table 1). In the L-lactate group, a lactated Ringer's solution containing 84 mEq/L of only L-lactate was prepared by adding sodium L-lactate (1 M solution, Shimizu Pharmaceutical Co., Ltd.) to L-lactated Ring-

Table 1. Chemical Composition of Plain Ringer's Solution and Two High-Concentrate Lactated Ringer's Solutions Used in the Three Study Groups

	Na	K	Ca	Cl	L-Lactate	D-Lactate
Plain Ringer's solution (nonlactate group)	147	4	4.5	155.5		
L-Lactated Ringer's solution (L-lactate group)	186	4	3	109	84	
DL-Lactated Ringer's solution (DL-lactate group)	186	4	3	109	42	42

Values are expressed as milliequivalents per liter.

er's solution (Solita, Shimizu Pharmaceutical). In the DL-lactate group, lactated Ringer's solution containing 42 mEq/L of sodium L-lactate and 42 mEq/L of sodium D-lactate was prepared by adding calculated amounts of DL-lactate (1 M solution, Otsuka Pharmaceutical) to DL-lactated Ringer's solution (Lactec, Otsuka Pharmaceutical).

After intravenous cannulation, normal saline solution (0.9% NaCl) was administered in all patients at a rate of 5 $mL \cdot kg^{-1} \cdot h^{-1}$. Anesthesia was induced with droperidol, fentanyl, thiopental, and succinylcholine chloride and maintained with a neuroleptic anesthesia technique (droperidol/fentanyl/nitrous oxide/oxygen). Pancuronium was used for neuromuscular blockade. Controlled mechanical ventilation was adjusted to maintain $Paco_2$ between 35 and 40 mm Hg, and rectal temperature was maintained between 36 and 37°C. Radial artery cannulation was used for serial blood sampling, and an indwelling urethral catheter was inserted to collect urine. After the collection of blood for baseline values (0 min), one of the three Ringer's solutions was infused at a rate of 500 mL for an initial 20 min, followed by 5 $mL \cdot kg^{-1} \cdot h^{-1}$ for a subsequent 3 h and 10 min. Blood samples were obtained at 30 min and 1, 1.5, 2.5, and 3.5 h after the initiation of infusion. All studies were completed before the end of surgery.

Measurement of pHa, $Paco_2$, HCO_3^-, and base excess was performed with an ABL-2 blood gas analyzer (Radiometer Co.). L-Lactate, D-lactate, and pyruvate were measured by enzymatic analysis and spectrophotometry. Measurement of D-lactate was based on the method previously described by Brandt et al. (1). Because L-lactate and pyruvate values may change over time during serum separation after blood collection (6), blood was deproteinized immediately after sampling with 1.5 M cooled perchloric acid and then centrifuged. The supernatant was used for the determination process. The values reported are for the whole-blood concentration. Blood glucose was measured enzymatically with a glucose analyzer (YSI Co.).

The values obtained are expressed as mean ± SD. A significant difference within groups was tested first by using the repeated-measures analysis of variance, and where indicated, the paired t-test was used to identify significant differences from the baseline value. Significant differences among groups were tested first by analysis of variance and, if indicated, were determined between two groups by using the Bonferroni modification of the t-test, as previously described (7,8). A value of $P < 0.05$ was considered significant.

Table 2. Clinical Characteristics of 40 Adult Patients Undergoing Tympanoplasty Under General Anesthesia

	Nonlactate group (n = 10)	L-Lactate group (n = 15)	DL-Lactate group (n = 15)
Gender (M/F)	5/5	9/6	8/7
Age (yr)	43.2 ± 12.1	41.3 ± 18.2	50.1 ± 18.3
Weight (kg)	58.1 ± 13.8	56.4 ± 8.9	54.5 ± 8.2

Duration of operation (h)	4.46 ± 0.78	4.99 ± 1.07	4.11 ± 0.89

M, male; F, female.

Values are expressed as mean ± SD or number of patients. There were no statistically significant differences between groups.

[a] Preoperative hemoglobin.

[b] Total volume of epinephrine (1:100,000) applied to operative fields during surgery.

Results

The three groups were similar in terms of gender, age, body weight, height, preoperative hemoglobin concentration, the time of starting anesthesia, doses of epinephrine applied to the operative field, and the volume of blood loss (Table 2).

Arterial blood gas data are presented in Figure 1. Arterial pH increased in both the L- and DL-lactate groups but not the nonlactate group. At all time points after 1 h, the values in both the L- and DL-lactate groups were significantly higher than those in the nonlactate group, and there were no significant differences between the L- and DL-lactate groups. Among groups, there were no significant differences

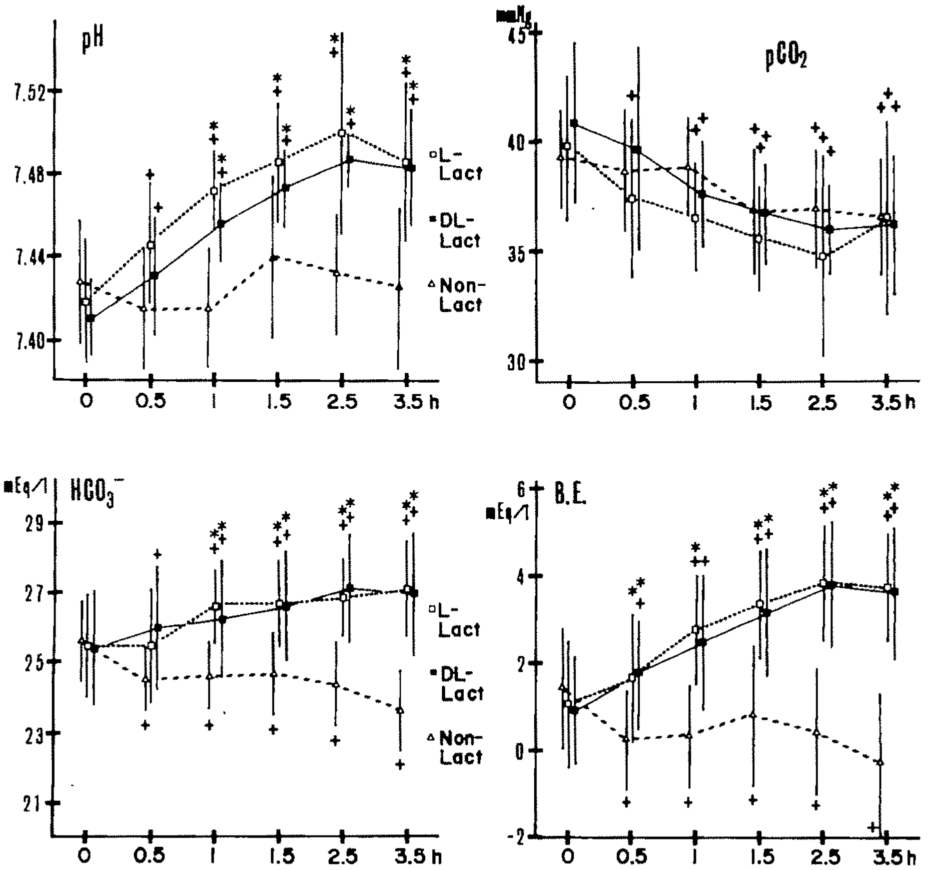

Figure 1. Effects of infusions of nonlactated (Non-Lact), L-lactated (L-Lact), or DL-lactated (DL-Lact) Ringer's solution on arterial blood gas tensions (mean ± SD). †Significant differences from 0-h (baseline) value among groups ($P < 0.05$). *Significant differences versus nonlactate group ($P < 0.05$). There was no significant difference between L-lactate and DL-lactate groups. B.E., base excess.

at any time in $Paco_2$, which was slightly decreased from baseline value. Both bicarbonate concentration and base excess values increased in the L- and DL-lactate groups but decreased in the nonlactate group. There were no differences between the L- and DL-lactate groups.

In the L-lactate group, the concentration of L-lactate in blood increased from 8.1 mg/dL (0.90 mEq/L) at baseline to 19.2 mg/dL (2.13 mEq/L) after 30 min, significantly higher than in the nonlactate and DL-lactate groups (Figure 2). Conversely, in the DL-lactate group, the D-lactate concentration increased from 0.24 mg/dL (0.03 mEq/L) at baseline to 6.06 mg/dL (0.67 mEq/L) after 30 min, significantly greater than that in the nonlactate and L-lactate groups. No difference was noted between the L- and DL-lactate groups in the concentration of pyruvate in blood, which increased from baseline value in both groups and was significantly greater than that in the nonlactate group at 30 min, 1 h, and 1.5 h (Table 3). The ratio of L-lactate to pyruvate (L/P ratio) was higher in the L-lactate group than in the DL-lactate or nonlactate group 30 min after administration. However, no difference was noted between the L- and DL-lactate groups in the ratio of (L-lactate + D-lactate) to pyruvate. There were no differences among groups in blood glucose (Table 3).

Excretion of L-lactate in urine during the entire study period was scarcely observed in the nonlactate group (mean 0.07 mmol) and was slight in both the L- and DL-lactate groups (0.25 and 0.19 mmol, respectively), showing <0.3% of the amount administered in 3.5 h. Slight excretion of D-lactate was also noted in the L-lactate group (0.02 mmol) but was significantly greater in the DL-lactate group (0.94 mmol), although the amount excreted in the DL-lactate group was only 1.5% of the amount administered.

No differences were noted among groups in urinary output, pulse rate, blood pressure, arterial oxygen tension, and arterial oxygen saturation. Awakening from anesthesia was smooth and uneventful in each patient. No impairment in cerebral function, such as agitation, confusion, and panic attacks, was observed postoperatively.

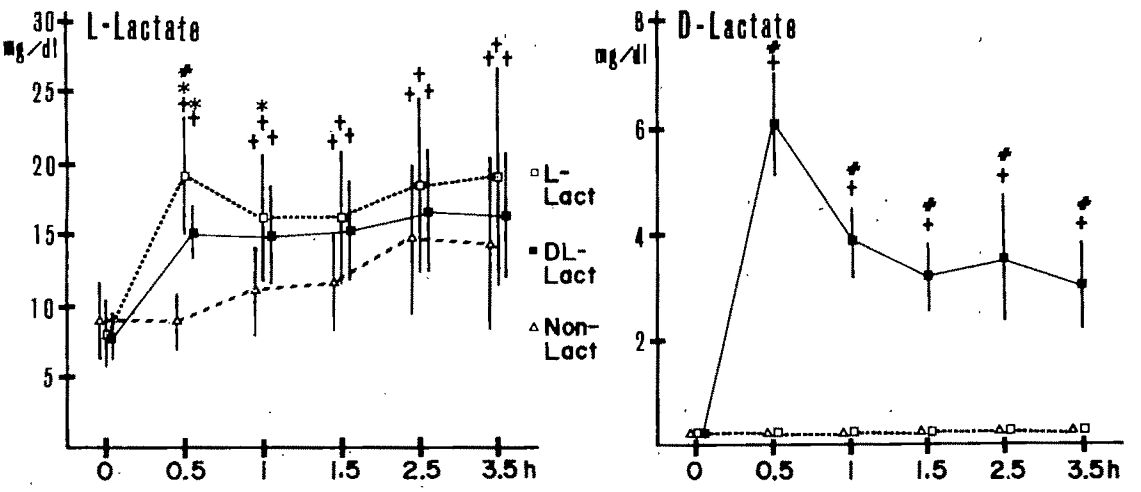

Figure 2. Blood L-lactate and D-lactate concentrations (mean ± SD) in the three study groups. †Significant differences from 0-h (baseline) value among groups ($P < 0.05$). *Significant differences versus nonlactate (Non-Lact) group ($P < 0.05$). ‡Significant differences between L-lactate (L-Lact) and DL-lactate (DL-Lact) groups ($P < 0.05$).

Discussion

The utilization of lactate for oxidation or gluconeogenesis either uses hydrogen or generates bicarbonate (9). Therefore, 1 mol of sodium lactate produces 1 mol of sodium bicarbonate, according to the following formulas:

Oxidation:

$$\begin{aligned} &CH_3CH(OH)COO^-Na^+ + HOH + 3\,O_2 \\ &\rightarrow Na^+ + OH^- + 3\,CO_2 + 3\,H_2O \\ &\rightarrow NaHCO_3 + 2\,CO_2 + 3\,H_2O \end{aligned} \qquad (1)$$

Gluconeogenesis:

$$\begin{aligned} &2\,CH_3CH(OH)COO^-Na^+ + 2\,H_2O + 2\,CO_2 \\ &\rightarrow C_6H_{12}O_6 + 2\,NaHCO_3. \end{aligned} \qquad (2)$$

Alpert and Root (3) reported that 10 min was required for 40% metabolism of the dosed amount of L-lactate in dogs. The calculated lactate utilization rate in humans was estimated to be approximately 200 mmol/h by Kreisberg (10). Therefore, bicarbonate is rapidly produced from lactate so that the concentration of bicarbonate at 30 min in the L-lactate group in our study was significantly higher than that of the nonlactate group.

Equations (1) and (2) were based on L-lactate but may be applied to D-lactate. D-Lactate was formerly considered to be transformed to L-lactate by lactate racemase or metabolized to pyruvate by D-lactate dehydrogenase, enzymes that are found in microorganisms. However, it is currently believed that D-lactate is metabolized to pyruvate in mammals by a nonspecific enzyme of D-2-hydroxy acid dehydrogenase (11,12). The metabolism after pyruvate remains the same as for L-lactate, although the proportion of oxidation to gluconeogenesis may be different between D- and L-lactate (13). Accordingly, the alkalinizing effects of both sodium lactates should depend on their metabolic rates.

It is commonly believed that the metabolism of D-lactate is slower than that of L-lactate and that D-lactate is poorly utilized in vivo. These views are derived from early studies. In 1929, Cori and Cori (2) reported that D-lactate was utilized four times more slowly than L-lactate and that 30% of the amount of D-lactate that was absorbed was excreted in the urine, whereas no excretion of L-lactate occurred during L-lactate absorption. Furthermore, Alpert and Root (3) reported that L-lactate required 10 min for 40% metabolism of the dosed amount in dogs, whereas the racemic form required 23 min. Therefore, based on the supposition that lactated Ringer's solution consisting of sodium L-lactate must be superior to the racemic form in its capacity to produce available buffer, a Japanese pharmaceutical company developed a lactated Ringer's solution consisting of sodium L-lactate, which has been available since 1982.

In the current study, the concentration of sodium lactate was made three times higher than the standard lactated Ringer's solution, and doses of 42 mEq of lactate were infused for an initial 20 min followed by 0.42 $mEq \cdot kg^{-1} \cdot h^{-1}$ for a subsequent 3 h and 10 min to allow us to detect differences among solutions. The rate of lactate administration of 0.42 $mEq \cdot kg^{-1} \cdot h^{-1}$ is equivalent to 15 $mL \cdot kg^{-1} \cdot h^{-1}$ of standard lactated Ringer's solution. No difference,

Table 3. Pyruvate, Lactate/Pyruvate Ratio, and Glucose Levels in Blood Before and After Start of Infusion

however, was noted between the L-lactate and racemic lactate groups as to the alkalinizing effect. Therefore, at the dose level used in this study, the metabolic rate of racemic lactate is the same as that of L-lactate.

Normal L-lactate concentration in blood is approximately 9 mg/dL (1 mEq/L). The highest concentration of L-lactate attained was 41.3 mg/dL (4.5 mEq/L) in a patient in the L-lactate group 3.5 h after the start of infusion. L-Lactic acidosis is defined as >5–6 mEq/L for L-lactate and <7.35 for pH (14). L-Lactate concentrations of 2–5 mEq/L represent a "gray area" of clinical significance and were seen in association with mild exercise or hypermetabolic disease (14).

Normal D-lactate concentration in blood is 0.21 mg/dL (0.023 mEq/L) (1). The highest concentration of D-lactate attained was 7.54 mg/dL (0.84 mEq/L) in a patient in the D-lactate group at 30 min after infusion. Elevation of blood D-lactate to >3 mEq/L has been associated with impaired cerebral function in patients and in experimental animals (15). The data obtained with D-lactate in our experiment were always below this level and were not associated with any side effects.

Both L- and D-lactate are metabolized predominantly in the liver and partially in the kidney and muscles, although their metabolic and utilization rates are different (4,16). Our study, however, was performed in patients with normal liver function. Further studies are required in patients with hepatic dysfunction.

The ratio of L-lactate to pyruvate (L/P ratio) has been used as a quantitative index of oxygen deficiency in the tissues and of the redox state in cytosol (17). At present, however, this ratio has not been considered useful because of problems that include difficulty in measuring pyruvate clinically (14). Because pyruvate is unstable once the sample is drawn, any lag time in processing the specimen can result in a lower value and an increased L/P ratio (4,6). Furthermore, the lack of in vivo equilibrium conditions when oxidation-reduction relations are determined is also problematic (14,18). The L/P ratio in this study indicated significantly higher values in the L-lactate group 30 min after administration than those in the DL-lactate group. However, whether a greater level of hypoxia or intracellular oxygen deficiency was caused by the administration of L-lactate compared with racemic lactate was not considered. It may simply be caused by the administration of doses of L-lactate in the L-lactate group that were two times larger than in the DL-lactate group. Accordingly, it is necessary in general to consider the reason why the L/P ratio was enhanced and to check the presence of lactate supplied extrasomatically, as indicated in this study, before presuming the hypoxic state in tissues. On the other hand, the L/P ratio on addition of D-lactate (i.e., [L-lactate + D-lactate]/pyruvate ratio) showed no difference between the L- and DL-lactate groups. If the metabolic rate from D-lactate to pyruvate is slower than that from L-lactate to pyruvate, then the ratio is considered to show the higher value in the DL-lactate group compared with that in the L-lactate group. From this result, too, the metabolic rate of racemic lactate must be nearly the same as that of L-lactate.

Lactate is a precursor of liver glycogen (2); therefore infusion of lactated Ringer's solution in diabetic patients may produce hyperglycemia (19). In this study, lactate was infused at a concentration three times higher than normal, but only small increases in blood glucose were observed.

Excretion of D-lactate in urine occurred in all groups, whereas L-lactate was minimally excreted in urine. Judge and van Eys (20) observed that normal humans excreted the nonphysiologic isomer of D-lactic acid and speculated about a difference in the renal threshold of L- and D-lactate (12). The total amount of D-lactate excreted over 3.5 h was larger in the DL-lactate group than in the L-lactate group but was only 1.5% of the dose infused. This corresponds to approximately one-twentieth of 30%, the value that was estimated by Cori and Cori (2). They administered racemic lactate at doses of 10–20 mmol/kg, more than 10 times larger than in our study. Therefore D-lactate in our study doses was presumed to be sufficiently utilized in vivo. Our results are in agreement with the report by Drury and Wick (16) that racemic lactate is completely metabolized in vivo in rabbits. Furthermore, Coran (21) reported that on administration of 1 L of racemic lactated Ringer's solution in baboons over 30 min, D-lactate steadily disappeared from the blood in a little longer time than that observed with L-lactate. However, there has as yet been no report with respect to humans.

In conclusion, sodium racemic lactate is metabolized at nearly the same rate as that of sodium L-lactate by infusion doses of 42 mEq for an initial 20 min, followed by $0.42\ \mathrm{mEq \cdot kg^{-1} \cdot h^{-1}}$ for a subsequent 3 h and 10 min of general anesthesia in patients without liver or renal dysfunction.

The authors thank Katsuhito Nakamaru, laboratory technologist, for his excellent technical skills in undertaking this experiment.

The influence of sedative doses of propofol or nitrous oxide on the electroencephalogram was studied in 11 mentally handicapped patients with treated epilepsy undergoing dental procedures. At one session, propofol was titrated to achieve conscious sedation. The mean (±SD) dose requirements were $5.5 \pm 1.1\ mg \cdot kg^{-1} \cdot h^{-1}$. In six patients, the electroencephalogram was unchanged during propofol administration. In three patients, there was a decrease in epileptic activity, and in two patients, paroxysmal discharges disappeared. At another session, nitrous oxide was administered by nasal mask. The mean (±SD) concentration of nitrous oxide needed was 43.6% ± 4.8%. The electroencephalogram did not change in nine patients, whereas in two patients epileptic activity decreased. There were no clinical epileptoid or other adverse manifestations during any treatment or up to 48 h thereafter. The results of the present study suggest that propofol or nitrous oxide can be administered in subanesthetic doses for conscious sedation in mentally handicapped patients with treated epilepsy.

(Anesth Analg 1992;75:708–14)

Propofol is the latest intravenous anesthetic to be introduced into clinical practice. It has been used for sedation in subanesthetic doses for short periods to supplement regional anesthesia (1,2) and for longer periods in patients in intensive care units (3,4). Discontinuation of propofol infusion results in rapid recovery because of its favorable pharmacokinetic profile (5). In a previous study, we administered propofol by continuous infusion for conscious sedation in mentally and physically handicapped patients undergoing dental procedures in whom nitrous oxide sedation had failed or was not possible to administer (6). However, there are conflicting data with respect to the proconvulsive or anticonvulsive properties of propofol (7–17). Because epilepsy is a common additional disorder in the handicapped patient, it is important to know whether intravenous sedation with propofol might provoke seizures or enhance interictal electroencephalographic (EEG) manifestations. The present study was designed to investigate the effects of propofol and nitrous oxide, titrated to achieve conscious sedation, on the EEG in epileptic patients undergoing dental procedures.

Methods

Eleven mentally handicapped patients with epilepsy who required dental treatment under sedation were prospectively studied. Pregnant patients and patients with a history of allergy to propofol or its vehicle were excluded from the study. Written, informed consent was obtained from the parents of the patients, and the study protocol was approved by the institutional ethics committee. A medical history was obtained from all patients. Weight, height, and arterial blood pressure were measured, and a physical examination was carried out. All preoperative medication was recorded and continued up to the time of the procedure.

Supported by a grant from ICI Farma, Ridderkerk, The Netherlands.

All patients were known to have primary or secondary epilepsy. The diagnosis of epilepsy was based on the presence of clinical seizures and confirmed by EEG demonstration of seizure activity. Epilepsy was adequately controlled with medication in all patients. Patients were randomly assigned to receive either propofol or nitrous oxide/oxygen for their first treatment and the alternative sedative regimen for the second treatment. Each patient was thus studied twice on different days. Patients for the morning sessions fasted; patients who were treated in the afternoon were allowed a light breakfast. No premedication was administered.

At each session, the initial procedures were performed without sedation. These involved explanation, adaptation to the surroundings, and oral examination where possible (step 1). Then either propofol or nitrous oxide sedation was introduced, and the following dental procedures were performed: removal of calculus and taking intraoral radiographs if indicated (step 2). The next stage included sealing of fissures, cavity preparation, and restoration and extraction if necessary (step 3). If the patient did not tolerate procedures during step 1, sedation was started. Articaine HCl was administered for local analgesia if necessary. The same dental surgeon performed the treatment in all patients.

The EEG was continuously monitored and recorded with a 12-channel Siemens-Elema recorder at a paper speed of 3 cm/s and with a time constant of 0.3, 0.6, or 1.2 s, according to the degree of restlessness of the patient. The gain was 70 or 100 μV/cm. The scalp electrodes were placed at F_{p1}, F_{p2}, T_3, T_4, C_3, C_4, O_1, and O_2 (International 10-20 System). The electrode impedance was ≤ 5 kΩ. A bipolar montage was used. All events and changes of dosages were manually marked, with indication of the time.

The EEG was recorded continuously throughout the dental procedure, starting with a 5-min baseline recording. The EEG recordings were continued for 15 min after discontinuation of sedation. The EEG was visually assessed for epileptic activity by a clinical neurophysiologist who was unaware of the sedative regimen used. Spikes, spike waves, and sharp waves with local or diffuse distribution were considered epileptic discharges.

A continuous infusion of propofol was started at an initial rate of 3.5 $\mathrm{mg \cdot kg^{-1} \cdot h^{-1}}$ via a Braun Secura FT syringe pump (B. Braun, Melsungen AG, Germany), and a loading dose of propofol (0.5–1 mg/kg) was administered by slow intravenous injection until sedation score 3 was reached (Table 1). Thereafter, the infusion rate was adjusted as necessary to maintain sedation score 3, avoiding unconsciousness (sedation score 5).

Nitrous oxide sedation was administered by the dental surgeon with the Porter MXR machine (Porter Instrument Co., Heatfield, Pa.) equipped with a Dameca scavenging system (Dameca, Copenhagen, Denmark) and a nasal mask (Dameca). The initial nitrous oxide concentration was 40% in oxygen. Nitrous oxide was administered and titrated to the same clinical endpoints of sedation as propofol (sedation score 3).

Table 1. Sedation Scores

1	Fully awake and oriented
2	Drowsy
3	Eyes closed, responds promptly to verbal commands
4	Eyes closed, arousable on mild physical stimulation
5	Eyes closed, unarousable on mild physical stimulation

In addition to EEG monitoring, the level of consciousness was constantly assessed using the sedation score. Continuous verbal and nonverbal communication with the patient was maintained. Nonverbal communication was maintained with those patients for whom verbal communication was difficult or impossible. Their hands were squeezed to assess their response. Any excitatory effects, such as spontaneous movements, twitching, or tremor, were noted. Electrocardiogram, heart rate, noninvasive arterial blood pressure, pulse oximetry ($\mathrm{Spo_2}$), and end-tidal carbon dioxide concentration ($\mathrm{P_{ET}CO_2}$) were continuously monitored using Hewlett Packard 78352A (Böblingen, Germany) and Ohmeda 4700 Oxicap (Englewood, Colo.) monitors. Ten minutes after the dental procedure was completed, the patients returned to their ward. The patients were observed by their personal attendants during the whole procedure and until 48 h after sedation for any side effects and complications.

The possibility of determining propofol blood concentration became available only at the end of the study. Therefore, propofol concentration was measured in the last three patients. Blood samples of 5 mL were obtained from the contralateral antecubital vein on ending the propofol infusion. Samples were collected in tubes containing potassium oxalate and stored at 4°C until assay of blood concentration of propofol by the combination of high-pressure liquid chromatography and fluorescence detection method (18).

A repeated measures analysis of variance was performed for each physiologic variable (arterial blood pressure, heart rate, oxygen saturation [$\mathrm{Spo_2}$], and $\mathrm{P_{ET}CO_2}$) using the statistical package BMDP (BMDP Statistical Software, Berkeley, Calif.). Differences between time trends in both sedation groups were tested. Results are expressed as mean ± SD. A value of $P < 0.05$ was considered to be statistically significant.

Table 2. Clinical Characteristics of Eleven Mentally Handicapped Patients With Epilepsy Undergoing Dental Treatment Under Sedation

Pt No./ Gender	Age (yr)	Wt (kg)	Diagnosis	Previous EEG	Medication	Epileptic attacks
1/M	25	43	Mental retardation, epilepsy	Focal ep act	Carbamazepine; valproic acid	1 Seizure in 7 mo
2/M	24	59	Mental retardation, epilepsy	Multifocal ep act	Carbamazepine	Seizure free
3/F	25	52	Mental retardation, epilepsy, deaf	Focal and generalized ep act	Valproic acid; carbamazepine	Twice a day
4/F	18	59	Mental retardation, epilepsy, spastic tetraparesis	Generalized ep act during HV	Valproic acid; diazepam	Once a day
5/F	19	41	Mental retardation, epilepsy, spastic tetraparesis	Multifocal and generalized ep act	Valproic acid	Seizure free
6/M	17	57	Mental retardation, epilepsy, spastic tetraparesis	Diffuse slow frequencies without ep act	Valproic acid; carbamazepine	1–2 Petit mal/wk; 1 seizure in 6 mo
7/M	30	105	Mental retardation, epilepsy	Generalized ep act during HV	Valproic acid	2–3 Seizures in 2 wk
8/F	21	40	Mental retardation, epilepsy, spastic tetraparesis, blind	Multifocal and generalized ep act	Carbamazepine	3 Seizures in 1 wk
9/F	18	40	Mental retardation, epilepsy, hydrocephalus	Normal	Phenobarbital; valproic acid	Seizure free
10/F	26	52	Mental retardation, epilepsy, spastic tetraparesis	Multifocal ep act	Carbamazepine; phenobarbital	Once a day
11/F	19	48	Tuberous sclerosis, mental retardation, epilepsy	Focal and generalized ep act	Phenytoin; carbamazepine	1 Petit mal/day; 1 seizure/day

EEG, electroencephalographic; N, nitrous oxide; P, propofol; Pt, patient.

[a] Numbers in parentheses are nitrous oxide concentrations (%) or propofol dose (bolus dose + total cumulative dose) (mg·kg^{-1}·h^{-1}).

[b] Epileptic activity including spikes, spike waves, and sharp waves.

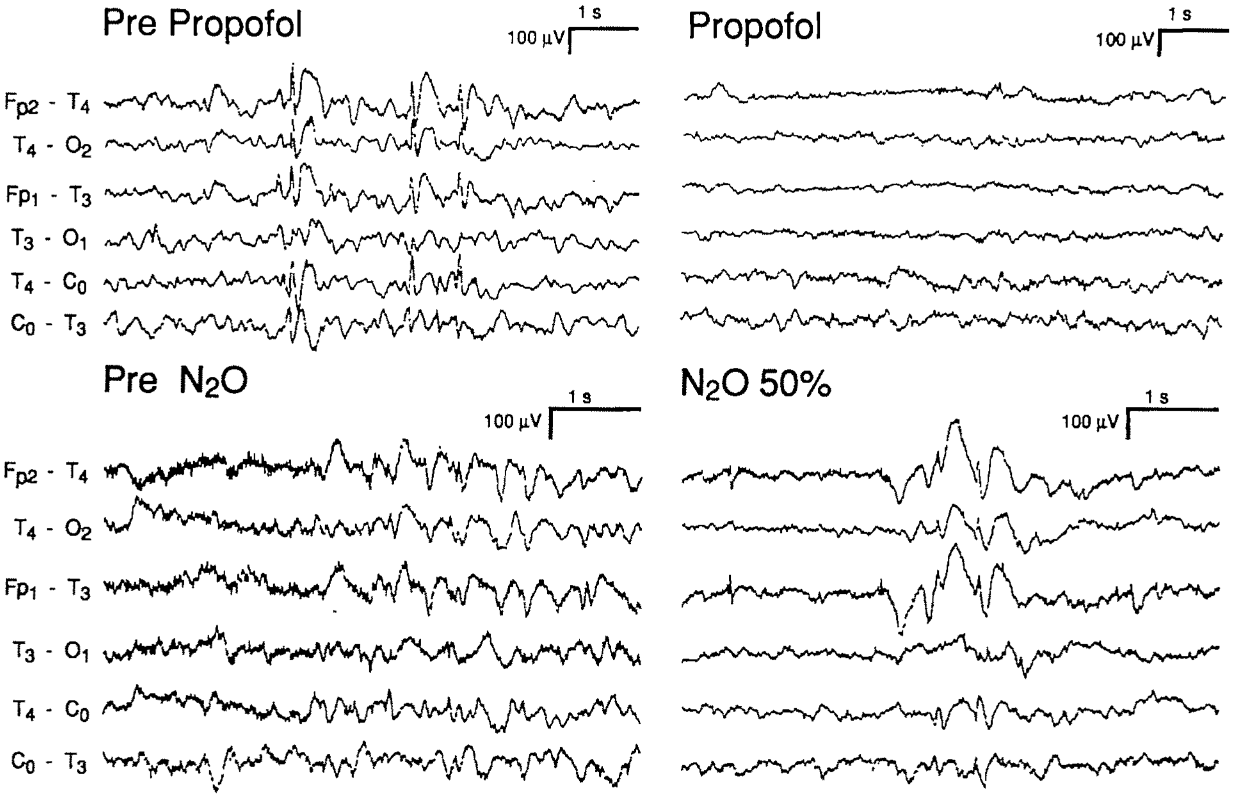

Figure 1. Representative EEG segments from a 19-yr-old patient (patient 11) with treated epilepsy before and during conscious sedation with propofol and nitrous oxide. Note absence of spike-and-wave complexes during propofol sedation.

Results

Demographic and clinical details of the patients (7 women, 4 men) are shown in Table 2. Eight of the 11 patients had multiple handicaps. Five patients were severely mentally retarded, two were moderately retarded, and four were mildly retarded. Apart from their mental disorder and physical handicap, all patients were in good health. All but one patient (patient 9) had EEG evidence of epileptic activity.

The EEG activity data before and during sedation are shown in Table 3. During propofol sedation, EEG activity did not change in six patients. Paroxysmal discharges disappeared in two patients (patients 1 and 7) and were decreased in three (patients 8, 10, and 11) (Figure 1). In three patients (patients 4, 6, and 8), there was an increase in fast activity in the beta band (13–30 Hz). During nitrous oxide sedation, the EEG did not change in nine patients. In two patients (patients 1 and 11), a decrease in epileptic activity was evident. Neither form of sedation was associated with any adverse effects. Specifically, there was no increase in the frequency or intensity of clinical epileptic manifestations during the 48 h after treatment.

The mean duration of sedation was 40.0 ± 9.6 min (range 27–62) for propofol and 41.5 ± 10.3 min (range 31–68) for nitrous oxide. The mean dose requirements were 5.5 ± 1.1 $mg \cdot kg^{-1} \cdot h^{-1}$ (range 3.7–6.6) for propofol and 43.6% ± 4.8% (range 35%–50%) for nitrous oxide. Figure 2 shows mean (±SD) values for arterial blood pressure, heart rate, Sp_{O_2}, and $P_{ET}CO_2$ during propofol and nitrous oxide sedation. Arterial blood pressure did not change significantly in the nitrous oxide group, whereas there was a significant decrease in the patients sedated with propofol. Compared with presedation values, heart rate decreased significantly in both groups (by 9 beats/min). The Sp_{O_2} remained above 95% in the propofol group and remained above 98% in the nitrous oxide group. The $P_{ET}CO_2$ was slightly higher ($P < 0.05$) in the propofol group (40 vs 35 mm Hg in the nitrous oxide group).

The level of consciousness during propofol or nitrous oxide sedation did not exceed sedation score 3 except in one patient, who reached sedation score 4 at the end of the propofol sedation. At that time, a short period of airway obstruction occurred that was immediately detected and corrected. Table 4 shows the blood concentrations of propofol in three patients at the end of sedation.

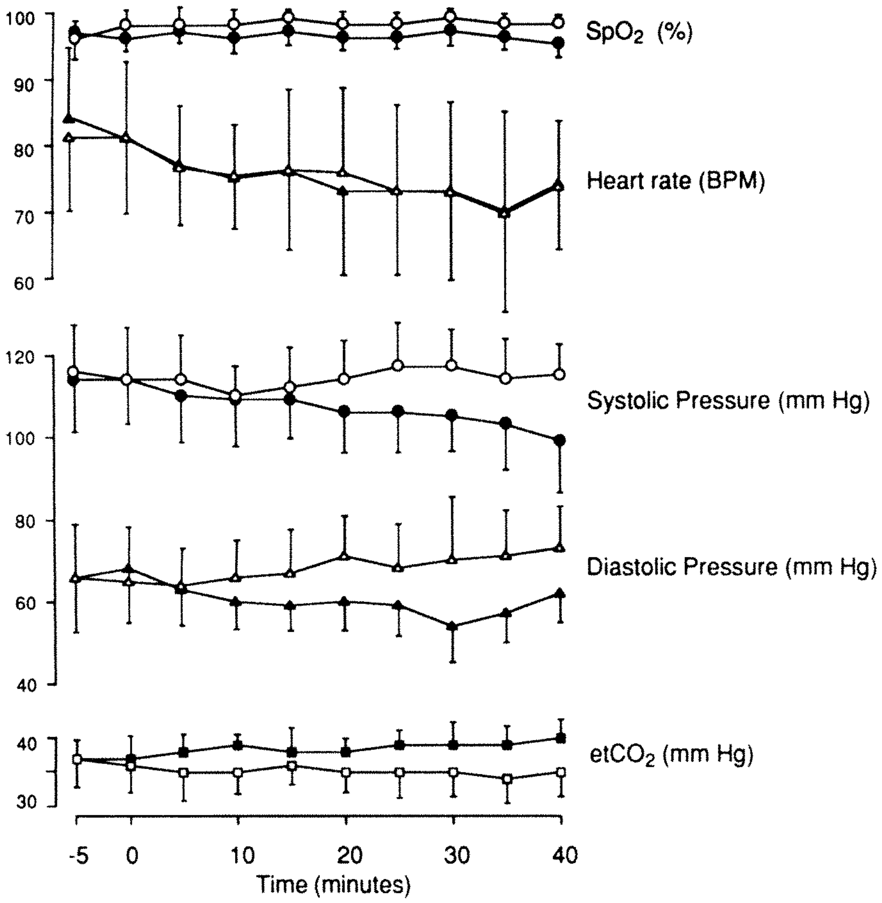

Figure 2. Mean (±SD) hemodynamic and respiratory variables during propofol and nitrous oxide sedation. *Solid symbols*, propofol; *open symbols*, nitrous oxide. Spo_2, oxygen saturation; BPM, beats/min; $etCO_2$ end-tidal CO_2 concentration.

Table 4. Plasma Concentration of Propofol at the End of the Infusion in Three Study Patients

Pt No.	Duration of infusion (min)	Bolus dose (mg/kg)	Infusion rate ($mg \cdot kg^{-1} \cdot h^{-1}$)	Blood conc (μg/mL)

Discussion

The provision of quality dental care to patients who are severely mentally and physically handicapped is a challenge. Behavior management combined with conscious sedation using nitrous oxide/oxygen has become an established technique for dental treatment in this group of patients. However, a small proportion of these patients cannot be adequately managed by this technique alone, because of restricted coping resources and the inability to carry out continuous nasal breathing, essential for nitrous oxide administration by nasal mask. In a previous study, we demonstrated that propofol by continuous intravenous infusion can be a suitable alternative to nitrous oxide for conscious sedation in dentistry or oral surgery. Sedation with propofol infusion is comparable to nitrous oxide/oxygen inhaled sedation in that recovery is rapid without side effects (6). However, there are conflicting data with respect to the proconvulsive or anticonvulsive properties of propofol. The results of the present study suggest that propofol administered in sedative doses neither provokes seizures nor enhances interictal EEG manifestations in patients with treated epilepsy.

Dystonic reactions have been reported to occur immediately after induction with propofol administered as the sole anesthetic agent in children (7). Opisthotonus and tonic-clonic seizures have been described after emergence from anesthesia with propofol and additional anesthetics (alfentanil and enflurane) (8) and after the use of propofol for sedation in the intensive care unit (9). This involved patients without a history of epilepsy. The EEG, recorded with surface electrodes after the acute states, demonstrated no evidence of epileptic activity. Two studies reported the effects of propofol administration during general anesthesia on the EEG recorded with chronically implanted subdural electrodes in epileptic patients. Hodkinson et al. (10) recorded discharges of epileptiform activity from the previously mapped epileptogenic foci during propofol infusion. They also observed new epileptic activity in other areas of the cortex that had showed no epileptic activity before the injection of propofol. Hufnagel et al. (11) observed maximal suppression of brain activity in the epileptogenic brain area in 12 of 20 patients and also suppression of spontaneous interictal activity present before the onset of anesthesia in 10 of 20 patients; in 5 of 20 patients, there was induction of epileptiform activity. In one patient, a seizure occurred. Our patients were conscious during propofol administration. The EEG recorded from surface electrodes did not show any evidence of increased epileptic activity. There is also considerable evidence that propofol may have anticonvulsive properties. Protection against epileptiform seizures induced by electroshock and pentylenetetrazol in mice was assessed by Lowson et al. (12). They concluded that intraperitoneal administration of propofol (50 mg/kg) has a strong anticonvulsant effect. Several studies comparing propofol and methohexitone in patients receiving electroconvulsive therapy have shown a shorter duration of seizure activity with propofol (13–15). Others have reported the successful use of propofol infusions in the control of intractable status epilepticus, resistant to conventional therapy (16,17). We conclude that the available data are inconclusive with respect to whether propofol administration is associated with enhancement of epileptic activity.

In a review of proconvulsant and anticonvulsant properties of anesthetic drugs, Modica et al. (19,20) concluded that the available evidence with regard to the cerebral stimulatory effects of nitrous oxide suggests that its epileptogenic potential is extremely low. In our study, the EEG was unchanged during nitrous oxide sedation in nine patients, whereas in two patients the frequency of paroxysmal discharges decreased. This suggests that nitrous oxide can be administered safely to patients with treated epilepsy.

In a previous study, we administered propofol for conscious sedation in nonepileptic patients (6). The mean infusion rate of propofol was 3.6 $mg \cdot kg^{-1} \cdot h^{-1}$ (range 2.5–5.4). In the present study, all patients had long-term treatment for epilepsy. Using the same sedation scoring system and titrating propofol to identical endpoints (sedation score 3), the mean infusion rate was 5.5 $mg \cdot kg^{-1} \cdot h^{-1}$ (range 3.7–6.6) in the epileptic patients. It is conceivable that this higher dose requirement is a result of hepatic enzyme induction, as a consequence of long-term antiepileptic medication (21,22).

With both sedative regimens there were no untoward changes in hemodynamic and respiratory variables. In all patients, Spo_2 remained above 95% and was higher during nitrous oxide sedation, as a result of a higher fraction of inspired oxygen. The higher P_{ETCO_2} and slightly lower Spo_2 values during propofol infusion indicate that close supervision of the airway and respiration is necessary. It is especially important not to exceed sedation score 3.

In conclusion, the results of the present study suggest that propofol and nitrous oxide can be administered in subanesthetic doses for conscious sedation in mentally and physically handicapped patients with treated epilepsy undergoing dental procedures. More EEG studies are needed to determine the epileptogenic potential of propofol.

We thank M. de Groot-Venema, MD, and Marjan van de Werken, EEG technician, Craeyenburch, for screening the patients and recording the EEGs; C. Romijn, AMC, for technical assistance and support; and Dr. J. Oosting, Department of Medical Physics and Statistics, Academic Medical Center, for performing the statistical analysis of the measurements.

Venous Air Embolism in Prone Dogs Positioned With the Abdomen Hanging Freely: Percentage of Gas Retrieved and Success Rate of Resuscitation

Alan A. Artru, MD

Department of Anesthesiology, University of Washington School of Medicine, Seattle, Washington

Based on reports of fatal venous air embolism (VAE) occurring during lumbar laminectomy and spinal fusion in prone patients positioned with the abdomen hanging freely, it has been recommended that monitoring for VAE should be used for such cases and that a multiorificed central venous catheter should be inserted for aspiration of VAE. The present study was designed to examine aspiration of VAE when prone dogs positioned with the abdomen hanging freely were given a fatal VAE via a femoral vein. Twenty-one dogs were anesthetized with halothane and nitrous oxide in oxygen and positioned with the abdomen ventral and hanging freely, the head fixed in a stereotaxic frame, the upper extremities resting on a surface approximately 10 cm below the level of the stereotaxic frame, and the lower extremities on a surface below the level of the upper extremities (to ensure that VAE entering the inferior vena cava would ascend toward the heart). In the control group (n = 7), a central catheter was placed but was not used to aspirate VAE. In a second group (n = 7), a Cook Bunegin-Albin multiorificed catheter was inserted; and in a third group (n = 7), an American Edwards 7F Swan-Ganz catheter was inserted. Dogs were then given a predetermined lethal dose of air (5 mL/kg) over 30 s via the femoral vein. In groups 2 and 3, attempts to aspirate VAE were begun with the first decrease in expired CO_2. The amounts of gas retrieved (expressed as a percent of the injected air) and the incidence of successful resuscitation were compared. Significantly greater percentages of injected venous air were retrieved with the Bunegin-Albin catheter (47% ± 20% [mean ± SD]) than with the Swan-Ganz catheter (8% ± 6%). However, the success rate of resuscitation was identical whether attempts to aspirate VAE were performed with Bunegin-Albin or Swan-Ganz catheters or no attempt was made to aspirate VAE (1 of 7 survivors in all three groups). It is concluded that in prone dogs positioned with the abdomen hanging freely, central catheters located near the junction of the right atrium and superior vena cava may be ineffective for retrieval of VAE reaching the heart via the inferior vena cava and do not increase the success rate of resuscitation.

(Anesth Analg 1992;75:715–9)

Recently Albin et al. (1) reported two cases of acute, fatal venous air embolism (VAE) in patients in the prone position undergoing lumbar laminectomy and spinal fusion. Both patients had been placed prone on a four-poster frame that allowed the abdomen to hang freely. It was speculated that in this position, the absence of external pressure on the abdominal contents probably resulted in negative pressure in the inferior vena cava (IVC). Negative pressure in the IVC and a considerable gravitational gradient between the vertebra and the right atrium (RA) favored the rapid entrainment of air into the venous circulation. On the basis of these and other reports of VAE in the prone position (2–4), Albin et al. (1) recommended "the need for serious consideration for complete monitoring for VAE whenever a patient is placed prone using any of the positioning techniques that allows for free movement of the abdomen." They stated that monitoring should include a multiorificed central venous catheter for aspiration of VAE, with the catheter tip localized at either the RA-superior vena cava (SVC) junction or at 2 cm in the RA.

Previous studies from my laboratory reported on the use of central catheters for aspiration of VAE in other positions. In three studies (5–7), dogs were placed in the upright position, a multiorificed central venous catheter or a pulmonary artery (PA) catheter, or both, were positioned near the location recommended by Albin et al. (1), and a lethal dose of air was injected into the jugular vein. In a fourth study

(8), dogs were placed prone lying on their chest and abdomen, a multiorificed central venous catheter or a PA catheter was positioned near the location recommended by Albin et al. (1), and a lethal dose of air was injected into the femoral vein. In all four studies, the catheters were aspirated after VAE, and the volume of gas retrieved and the success rate of resuscitation were determined.

There have been no reports on the volume of gas aspirated and the success rate of resuscitation after lethal VAE in prone dogs positioned so that the abdomen hangs freely. The present study was designed to examine the efficacy of the two most commonly studied catheters, a Cook Bunegin-Albin multiorificed central venous pressure (CVP) catheter and a 7F American Edwards Swan-Ganz catheter, for gas aspiration and resuscitation in prone dogs with a freely hanging abdomen.

Methods

The experimental protocol was similar to that outlined in four previous studies from this laboratory (5–8). The study was approved by the Institutional Animal Care Committee, and 21 dogs (weight 15–22 kg) were anesthetized with 2% inspired halothane and 66% N_2O in O_2. The dogs' lungs were ventilated to maintain Pa_{O_2} >120 mm Hg and Pa_{CO_2} at 35–40 mm Hg. Expired CO_2 was continuously monitored using a Capnogard model 1250 End Tidal Monitor (Novametrix Medical Systems Inc.). An electronic offset was used to minimize interference by expired N_2O on the strip-chart recorder display. The right jugular vein was cannulated with either a Cook Bunegin-Albin multiorificed catheter or a 7F American Edwards Swan-Ganz catheter for measurement of RA pressure or CVP and, where appropriate, retrieval of injected air. The right femoral vein was cannulated for fluid administration and injection of air. A femoral artery was cannulated for sampling of blood to measure hemoglobin and gas tensions and for continuous monitoring of systemic arterial pressure and heart rate. Mean arterial pressure was determined by electronic integration. Temperature was monitored by a nasopharyngeal thermistor probe and maintained at 37.0 ± 0.5°C by heat lamps or ice packs. Vascular volume was maintained by continuous infusion of saline (4–6 $mL \cdot kg^{-1} \cdot min^{-1}$).

At the conclusion of the surgical preparation, wound edges were infiltrated with 0.5% bupivacaine, and the concentration of halothane was decreased to 0.5% inspired (%N_2O unchanged). Dogs were positioned with the abdomen ventral and hanging freely, the head fixed in a stereotaxic frame, the upper extremities resting on a surface approximately 10 cm below the level of the stereotaxic frame, and the lower extremities on a surface below the level of the upper extremities. Thus, in this study the trunk was positively inclined in the cephalad direction, unlike previous studies from this laboratory, where the head was elevated but the trunk was positioned horizontally (8). This position was chosen so that the IVC would be positively inclined toward the RA, assuring that VAE entering the IVC would ascend toward the RA (due to the buoyancy of air) and not simply collect in the engorged abdominal vessels. Up to 200 mL of saline was administered to achieve a mean RA pressure or CVP of approximately 2 mm Hg with the transducer zeroed at the RA. Once systemic variables had stabilized (25 min after decreasing halothane to 0.5%), baseline values for systemic variables were recorded. These included CVP or RA pressure, PA occlusion pressure, mean arterial pressure, heart rate, arterial blood gas tensions, arterial blood hemoglobin levels, and nasopharyngeal temperature.

Dogs were randomly assigned to one of three groups. In the control group ($n = 7$), a Bunegin-Albin multiorificed catheter ($n = 4$) or a Swan-Ganz catheter ($n = 3$) was inserted and was used to measure CVP but was not used for aspirating air. In the second group ($n = 7$), a Bunegin-Albin multiorificed catheter was inserted for measurement of CVP and was used for aspirating air. In the third group ($n = 7$), a Swan-Ganz catheter was inserted for measurement of PA occlusion pressure and RA pressure and was used for aspirating air. As in previous studies from this laboratory, the Bunegin-Albin and Swan-Ganz catheters were examined in the position reported by Bunegin et al. (9) as optimum for aspirating air when VAE entered through the SVC. With the Bunegin-Albin catheter, the proximal orifice was placed near the SVC-RA junction and distal orifice near the mid-RA. With the Swan-Ganz catheter, the RA port was positioned near the SVC-RA junction, and the PA port was placed in the PA. Catheters were positioned by using the catheter as an exploring electrocardiographic lead (10) and, for the Swan-Ganz catheter, using the PA pressure trace to confirm placement of the PA port in the PA.

The multiorificed portion of the Bunegin-Albin catheter and the RA port of the Swan-Ganz catheter were advanced until the point of maximal negative P-wave deflection with no positive P-wave component. This point was taken to indicate that the multiorificed portion of the Bunegin-Albin catheter and the RA port of the Swan-Ganz catheter were at the SVC-RA junction. The Bunegin-Albin catheter was advanced 1–2 cm once the point of maximal P-wave deflection was reached. Because the proximal and distal orifices are approximately 5 cm apart, this maneuver placed the proximal orifice approximately 1 cm above the SVC-RA junction and the distal orifice

Table 1. Systemic Variables in the Three Study Groups

	Controls ($n = 7$)	Bunegin-Albin multiorifice catheter ($n = 7$)	Swan-Ganz catheter ($n = 7$)
Pa_{O_2} (mm Hg)	139 ± 22	141 ± 16	138 ± 14
Pa_{CO_2} (mm Hg)	37.9 ± 1.8	37.9 ± 1.9	37.4 ± 1.8
pH	7.36 ± 0.04	7.37 ± 0.02	7.36 ± 0.03
Bicarbonate (mEq/L)	20.7 ± 0.8	21.5 ± 1.3	21.3 ± 1.5
Hemoglobin (g/dL)	12.8 ± 1.5	13.2 ± 2.1	13.3 ± 2.0
Mean arterial blood pressure (mm Hg)	106 ± 20	103 ± 20	105 ± 18
Central venous pressure (mm Hg)	3 ± 1	2 ± 1	3 ± 2
Pulmonary artery occlusion pressure (mm Hg)	—	—	8 ± 5
Heart rate (beats/min)	105 ± 14	100 ± 18	107 ± 13
Temperature, nasopharyngeal (°C)	37.2 ± 0.5	37.1 ± 0.5	37.2 ± 0.5

Values are mean ± SD.

in the mid-RA (10). The RA port of the Swan-Ganz catheter was withdrawn approximately 1–2 cm once the point of maximal P-wave deflection was reached.

The dose of air chosen for injection in this study was 5 mL/kg. This dose was chosen on the basis of previous reports from this laboratory that 5 mL/kg was the mean fatal VAE for dogs in both the prone and upright positions when doses of 3, 5, or 7 mL/kg of air were administered intravenously (5,6,8). In this study, as in the previous ones, 5 mL/kg of air was injected over 30 s. Resuscitation was not attempted in the control group but was attempted in the other two groups. The only method of resuscitation used was aspiration of VAE. Attempts to retrieve VAE were made using 50-mL syringes attached to the catheter. One syringe was used with the Bunegin-Albin catheter, and two syringes (one for the RA port and one for the PA port) were used with the Swan-Ganz catheter. Aspiration was begun as soon as expired CO_2 decreased after injection of air. With the Swan-Ganz catheter, both syringes were aspirated simultaneously. The "plunger" of the 50-mL syringe was pulled back manually with as much force as could be generated by hand. The negative force generated during aspiration was not measured. Aspiration was continued until gas no longer was seen to be entering the syringe. In cases where large amounts of gas were retrieved, an additional 50-mL syringe was used. Invariably, blood was aspirated, but because the amount of blood was small (10–40 mL) and in previous studies was not significantly different among groups (5–8), no attempt was made to reinfuse the aspirated blood.

The volume of gas retrieved was expressed as a percent of injected air. The term "gas" is used because the retrieved gas was comprised of both the injected air and whatever amount of N_2O might have diffused into the injected air. In the present study, this percent and systemic variables were compared among groups by use of analysis of variance. The incidence of successful resuscitation among groups and the percentage of VAE that was retrieved in survivors and nonsurvivors was compared using the variance ratio test (11). A P value <0.05 was considered statistically significant. Values are reported as mean ± SD.

Table 2. Retrieval of Intravenously Injected Air and Success Rate of Resuscitation in the Three Study Groups

	Controls ($n = 7$)	Bunegin-Albin multiorifice catheter ($n = 7$)	Swan-Ganz catheter ($n = 7$)
Air injected (mL)	100 ± 8	89 ± 8	95 ± 8
Air retrieved (%)	0	47 ± 20^a	8 ± 6
Air plus blood retrieved (mL)	0	89 ± 15^a	22 ± 8
Proportion of surviving dogs	1/7	1/7	1/7

Values are mean ± SD or number.
^{a}Significantly different from Swan-Ganz catheter; $P < 0.05$.

Results

There were no differences among groups with respect to systemic circulatory variables or blood chemistries before infusion of air (Table 1).

A significantly greater amount of gas as a percent of the 5-mL/kg VAE dose was retrieved using the Bunegin-Albin catheter (47% ± 20%) than either with the Swan-Ganz RA and PA ports (8% ± 6%) or in the control dogs, where no attempt was made to retrieve VAE (0%) (Table 2). Also, a significantly greater volume of air plus blood was retrieved using the Bunegin-Albin catheter (89 ± 15 mL) than either with the Swan-Ganz RA and PA ports (22 ± 8 mL) or in the control dogs, where no attempt was made to aspirate air or blood (0 mL). The incidence of successful resuscitation from VAE did not differ among groups (one of seven dogs in all three groups).

Discussion

The present results are consistent with previously reported findings from this laboratory in prone dogs given VAE via the femoral vein and in upright dogs given VAE via the jugular vein (6–8). The results of those studies and the present one indicate that the choice of venous catheter may have clinical implications for aspiration of venous air. In this study, as in the previous ones, the Bunegin-Albin multiorificed catheter and not the Swan-Ganz catheter allowed retrieval of a large percentage of intravenously infused air. Similar findings for the Swan-Ganz catheter were reported by Sink et al. (12) in both prone and upright dogs given VAE via the jugular vein.

In contrast to previously reported findings from this laboratory, the incidence of successful resuscitation in this study was not directly related to the amount of air retrieved (5–8). Also in contrast to previous studies, in the present study the Bunegin-Albin catheter did not increase the rate of successful resuscitation from a lethal dose of venous air. The differences in results between this and previous studies probably relate to site of air entry, body position, and catheter location.

In upright dogs given VAE via the jugular vein, use of the Bunegin-Albin multiorificed catheter or a modified Arrow prototype multiorificed catheter permitted 63% ± 14% (mean ± SEM) or 73% ± 13% (mean ± SD), respectively, of injected venous air to be retrieved and four of six dogs (with either catheter) to be successfully resuscitated (6,7). Presumably, in the upright position the buoyancy of gas acts along the axis of the SVC so that VAE disperse into zones of high flow velocity. In the case of VAE entering the heart via the SVC, it has been demonstrated by echocardiography that SVC flow carries VAE to the SVC-RA junction, where the air tends to localize (13). After accumulating at the SVC-RA junction, small VAEs break off from large bubbles to move through the tricuspid valve or into the upright portions of the RA. A relatively long time is available for aspiration via a SVC-RA catheter.

In prone dogs lying on their chest and abdomen, with the head elevated and the trunk positioned horizontally, that were given VAE via the femoral vein, use of the Bunegin-Albin multiorificed catheter permitted 60% ± 7% (mean ± SEM) of injected venous air to be retrieved and six of nine dogs to be successfully resuscitated (8). Presumably, in the prone position, the buoyancy of gas favors accumulation of VAE against the nondependent (superior) walls of the IVC and RA. Because these are zones of low flow velocity, VAE may not be quickly "washed away," and a relatively long time may be available for aspiration via a SVC-RA catheter.

In the present study, dogs were positioned prone with the abdomen hanging freely and the head and upper extremities higher than the lower extremities. Venous air embolism was injected via the femoral vein, and the Bunegin-Albin multiorificed catheter permitted 47% ± 20% of injected air to be retrieved and one of seven dogs to be successfully resuscitated. The numerically smaller percentage of injected air retrieved in this study compared with the previous ones (6–8) suggests that air injected into the femoral vein of prone dogs with the abdomen hanging freely either (a) in part remains in engorged abdominal vessels or (b) does not localize at a site from which it can be easily aspirated via a catheter positioned in the mid to high RA. The first proposal, that abdominal vessels engorged because of the negative pressure in the IVC with absence of external pressure on the abdomen (1) "trap" a portion of the air injected into the femoral vein, seems unlikely considering the present findings. If a portion of the air injected into the femoral vein remained in engorged abdominal veins, the percent of injected air that was retrieved would be low (as was observed), but also the percentage of animals killed by 5 mL/kg of injected air would be significantly <100%, contrary to the present finding that only one of seven control dogs survived. The high death rate in controls after 5 mL/kg of air was injected into the femoral vein suggests that VAE dispersed into the IVC and ascended into the heart. There are no reported echocardiographic studies in the upright position of VAE entering the heart via the IVC. However, it seems likely that IVC flow carries VAE to the IVC-RA junction where air either localizes (assuming flow patterns at this junction similar to those at the SVC-RA junction), moves through the tricuspid valve (following the principal path of IVC flow), or ascends (against the principal path of RA flow) to the upright portion of the RA. Presumably, IVC and thoracic pressure at end expiration is more positive in prone dogs lying on their chest and abdomen than in prone dogs with their chest and abdomen hanging freely, and this pressure opposes localization of VAE at the IVC-RA junction or movement through the tricuspid valve, or both, and favors ascent into the superior RA, accounting for the numerically smaller percentage of VAE retrieval in this study.

That retrieval of large amounts of VAE increases the likelihood of surviving a fatal dose of air can be appreciated from this study and the previous ones from this laboratory. In the four previous studies, >62% of injected air was retrieved with a multiorificed device in 21 of 39 dogs, and 23 of 39 dogs survived (5–8). The percentage of injected air retrieved and the success rate of resuscitation were significantly increased compared with control dogs, where none of the injected air was retrieved and 1 of 25 dogs survived. In the present study, >62% of injected air was retrieved in one of seven dogs, and that dog survived. The survival rate was not different from control dogs (one of seven).

It should be noted that in this model, VAE was administered as a bolus dose. In the clinical situation, VAE is considered to occur most commonly as a continuous entrainment of small quantities of air. This difference may limit extrapolation from the present study to the clinical setting. To the extent that the results of this study are relevant to the clinical setting, they may have implications for the clinical care of prone patients positioned with their abdomen hanging freely compared with prone patients lying on their chest and abdomen and with patients in the sitting position.

The present results suggest that, with a catheter placed in the mid or high RA and the trunk positively inclined in the cephalad direction, IVC VAE may be more difficult to aspirate in prone patients positioned with their abdomen hanging freely than in patients in the other positions. The present results also suggest that with a catheter in the mid or high RA and the trunk positively inclined, retrieval of IVC VAE in prone patients with their abdomen hanging freely may not provide a greater likelihood of successful resuscitation than when no attempt is made to retrieve IVC VAE. Additional studies are needed to determine whether the finding of difficult resuscitation from lethal VAE in prone dogs positioned with their abdomen hanging freely is reproducible in other species, with other volumes and rates of infusion of VAE, with the air aspiration catheter in other locations, and with other body positions. If so, the difficulty of resuscitation from VAE in this position should be mentioned when informed consent is obtained from patients scheduled for surgery in this position, and efforts should be made to modify patient position or other surgical conditions to minimize the likelihood of VAE occurring. Additional studies also are needed to determine whether positioning of a multiorifice central venous catheter in a location other than near the SVC-RA junction would improve the percentage of IVC VAE retrieval and also improve the success rate of resuscitation from VAE.

Effect of Halothane, Fentanyl, and Ketamine on the Threshold for Transpulmonary Passage of Venous Air Emboli in Dogs

Naoki Yahagi, MD, Hitoshi Furuya, MD, Yoshikazu Sai, MD, and Yoshikuni Amakata, MD

Department of Anesthesiology and Intensive Care Unit, Shiga University of Medical Science, Ohtsu, and Department of Anesthesiology, Nara Medical University, Kashihara, Nara, Japan

We assumed that the capacity of the lungs to filter gas bubbles would vary as a function of anesthetic management. The effects of halothane (1% inspired concentration [group 1, $n = 8$]), fentanyl (100 μg/kg IV, followed by 1 $\mu g \cdot kg^{-1} \cdot min^{-1}$ [group 2, $n = 7$]), and ketamine (10 mg/kg IV, followed by 0.2 $mg \cdot kg^{-1} \cdot min^{-1}$ [group 3, $n = 6$]) on the passage of bolus injections of air across the pulmonary circulation were studied in dogs by using transesophageal echocardiography to detect air in the left atrium or the aorta, or both. The thresholds for bolus air detection during halothane, fentanyl, and ketamine administration were 0.05 mL/kg (range 0.01–0.1), 0.5 mL/kg (range 0.2–1.0), and 0.35 mL/kg (range 0.1–0.5), respectively. We conclude that the threshold during fentanyl- or ketamine-induced anesthesia was significantly higher than during halothane-induced anesthesia. Therefore, halothane interferes with the capacity of the lungs to filter air from the pulmonary circulation.

(Anesth Analg 1992;75:720–3)

The lungs are an important physiologic filter for venous air emboli. This filtering capacity can be impaired by overloading the pulmonary vessels with gas infusion (1–3) and by the use of drugs (2) or anesthetics (4–6). In a previous study, we demonstrated that the threshold for transpulmonary passage of a venous air embolism was higher during pentobarbital-induced anesthesia, with or without halothane, than during anesthesia with halothane alone (4). We did not determine whether halothane decreased or pentobarbital increased the threshold compared with unanesthetized animals, because the transesophageal echocardiographic probe could not be successfully used in awake dogs. However, the study demonstrated that anesthetics could exert important effects on the outcome of both clinical and experimental venous air emboli.

Fentanyl and ketamine have been extensively used as intravenous anesthetics both in humans and in laboratory animals; however, there have been no previous reports concerning the influence of these anesthetics on outcome after venous air embolism. In this study, we assessed the effects of fentanyl and ketamine on the threshold for transpulmonary passage of venous air emboli in dogs.

Methods

Twenty-one mongrel dogs weighing between 10 and 15 kg (12.0 ± 1.0 kg [mean ± SD]) were studied in a protocol approved by the Institutional Animal Care and Use Committee. Animal care followed the institutional guidelines for animal experimentation.

The dogs were randomly separated into three groups that were anesthetized with halothane (group 1, $n = 8$), fentanyl (group 2, $n = 7$), and ketamine (group 3, $n = 6$). Anesthesia was induced with halothane (2%–4% inspired concentration) administered by mask, intravenous fentanyl (100 μg/kg) over 20 min, or intravenous ketamine (10 mg/kg) over 20 min. The dogs were placed in the supine position. After tracheal intubation, their lungs were mechanically ventilated with a mixture of oxygen/nitrogen (1:2) to achieve a Pa_{CO_2} of 35–40 mm Hg. After induction, anesthesia was maintained using the following doses: halothane, 1.0% inspired concentration; fentanyl, 1.0 $\mu g \cdot kg^{-1} \cdot min^{-1}$; or ketamine, 0.2 $mg \cdot kg^{-1} \cdot min^{-1}$. The dogs were paralyzed with pancuronium bromide (0.2 mg/kg), with supplemental doses administered every hour. The esophageal temperature was maintained at 37.5 ± 0.5°C with a heating blanket and an infrared light.

Under topical anesthesia with 1% lidocaine, the following procedures were undertaken. A 5F pulmonary artery thermodilution catheter (Edwards Laboratories, Inc., Santa Ana, Calif.) was inserted into the main pulmonary artery through the femoral or the right external jugular vein. A 5F pigtail catheter (Cook Group Company, Bloomington, Ind.) was inserted into the left ventricle through the right carotid artery to measure the left ventricular end-diastolic pressure. Another catheter was inserted through the left external jugular vein into the right atrium to measure the right atrial pressure. For systemic arterial pressure measurements and blood sampling, a catheter was inserted in a femoral artery. A 3.5-MHz transesophageal M-mode/two-dimensional, changeable echocardiographic probe (Aloka Industries Ltd., Tokyo, Japan), interfaced with an echoinstrument (model SSD-110, Fukuda Denshi Inc., Tokyo, Japan), was inserted into the esophagus for air detection (4,7,8). The probe was positioned so that the left atrium and the aortic cavity could be visualized simultaneously with the M mode. The diameter of the air bubbles at the tip of the pulmonary artery catheter varied between 1.4 and 3.0 mm when infused into stationary saline at an air dose of 1.4 and 180 mL/min, as verified by a microvideoscopic technique (Zeiss, Zurich, Switzerland and Hitachi, Tokyo, Japan).

After a 30-min period of stabilization under the selected anesthetic conditions, control hemodynamic measurements were made, and 0.2 mL/kg of air was injected over a 5-s period through the pulmonary artery port of the pulmonary artery catheter to avoid passage through possible intracardiac septal defects. The presence of air in the left atrium or the aorta, or both, was validated by a scratchlike or flufflike appearance on the echocardiogram by an observer who was unaware of the type of study anesthesia. If no air was detected, additional bolus doses of 0.5 and 1.0 mL/kg were injected. At least 20 min was allowed between incremental air injections. If air was detected on the echocardiogram after a 0.2-mL/kg injection of air, decreasing doses of 0.1, 0.05, and 0.01 mL/kg of air were injected. In each dog, the minimal quantity of injected air required for detection in the left atrium or the aorta, or both, was regarded as the threshold value for transpulmonary passage of venous air.

Mean arterial pressure, right atrial pressure, mean pulmonary arterial pressure (MPAP), heart rate, cardiac output (CO), and left ventricular end-diastolic pressure (LVEDP) were measured before (as the baseline value for each air injection) and 30 s after air injection. Body surface area (BSA) (m^2) was calculated as $0.112 \times \text{weight (kg)}^{2/3}$. Cardiac index (CI) was defined as CO/BSA. Pulmonary vascular resistance index (PVRI, $\text{dyne}\cdot\text{s}\cdot\text{cm}^{-5}\cdot\text{m}^2$) was calculated as (MPAP − LVEDP) × 79.9/CI. To calculate ve admixture, arterial and mixed venous blood sa were obtained simultaneously in plastic prehe ized syringes and iced immediately before analyzed within 10 min on an automated ana (ABL2, Radiometer, Copenhagen, Denmark). rial blood gas tensions were corrected for body perature. Alveolar oxygen tension (P_{AO_2}) was lated using the formula:

$$P_{AO_2} = (P_B - P_{H_2O})(F_{IO_2}) - P_{aCO_2}/R,$$

where F_{IO_2} is the fraction of inspired oxygen, the arterial carbon dioxide partial pressure, P barometric pressure, and R the respiratory quo assumed to be 1.0. Water vapor pressure (P_{H_2O} corrected for temperature. A standard shunt fo was used for calculating the shunt fraction:

$$Qs/Qt = 100 \times (Cc_{O_2} - Ca_{O_2})/(Cc_{O_2} - C\bar{v}_{O_2}),$$

where Qs/Qt is the shunt fraction, Cc_{O_2} the calc capillary oxygen content obtained from the al air equation, Ca_{O_2} the arterial oxygen content lated as (1.35 × hemoglobin × % saturation) + × P_{AO_2}, and $C\bar{v}_{O_2}$ the mixed venous oxygen co calculated using $P\bar{v}_{O_2}$ obtained from the pulm artery catheter.

The threshold data were analyzed using the Kr Wallis test for analysis of variance and the Whitney U-test. The baseline hemodynamic before each bolus air injection within each anes procedure were compared using an analysis of va for all measurements. When there was no diff among the baseline values, the individual val bolus air injection was compared with its baseline (the value before the air injection) by the paire dent's *t*-test. Comparisons of the hemodynamic obtained during halothane anesthesia (a control during the other anesthetic procedures were perf using Dunnett's method. $P < 0.05$ was consi significant for all tests.

Results

The bolus doses of air required for passage in systemic circulation are shown in Table 1. Duri halothane anesthesia, the threshold was 0.05 m The threshold with fentanyl (0.5 mg/kg) or ket (0.35 mg/kg) was significantly greater. There w significant difference between the threshold d anesthesia with fentanyl or ketamine. No an died during air injection.

The MPAP and PVRI increased significantl ing each bolus air injection at each dose (>0.1 m with each agent. In dogs anesthetized with fe and ketamine, MPAP and PVRI increased more in halothane-anesthetized dogs. The shunt fr

increased significantly from baseline in dogs anesthetized with halothane or ketamine (Table 2).

Mean arterial pressure and heart rate did not change significantly after air injection in any group.

Discussion

This study demonstrated that during halothane-induced anesthesia, the threshold for transpulmonary passage of bolus injections of air into the pulmonary artery was lower (0.05 mL/kg) than that observed during anesthesia with fentanyl (0.5 mL/kg) or ketamine (0.35 mL/kg) (Table 1). These results suggest that the lung is an effective filter for gas bubbles during administration of these intravenous anesthetics and that this filtering ability is greatly impaired by the use of halothane. We have previously shown that pentobarbital also increased the threshold for air passage compared with that during halothane anesthesia (4). These two studies showed the lower filtering ability of air during halothane anesthesia.

The mechanism by which anesthetics influence the threshold for transpulmonary passage of venous air embolism is unknown but may be mediated through effects on pulmonary blood flow at the level of the arterioles, shunt vessels, or capillaries. Every bolus injection >0.1 mL/kg increased the MPAP and PVRI during all anesthetics, and fentanyl- and ketamine-anesthetized dogs showed a greater increase in MPAP and PVRI compared with halothane-anesthetized dogs (Table 2). Because the arteriole is the major determinant of MPAP and PVRI, we might expect an arteriolar effect to be reflected in this change in MPAP and PVRI. In previous studies in pentobarbital-anesthetized dogs, air bubbles lodged in pulmonary arterioles were eliminated from that site (9) in proportion to the MPAP level (10,11).

Furthermore, the threshold for transpulmonary passage of air in the halothane-anesthetized dogs was smaller (0.12–0.75 mL) and showed no apparent change in any pulmonary measurement or calculation. Based on the conditions of our study, we cannot speculate about contributing mechanisms, such as inhibition of hypoxic pulmonary vasoconstriction (5) or opening of possible intrapulmonary shunts such as the Sperr arteries (12) during halothane anesthesia.

Anesthetic effects on transpulmonary arteriovenous shunting were analyzed by Cheney et al. (13) who measured shunt fraction during venous embolism in pentobarbital-anesthetized dogs using a radioactive microsphere technique. During embolism, pentobarbital caused a 2.5-fold increase of PVRI relative to control dogs, with no effect on cardiac output or shunt fraction. This results in an increase of resistance against emboli to passage through the shunt fraction, which may coincide with the increased threshold of the transpulmonary passage of bolus injections of air into the pulmonary artery in pentobarbital-anesthetized dogs (4).

We did not use additional bolus injections of air much larger than the threshold dose so as to avoid the possible deterioration of the pulmonary vasculature

MPAP, mean pulmonary artery pressure; PVRI, pulmonary vascular resistance index; Qs/Qt, intrapulmonary shunt fraction.
Values are mean ± SD. There were no differences between baseline values within each anesthetic procedure (analysis of variance).

[a] $P < 0.05$ compared with baseline just before each bolus air injection by paired *t*-test.

[b] $P < 0.05$ compared with halothane.

by repetitive air embolism. Furthermore, quantitative assessment of air in the left heart was difficult using transesophageal echocardiography. Therefore, we could not compare the effects of embolism of much larger doses of air among anesthetics; however, our data permit speculation that fentanyl or ketamine may protect against paradoxical air embolism relative to halothane anesthesia. Further studies are indicated to assess the effects of other intravenous and inhaled anesthetics.

This potential prophylactic effect may merit consideration among the many factors involved in selection of an anesthetic regimen, particularly in surgical procedures thought to have the highest risk for venous air embolization, such as craniectomy, cardiac surgery or right ventriculotomy, and peritoneal insufflation, especially considering the increasing popularity of laparoscopic techniques in general surgery that use hyperbaric gas insufflation (14,15).

In summary, we found that during fentanyl or ketamine anesthesia, the threshold doses for the transpulmonary passage of bolus injections of air into the pulmonary arteries of dogs were significantly higher than during anesthesia with halothane.

Isoflurane and Nitrous Oxide: Comparative Impact on Cerebrospinal Fluid Pressure in Patients With Brain Tumors

Richard Jung, MD, Ruth Reinsel, PhD, William Marx, MD, Joseph Galicich, MD, and Robert Bedford, MD

Anesthesiology Service and Neurological Surgery Service, Memorial Sloan-Kettering Cancer Center, and Cornell University Medical College, New York, New York

The relative effects on cerebrospinal fluid pressure (CSFP) of equipotent concentrations of isoflurane and N_2O were compared in 20 patients with brain tumors who had lumbar subarachnoid catheters in place. Patients were randomly assigned to receive one of two anesthetic sequences: group 1, 0.7% end-tidal isoflurane in O_2, which was changed to 70% N_2O in O_2; or group 2, 70% N_2O in O_2, which was changed to 0.7% end-tidal isoflurane in O_2. End-tidal Pco_2 and percent end-tidal N_2O and isoflurane were monitored by mass spectrometry from just before changing anesthetics (time = 0 min) until the end of a 20-min observation period (time = 20 min). Ventilation was held constant at $Paco_2 = 36 \pm 1$ mm Hg (mean ± SE). The patients in group 1 sustained an increase in CSFP that reached a maximum of 33% above the value at 0 min, despite a 3-mm Hg decrease in $Paco_2$ ($P < 0.05$). By contrast, CSFP remained unchanged in group 2. Although the absolute increase in CSFP after replacement of isoflurane/O_2 by N_2O/O_2 anesthesia was relatively small (9 ± 1 to 12 ± 2 mm Hg; $P < 0.05$), the absence of a similar effect in patients where N_2O was replaced by isoflurane suggests that replacement of isoflurane by an equipotent concentration of N_2O is more likely to lead to an increase in CSFP in patients with altered intracranial dynamics than is replacement of N_2O by isoflurane.

(Anesth Analg 1992;75:724–8)

Virtually all inhaled anesthetics are capable of causing undesirable increases in cerebrospinal fluid pressure (CSFP) in patients who have compromised intracranial elastance. Despite this, these drugs are often chosen for patients undergoing craniotomy. At the present time, both N_2O and isoflurane are widely used in neuroanesthesia practice, although both agents are associated with increases in CSFP, even if combined with hyperventilation (1,2). Recent studies of cerebral blood flow (CBF) in humans (3) and rodents (4) indicate that N_2O is a more potent cerebral vasodilator than is an equipotent dose of isoflurane. Because changes in CBF do not always correlate with changes in CSFP, and even small differences in cerebrospinal fluid dynamics may be important in patients who have critical intracranial lesions, we compared the impact of equipotent doses of isoflurane and N_2O on CSFP in patients with brain tumors, using a randomized, crossover protocol, with each patient serving as his or her own control.

Methods

The subjects of this study were 20 patients scheduled for excision of supratentorial tumors not located near the base of the skull. The protocol was approved by the local Institutional Review Board, and written, informed consent was obtained from each patient on the evening before surgery. The preoperative computed tomography scan of each patient's head was evaluated with regard to the following features: (a) widest diameter of tumor (mm); (b) lateral shift of midline structures (mm); and (c) amount of peritumoral edema on a scale of 0–3+, where 1+ = a small rim of edema, 2+ = a wide rim of edema, and 3+ = edema extending throughout the ipsilateral hemisphere.

All patients received dexamethasone (20 mg/day) for a period of 3–4 wk before surgery. Preoperatively, all were alert, verbally responsive, and oriented; none had neurologic signs of elevated CSFP before induction of general anesthesia.

No premedication was administered. General anesthesia was induced with thiopental (5 mg/kg IV) in divided doses; vecuronium (0.1 mg/kg) was used to facilitate endotracheal intubation; and ventilation was controlled to maintain a constant end-tidal CO_2 ten-

Table 1. Demographic Data for the Two Patient Groups

Anesthetic sequence	Pt age (yr)	Primary tumors	Secondary tumors	Tumor diameter (mm)	Brain edema scale (0–3+)[a]	Midline shift (mm)
Group 1 (isoflurane to N_2O; *n* = 10)	51 ± 5	5	5	31 ± 3	1 ± 0.3	5 ± 1
Group 2 (N_2O to isoflurane; *n* = 10)	51 ± 5	6	4	35 ± 6	2 ± 0.3	5 ± 2

Values are mean ± SE or number.

[a] 1+ = small rim of edema; 2+ = wide rim of edema; 3+ = edema extending throughout the ipsilateral hemisphere.

sion between 30 and 35 mm Hg (Perkin-Elmer Mass Spectrometer).

Patients were randomly assigned to one of two anesthetic techniques: group 1, 0.7% end-tidal isoflurane in O_2; and group 2, 70% N_2O in O_2. After anesthesia was induced, a 20-gauge radial artery catheter and an 18-gauge lumbar subarachnoid catheter were inserted for continuous monitoring of blood pressure and CSFP, respectively. Pressure transducers were zeroed to the level of the midcranium. Continuity of the cerebrospinal fluid compartment was verified by an elevation in CSFP with elevation of the patient's head. Heart rate was determined from electrocardiographic lead II.

During a period of stable hemodynamics and absent surgical stimulation (approximately 30 min after induction of anesthesia), baseline heart rate, blood pressure, and CSFP were recorded, and a blood sample for determination of arterial blood gas tensions was collected anaerobically. Immediately thereafter, at time (T) = 0 min, the inspired anesthetic was abruptly changed as follows: in group 1, isoflurane was discontinued, and 70% N_2O in O_2 was begun; in group 2, N_2O was discontinued, and isoflurane, 1%–2% inspired concentration, was adjusted such that end-tidal isoflurane concentration was constant at 0.7%. The fresh-gas flow rate was 10 L/min throughout the study to facilitate rapid uptake and elimination of anesthetics.

After the change in anesthetic, CSFP and cardiovascular variables were recorded continuously during a 20-min observation period. End-tidal N_2O and isoflurane concentrations were tabulated, and arterial blood gas tensions were determined just before changing anesthetics (T = 0 min) and at the end of the 20-min observation period (T = 20 min). Throughout the data collection period, end-tidal CO_2 tension was held constant, and external sensory stimuli were avoided. After acquisition of data was completed, each patient was hyperventilated to lower CSFP to approximately 5 mm Hg (end-tidal P_{CO_2} = 20–25 mm Hg). Anesthesia was supplemented with either an opioid or additional isoflurane, and surgery commenced.

Data acquired at T = 0 and 20 min were subjected to statistical comparisons using analysis of variance for repeated measures and Student's *t*-test for paired and nonpaired data, as appropriate. Furthermore, to minimize the effect of minute-to-minute variability, CSFP measurements obtained after T = 0 min were averaged over four successive 5-min periods. These four averages were then subjected to repeated measures analysis of variance to separate the main effects of the factors drug and time, as well as their interaction (Drug × Time). To identify where differences occurred, orthogonal contrasts were computed between the T = 0 min values and those of the successive 5-min periods. For all comparisons, $P < 0.05$ was regarded as significant.

Results

Demographic data for the patients are shown in Table 1. There were no differences between the two groups with regard to patient age, origin of brain tumor, tumor size, shift of midline intracranial structures, or amount of peritumoral brain edema seen preoperatively on computed tomography scan.

Table 2 summarizes the baseline and final values for the measured variables during the 20-min observation period. In group 1 (isoflurane to N_2O), there was a small but statistically significant 33% increase in CSFP, despite a 3-mm Hg decrease in Pa_{CO_2}. By contrast, no change in CSFP occurred in group 2 (N_2O to isoflurane). There was no difference between the two groups with regard to baseline CSFP, nor was there a change in mean arterial pressure or heart rate in either group at any time during the study. For both groups, the end-tidal concentrations of isoflurane and N_2O were at equipotent doses (5) just before changing anesthetics (T = 0 min) and at the end of the observation period (T = 20 min). At the end of the data collection period, regardless of the anesthetic administered, CSFP was easily lowered to a target of approximately 5 mm Hg by institution of hyperventilation (Pa_{CO_2} = 20–25 mm Hg).

Figure 1 shows the changes in mean CSFP during

Table 2. Measurements at Beginning and End of 20-Minute Observation Period in the Two Study Groups

	Group 1 (Isoflurane to N_2O)		Group 2 (N_2O to isoflurane)	
	0 Min	20 Min	0 Min	20 Min

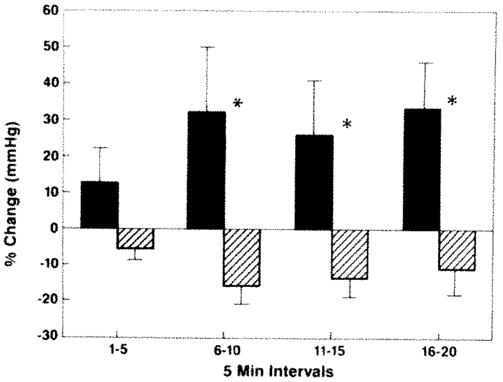

Figure 1. Changes in CSFP during the 20-min observation period for patient groups 1 (*solid bars*) and 2 (*shaded bars*). Each bar represents the average CSFP during each successive 5-min interval. Data are plotted as percent change from CSFP at time = 0 min. Values are mean ± SEM. *$P < 0.03$ vs value at time = 0 min.

sequential 5-min periods for the two anesthetic groups studied. The drug × time interaction was significant (F4,72 = 4.33; $P < 0.004$), indicating that the time-course of change in CSFP differed significantly between the two groups. Patients in group 1 sustained a gradual increase in CSFP that became statistically significant during the second 5-min interval and persisted unchanged for the remainder of the observation period. By contrast, CSFP was unchanged from baseline values in the patients in group 2. No statistically significant change in any vital sign occurred in any time period during data collection.

Discussion

Replacement of volatile anesthetics by N_2O is frequently used during general anesthesia, usually when arterial hypotension is thought to be caused by the volatile anesthetic. This study demonstrates that in patients who have compromised intracranial dynamics, replacement of isoflurane by an equipotent dose of N_2O is likely to result in an increase in CSFP, potentially resulting in compromised cerebral perfusion pressure. The increase in CSFP occurred despite a small but statistically significant decrease in Paco$_2$. Our CSFP data are in agreement with recently published studies examining the relative cerebrovascular effects of these two anesthetics at equipotent doses (3,4). Although the concentrations of N_2O and isoflurane that we studied would not produce adequate surgical anesthesia, we believed that it was important to examine the relative effects of these anesthetics at equipotent doses and that it was legitimate to use light levels of anesthesia in the absence of auditory and tactile stimuli.

Nitrous oxide increases CSFP in humans predominantly during the first 10 min of administration (1), concomitant with uptake of the anesthetic. After uptake is substantially completed, however, no further increase in CSFP would be expected to occur; indeed, this was observed in group 1 patients, who had been receiving isoflurane and were changed to N_2O. A similar time-course was reported by Archer et al. (6) for cerebral blood volume increases when they added 50% N_2O to opioid anesthesia.

It might be argued that because isoflurane is more lipid soluble than N_2O, our findings in the group 1 patients reflect the impact of both incoming N_2O and residual isoflurane in their brains and cerebral vessels, despite the fact that end-tidal isoflurane was undetectable at T = 20 min. If this were the case, it in no way detracts from our conclusion that substitution of isoflurane by N_2O may result in undesirable increases in CSFP in patients with diminished intracranial elastance.

The limitations imposed by the 20-min observation period likewise apply to group 2 patients. Thus, it is possible that the cerebral vasculature might not have achieved equilibrium with the incoming isoflurane. This would cause the brain concentration of isoflurane at the end of data collection to be less than equipotent with the 70% N_2O that preceded it. This might explain the lack of change in CSFP in group 2, which otherwise might be expected to decrease by an amount similar to the CSFP increase in group 1.

Archer et al. (6), however, noted that the effects of 2% isoflurane on cerebral blood volume were complete within 20 min of initiating administration of the anesthetic. Furthermore, the lack of any trend in CSFP in our group 2 patients at least suggests that continued uptake of 0.7% isoflurane would not have caused an increase in CSFP if the observation period had been longer.

One method for avoiding the problems of simultaneous anesthetic uptake and elimination would have been to add 1/2 MAC multiples of one agent to the other, as has been done in some recent studies of CBF (3,4). This protocol, however, is subject to possible error in interpretation, owing to the known synergistic impact of N_2O and volatile anesthetic on CBF (7). Accordingly, we chose to compare the effects of the two anesthetics at a point that we hoped would be near the end of uptake for one and elimination of the other.

Given the observed increase in CSFP that occurred in group 1 after the change from isoflurane to N_2O, it is somewhat unexpected that the CSFP at T = 0 in group 2 was not higher than that in group 1. Although this may have been the result of the somewhat lower initial $Paco_2$ in group 2 versus group 1, it also may have been due to unfortunate randomization, with patients in group 1 who were less prone to elevations in CSFP than those in group 2. Again, this in no way detracts from our observation that replacement of isoflurane by N_2O raises CSFP in patients with compromised intracranial dynamics.

The use of near normocarbia in the present study requires explanation. We decided to maintain normocarbia ($Paco_2$ = 35–40 mm Hg) throughout the protocol so that any drug-induced change in intracranial volume could be identified as a change in CSFP. Although hyperventilation to a $Paco_2$ of 20–25 mm Hg more closely resembles usual neuroanesthetic practice, the resultant reduced cerebral blood volume would have placed the patients on the horizontal portion of their CSFP-intracranial volume relationship, thus obscuring any changes induced by the anesthetics under investigation. We speculate that we were able to measure drug-induced changes in CSFP in these patients with brain tumors because relative normocarbia placed their CSFP-intracranial volume relationship close to the "knee" of its hyperbolic curve. We believe that it is likely that if our patients had had overt intracranial hypertension at T = 0, we would have observed far greater increases in CSFP when isoflurane anesthesia was changed to N_2O.

Experimental support for this speculation is provided by Archer et al. (6) who noted that the addition of 50% N_2O to an opioid anesthetic during normocapnia caused an 11% increase in cerebral blood volume, whereas there was no increase when $Paco_2$ was 20–30 mm Hg. Similarly, when 2% isoflurane was added to the same opioid anesthetic at normocarbia, there was a 31% increase in cerebral blood volume, whereas there was only a 15% increase in cerebral blood volume at $Paco_2$ = 20–30 mm Hg.

Clinical studies also support our speculation: 66% N_2O has long been known to increase CBF (8) and has been associated with large increases in CSFP, even in hyperventilated patients who had compromised intracranial compliance (1). By contrast, the CBF effects of 1.0% isoflurane (added to 60% N_2O/fentanyl anesthesia) have been found to be minimal in patients with brain tumors (9). When an increase in CSFP has been reported during isoflurane anesthesia, it was in the presence of normocarbia (10) or during modest hyperventilation in patients who had computed tomography evidence of seriously compromised intracranial compliance (2).

An additional advantage to performing this study at near normocarbia is that it avoids the confounding influence of anesthetic-induced differences in cerebrovascular responses to hypocapnia. Drummond and Todd (11) have shown in cats that there is a more profound reduction in CBF during the change from normocapnia to hypocapnia with isoflurane than with N_2O anesthesia. If this were true in humans, then one might anticipate that hyperventilation would be less effective in reducing CSFP during N_2O anesthesia than during isoflurane anesthesia.

Although we found that hyperventilation instituted after T = 20 min resulted in prompt reduction of CSFP to approximately 5 mm Hg in both groups of patients, we did not attempt to compare the impact of the different anesthetics on CSFP response to hypocapnia. The decreases in CSFP, however, were consistent with those observed in animal studies using N_2O (6) and in human studies using isoflurane (10).

In summary, we found that in normocapnic patients who have compromised intracranial dynamics, changing from isoflurane to an equipotent concentration of N_2O resulted in increases in CSFP. Although this change in anesthetic is frequently used clinically, we conclude that it may be problematic in patients at risk for intracranial hypertension.

Effect of Partial Neuromuscular Blockade on Intraoperative Electromyography in Patients Undergoing Resection of Acoustic Neuromas

Robert L. Lennon, DO, Michael P. Hosking, MD, Jasper R. Daube, MD, and
Jeffrey O. Welna, DO

Departments of Anesthesiology and Neurology, Mayo Clinic, Rochester, Minnesota

---

Intraoperative electromyographic monitoring of the facial nerve during acoustic neuroma excision provides early detection of nerve injury and improved outcome. To determine whether a useful level of peripheral neuromuscular blockade could be achieved without compromise of facial electromyographic monitoring, we studied 10 patients undergoing resection of acoustic neuroma. Facial nerve monitoring was accomplished by placement of wire electrodes in the orbicularis oris, orbicularis occuli, and mentalis muscles. Peripheral neuromuscular blockade was assessed by recording unprocessed hypothenar compound muscle action potentials (CMAPs). After induction of anesthesia, an infusion of atracurium (1.0 $\mu g \cdot kg^{-1} \cdot min^{-1}$) accompanied by a bolus dose of 50 $\mu g/kg$ was administered. The infusion was then increased in increments of 0.5 $\mu g \cdot kg^{-1} \cdot min^{-1}$ until a 50% reduction in hypothenar single-twitch CMAP was obtained. Facial nerve function was continuously monitored by comparison of facial CMAPs produced by stimulation of the nerve proximal and distal to the tumor bed. The mean (±SD) infusion rate of atracurium was 2.55 ± 0.75 $\mu g \cdot kg^{-1} \cdot min^{-1}$. Decrements in facial nerve CMAPs were detected in 6 of 10 patients, and all demonstrated moderate to severe facial nerve dysfunction. In no patient was an unexpected deficit present postoperatively. Moderate degrees of peripheral neuromuscular blockade can be achieved without compromising facial nerve electromyographic monitoring.

(Anesth Analg 1992;75:729–33)

Acoustic neuromas are the most common benign tumors of the posterior cranial fossa. Cranial nerve involvement with acoustic neuromas is common (1–7). Auditory nerve impairment is present in almost all cases. In addition, nerve conduction studies before any surgical procedures reveal electrical evidence of neuropathy of the facial nerve in 83% of patients (1). The close proximity of the facial auditory nerves within the internal auditory canal accounts for the combined cranial nerve involvement commonly seen with acoustic neuromas (Figure 1). Intraoperative electromyographic (EMG) monitoring of the facial nerve during acoustic neuroma resection allows early detection of surgical stimulation and reduces nerve dysfunction postoperatively. The gains achieved by advances in monitoring technology, however, may place additional constraints on the anesthetic management of these patients. Neuromuscular blocking agents have been avoided for these types of procedures to exclude any compromise of facial EMG monitoring capability. Simultaneous monitoring of brainstem auditory evoked potentials may limit the use of volatile anesthetic agents.

The retrosigmoid approach to acoustic neuroma resection maximizes facial nerve preservation. However, the additional hazards of posterior fossa exploration are encountered. Delicate microsurgical resection of these tumors demands absolute immobility of the patient. Close proximity of the trigeminal nerve and brainstem structures may result in unintentional stimulation of these structures, producing rapid motor or hemodynamic reflexes. Ensuring immobility in the lightly anesthetized, unparalyzed patient under these circumstances may be difficult. The intent of this report is to examine the possibility of introducing controlled levels of neuromuscular blockade while preserving the ability to adequately monitor facial nerve EMGs.

Methods

Ten patients undergoing acoustic neuroma resection with standard facial nerve EMG monitoring were studied. The protocol was approved by the Mayo Institutional Review Board, and written, informed

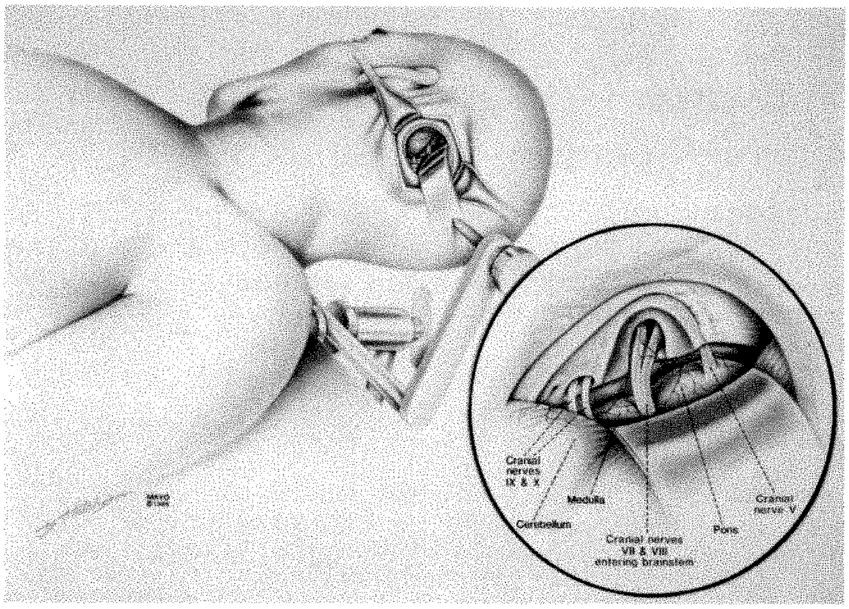

Figure 1. Diagram of the operative field during acoustic neuroma resection demonstrating the proximity of the auditory and facial nerves. (Modified with permission from Harner SG, Daube JR, Ebersold MJ, Beatty CW. Improved preservation of facial nerve function with use of electrical monitoring during removal of acoustic neuromas. Mayo Clin Proc 1987;62: 92–102.)

consent was obtained from all patients. Preoperative electrophysiologic studies of facial nerve function included EMG and nerve conduction studies, and these results were evaluated by a staff electromyographer. In all patients, a posterior fossa (retrosigmoid) approach was used. All patients were monitored by electrocardiography, pulse oximetry, and esophageal temperature probe. An intraarterial catheter was inserted in the radial artery and zeroed at midcardiac level. Expired gas concentrations were monitored by mass spectroscopy.

Intraoperative monitoring of facial nerve function consisted of two components. First, visual and auditory monitoring of facial nerve EMG activity was used during surgical exposure. Second, compound muscle action potentials (CMAPs) were recorded in response to direct stimulation of the facial nerve by the surgeon after exposure of the nerve.

An electromyographer monitored intraoperative facial nerve function continuously during the operative procedure. Electromyographic monitoring was accomplished by preoperative placement of wire electrodes in muscles innervated by the facial nerve. Insulated nickel and chromium wire electrodes (0.03 mm) were inserted into the orbicularis oris, orbicularis occuli, and mentalis muscles, with a reference electrode placed within the same muscle. The wires were connected to preamplifiers attached to the operating table by probit connectors. Recordings were made at 200-μV gain, with 32-Hz low and 16-kHz high filter settings. Oscilloscope sweep speed was 10 ms/cm. A filter switch on the cautery pedal suppressed cautery noise. Electromyographic activity was recorded continuously on magnetic tape as well as viewed on the oscilloscope. In addition, the signal was played over an audio amplifier and loudspeaker for continuous auditory monitoring by the surgeon.

The CMAPs of the facial nerve were produced by direct constant-voltage stimulation of the nerve in the surgical field. Square-wave pulses (0.05 ms, 10–50 V) via a bipolar electrode were delivered to the muscle through a silver-cadmium alloy wire. The CMAPs were recorded by the wire electrodes in the muscle or from 8-mm tin disks applied with collodion over the nasalis and mentalis muscles. Baseline responses were recorded before induction of anesthesia. Responses were tape-recorded and photographed on direct writing paper. Neuronal damage was determined by the relative amplitudes of the CMAPs at the most proximal and distal stimulation sites.

Peripheral neuromuscular blockade was monitored by recording unprocessed hypothenar CMAPs elicited by stimulation of the ulnar nerve at the wrist. Wire electrodes were inserted along the ulnar nerve, and surface tin disk electrodes were placed over the belly of the hypothenar muscles and secured with collodion to record the CMAPs. The peak-to-peak changes were recorded on photosensitive paper for measurement.

Anesthesia was induced with thiopental (3–5 mg/kg) and fentanyl (5–10 μg/kg). Tracheal intubation was facilitated with atracurium (0.4 mg/kg). Anesthesia was supplemented with a continuous infusion of fentanyl (1–2 $\mu g \cdot kg^{-1} \cdot h^{-1}$). Mechanical ventilation was initiated immediately after endotracheal intubation with 50% nitrous oxide in oxygen, and controlled hyperventilation was begun when clinically indicated. Isoflurane was introduced as needed and was maintained below 1% end-expired concentration.

Hypothenar muscle EMGs were recorded after ulnar nerve stimulation at 2 and 20 Hz for 2–3 s, with 0.2-ms duration at 15-min intervals until complete recovery was observed consistent with preinduction baseline values. After recovery of neuromuscular function and observation of the return of neurotonic discharges from the facial nerve, the atracurium infusion was initiated. An initial infusion rate of 1.0 $\mu g \cdot kg^{-1} \cdot min^{-1}$ preceded by a bolus dose of 50 μg/kg was administered in an effort to rapidly reach a stable level of neuromuscular blockade. At 10-min intervals, we administered a bolus dose of 25 μg/kg of atracurium and increased the infusion in increments of 0.5 $\mu g \cdot kg^{-1} \cdot min^{-1}$. Once a 50% decrement of the hypothenar single-twitch CMAP was obtained, the infusion rate was fixed and the level of peripheral neuromuscular blockade was evaluated every 10 min. Adjustments to the infusion rate were made as necessary to maintain a 50% decrement in the hypothenar CMAP amplitude.

During critical periods in the operative procedure, the facial nerve was directly stimulated with a bipolar electrode by the surgeon. The facial CMAPs generated were used as a guide for further dissection and as a gauge of intraoperative preservation of facial nerve function. If at any time the electromyographer determined that the quality of monitoring was compromised, the infusion would be decreased or terminated as needed.

After the head dressing had been applied, the anesthetic was terminated. Grip strength, positive expiratory pressure, negative inspiratory force, tidal volume, and head lift were evaluated to clinically assess the presence of muscle weakness. Residual neuromuscular blockade was antagonized with intravenous edrophonium (0.5 mg/kg) and atropine (7 μg/kg). Extubation of the trachea was performed when the patient was awake and following commands and neuromuscular blockade had been effectively antagonized. Postoperatively, facial nerve function was evaluated by a neurologist and the neurosurgeon.

Results

Preoperatively, all 10 patients demonstrated clinically normal facial nerve function. Five patients had large tumors (>2.5 cm), and five had medium-sized tumors (1.0–2.5 cm). Electromyographic analysis before surgery revealed normal function in four patients, mild facial nerve neuropathy in five patients, and a moderate degree of neuropathy in one patient.

Adequate intraoperative facial nerve monitoring was accomplished in all patients in the presence of moderate degrees of peripheral neuromuscular blockade. The maximal decrement in facial nerve EMG amplitude observed during 50% reduction of hypothenar twitch height was 6% from control. In six patients, impaired facial nerve function was detected by intraoperative facial EMG analysis. Impaired facial nerve function was indicated by loss or reduction of facial CMAPs after direct intraoperative stimulation of the nerve proximal to the tumor with preservation of facial CMAP following stimulation of the facial nerve distal to the tumor bed (Figure 2). Two patients demonstrated a reduction in the proximal, relative to the distal, CMAP, whereas four patients experienced complete loss of the proximal facial nerve CMAP. All six patients had moderate to severe facial nerve dysfunction postoperatively. In no patient was an unexpected deficit present postoperatively.

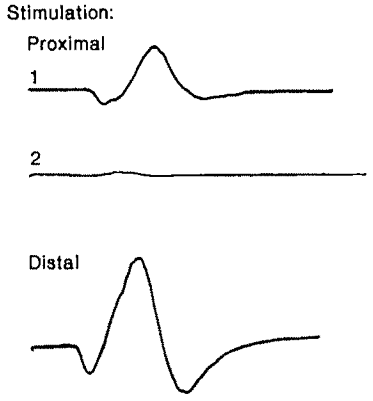

Figure 2. Facial EMG demonstrating (*1*) initial proximal stimulation; (*2*) loss of proximal EMG after acoustic neuroma resection and distal stimulation.

Stable levels of neuromuscular blockade were readily achieved and maintained in all patients. In all patients, the hypothenar CMAPs were reduced to 50% of control, whereas facial nerve CMAPs were spared, and continuous monitoring of facial nerve function was possible. To achieve a 50% decrement in first-twitch amplitude, the mean maintenance infusion rate was 2.55 ± 0.75 (SD) $\mu g \cdot kg^{-1} \cdot min^{-1}$, and the mean total bolus dose was 118 ± 32 μg/kg. The mean duration of atracurium infusion was 162.7 ± 39.8 min. It was not necessary to decrease or discontinue the atracurium infusion in any patient. After emergence from anesthesia, but before antagonism of neuromuscular blockade, all patients had muscle weakness manifested by decreased grip strength and impaired ventilatory mechanics. Muscle weakness resolved rapidly in all patients after administration of edrophonium and atropine.

Discussion

In patients undergoing acoustic neuroma resection, intraoperative EMG monitoring of the facial nerve has resulted in improved preservation of facial nerve function postoperatively (1).

The anesthetic management of these patients should provide hemodynamic stability while preserving an optimal environment for facial EMG and brainstem auditory evoked potential monitoring. To preserve facial nerve EMG monitoring, neuromuscular blockade has been avoided during resection of acoustic neuromas (1,2,5,6). The results of this study demonstrate the ability to achieve moderate levels of peripheral neuromuscular blockade while preserving facial EMG monitoring by careful titration of an intermediate-acting, nondepolarizing muscle relaxant.

The only previous evaluation of the effects of neuromuscular blockade on facial nerve monitoring during acoustic neuroma resection differed methodologically from the present study. Ho et al. (8) used mechanomyographic assessment of facial and hypothenar function by means of accelerometery. A single large bolus dose of atracurium was administered, and recovery of facial and hypothenar responses were compared. No patients demonstrated facial nerve dysfunction postoperatively, preventing an evaluation of the potential for false-negative results. In addition, because EMG monitoring was not used and stable levels of neuromuscular blockade were not achieved, the impact of partial blockade on neurotonic discharges could not be evaluated. A strong correlation has been demonstrated between the intensity of neurotonic discharges and the extent of surgical trespass and postoperative facial nerve function (1).

The simple infusion protocol used in this study produced moderate levels of neuromuscular blockade while preserving facial nerve EMG potentials. Ease of administration, stability in normal saline solution, and rapid titratability and reversibility make atracurium an attractive choice for these purposes (9). Electromyographic monitoring of neuromuscular blockade is less sensitive to depression than mechanomyographic methods, and EMG values exceed corresponding mechanomyographic values by approximately 15% (10). Thus, a 50% decrement in the twitch height of the EMG correlates with a 65% reduction in twitch height measured by mechanomyographic means. This correlates with a receptor occupancy of 80%–85% (11). Although this level of blockade does not ensure complete paralysis, neuromuscular transmission is significantly reduced. Adequate surgical relaxation may occur with 55%–60% EMG twitch height reduction (10), levels approximated in this study.

Two of the six patients experiencing facial nerve EMG decrements demonstrated a partial reduction in amplitude without complete loss of the EMG signal. Partial preservation of facial nerve electrical function correlates well with long-term recovery of facial nerve function (12). The two patients in this study subsequently recovered facial nerve function. Thus, partial peripheral neuromuscular blockade did not impair the capacity of facial nerve EMG monitoring to detect facial nerve injury that was potentially reversible. In addition, the controlled level of neuromuscular blockade allowed rapid and predictable reversal of blockade at the end of the procedure. Four patients experienced complete loss of facial nerve CMAP during surgery, and all four experienced severe weakness or total facial nerve paralysis. All four patients had large tumors (>2.5 cm). These results are consistent with those reported by Moffat et al. (13) documenting a 79% rate of facial nerve division with large tumors. Previous reports may not have differentiated between anatomic and functional preservation of the facial nerve, thus implying a falsely low rate of facial nerve injury. This high-risk cohort permitted us to document for the first time the capacity to detect facial nerve injury during moderate degrees of peripheral neuromuscular blockade.

Intraoperative anesthetic management of patients undergoing acoustic neuroma resection is made more difficult by marked variation in the level of surgical stimulation due to intraoperative manipulation of the cranial nerves. The goals of anesthetic management include maintenance of hemodynamic stability while preserving an optimal environment for monitoring of cranial nerve function. Controlled infusion of atracurium titrated to a 50% reduction in hypothenar EMG twitch height did not impair the capacity of facial nerve EMG monitoring to detect facial nerve injury. The capacity to safely monitor facial nerve EMG activity during partial neuromuscular blockade has thus been demonstrated.

Comparison Among Intrathecal Fentanyl, Meperidine, and Sufentanil for Labor Analgesia

James E. Honet, MD, Valerie A. Arkoosh, MD, Mark C. Norris, MD, H. Jane Huffnagle, DO, Neil S. Silverman, MD, and Barbara L. Leighton, MD

Departments of Anesthesiology and Obstetrics and Gynecology, Division of Maternal Fetal Medicine, Jefferson Medical College, Thomas Jefferson University, Philadelphia, Pennsylvania

This study compared the analgesic efficacy of intermittent injections of intrathecal fentanyl (10 μg), meperidine (10 mg), or sufentanil (5 μg) administered to 65 parturients during the first stage of labor. The groups did not differ in onset or duration of effective analgesia. The meperidine group, however, had significantly lower pain scores once cervical dilation progressed beyond 6 cm. Side effects included mild pruritus and nausea. After intrathecal drug injection, variable decelerations of the fetal heart rate increased in the fentanyl and meperidine groups. All neonates had a 5-min Apgar score of 7 or more. We conclude that intermittent intrathecal injections of fentanyl, meperidine, or sufentanil can provide adequate first-stage labor analgesia. Meperidine appears to provide more reliable analgesia as the first stage of labor progresses.

(Anesth Analg 1992;75:734–9)

Intrathecal opioids relieve labor pain (1–3) with few of the systemic side effects associated with epidural injection of opioids and local anesthetics (4). Additionally, intrathecal opioids appear to have no effect on the fetus during either the intrapartum or immediate postpartum period (1–3).

Several studies describe the administration of intrathecal morphine during parturition (1–3,5). Morphine, a highly ionized, water-soluble opioid, produces analgesia of long duration but slow onset. This slow onset, plus a high incidence of side effects, such as nausea, vomiting, pruritus, and the potential for delayed respiratory depression, limit the usefulness of intrathecal morphine for labor analgesia. Intrathecal injection of a more lipid-soluble opioid leads to rapid relief of labor pain with fewer side effects, but the duration of analgesia is relatively short (6,7). Thus, in most patients, a single intrathecal injection of a lipid-soluble opioid is insufficient to produce analgesia for the entire duration of labor.

Recently developed small-gauge spinal catheters allow repeated intrathecal opioid injection (8). These catheters have been used successfully to provide labor analgesia by allowing administration of multiple intrathecal doses of a lipid-soluble opioid, such as fentanyl, meperidine, or sufentanil (9–13). Because no study has systematically compared these three drugs, we examined their analgesic efficacy, duration of action, and hemodynamic and other side effects during the first stage of labor.

Methods

Healthy women at term of pregnancy gave informed consent to participate in this prospective, double-blind study, approved by our Institutional Review Board. All patients were in active labor, with cervical dilation between 2 and 7 cm. Fetuses presented by the vertex, and fetal heart rate (FHR) traces appeared normal. Women with moderate or severe pregnancy-induced hypertension or multiple gestations were excluded from the study. Monitoring included the use of a cardiotocodynamometer and a noninvasive maternal blood pressure device. Using either a 22-gauge Levi point needle ($n = 5$) or a 22-gauge ramped Sprotte needle ($n = 60$) (Figure 1), we placed a 28-gauge polyurethane spinal catheter (Preferred Medical Products) at the L2-3 or L3-4 interspace via a paramedian approach. After catheter insertion, patients assumed a semirecumbent position with left uterine displacement, and a 250-mL intravenous bolus dose of a balanced salt solution was infused. Patients remained at bed rest for the remainder of their labor. A 1-mL solution containing fentanyl (10 μg), meperidine (10 mg), or sufentanil (5 μg) in preservative-free normal saline (as determined by a

table of random numbers) was then injected into the intrathecal space. These doses were based on preliminary unpublished work using this spinal technique. If analgesia was inadequate after 15 min, a second dose of the same study solution was injected. After 30 min, if analgesia was still inadequate, intrathecal bupivacaine (2.5 mg) (1 mL 0.25%) was administered. After bupivacaine injection, a lack of sensory block was assumed to indicate that the catheter tip was not in the intrathecal space, in which case the catheter was removed and the patient excluded from further study. As labor progressed and the patient requested additional analgesia, this protocol was repeated.

Before intrathecal injection and every 5 min thereafter for up to 30 min, patients rated their pain, nausea, and pruritus on unmarked 10-cm horizontal visual analogue scales (VAS). They continued to rate these variables every 30 min until they requested additional pain relief. Concurrently, we measured blood pressure (BP) and evaluated sensory (alcohol pad) and motor (Bromage scale) blocks. These determinations were also made immediately before and 15 min after each reinjection. Obstetricians measured cervical dilation as clinically indicated. Termination of the study occurred when the patient reached 10-cm cervical dilation or required bupivacaine to achieve adequate analgesia. We defined the duration of effective opioid analgesia as the time from initial study drug injection until termination of the study. Once a patient was given bupivacaine, she received only local anesthetic until delivery. We recorded the time and type of delivery (spontaneous vaginal, instrumented vaginal, or cesarean section).

We collected FHR-uterine activity tracings from 10 min before until 20 min after injection of the study drug. The perinatologist interpreting the data was unaware of which study solution was being administered. Tracing analysis included baseline FHR, number of accelerations per 20 min, short-term variability, decelerations (variable, late, and early), and number of uterine contractions per 20 min. We defined adequate short-term FHR variability as ≥10 beats/min and decreased short-term variability as <10 beats/min.

Obstetricians collected arterial and venous umbilical cord blood samples at their discretion. We recorded the Apgar scores of all neonates.

We inquired about the presence and severity of spinal headache at 24 h after delivery. The patients rated their headache as none, mild, moderate, or severe. A headache was considered mild if it did not limit the patient's activity and moderate if it did. An incapacitating headache was rated as severe.

To control for the unpredictable duration of labor, we evaluated the pain VAS versus the cervical dilation. In each patient, we analyzed the lowest pain score achieved with intrathecal opioids alone for each cervical dilation. For any cervical dilation without a simultaneously recorded pain score, we used the pain score from the last measured cervical dilation that had a concurrently reported pain score. If intrathecal opioids no longer provided adequate pain relief and the parturient required bupivacaine for labor analgesia, we recorded the last pain score reported with intrathecal opioids alone (usually >8) for the remaining cervical dilations. For patients who delivered by cesarean section, we stopped recording the pain score at the last known cervical dilation before surgery.

We used one-way analysis of variance or the Kruskal-Wallis test where appropriate for the comparison of demographic data, time to delivery, method of delivery, incidence of headache, number of bolus doses to make the patient comfortable, fetal umbilical cord blood gas tensions, Apgar scores, and FHR data. We applied analysis of variance for repeated measures to BP, pain, nausea, and pruritus VAS, sensory blockade data, and cervical dilation versus pain VAS. To compare the duration of analgesia after the first dose of opioid and the total duration of effective opioid analgesia, we used product limit survival analysis and Gehan Wilcoxon's test. For all statistical analysis, we considered results at $P < 0.05$ significant.

Results

Sixty-five patients consented to participate in this study. We excluded four patients from the study, because the spinal catheter failed secondary to misplacement or dislodgment. One patient in the sufentanil group experienced a severe deterioration in the FHR tracing and proceeded to emergency cesarean section 10 min after her initial dose. At delivery, the obstetrician noted that the umbilical cord was wrapped twice around the neck of the fetus. This patient is included only in baseline statistical evaluation; however, we enrolled an additional sufentanil-group patient to achieve an equal number of patients who completed the study ($n = 20$) in each group.

[b] Potential range of analgesia unknown because some patients delivered without receiving intrathecal local anesthetic. No significant differences among the groups.

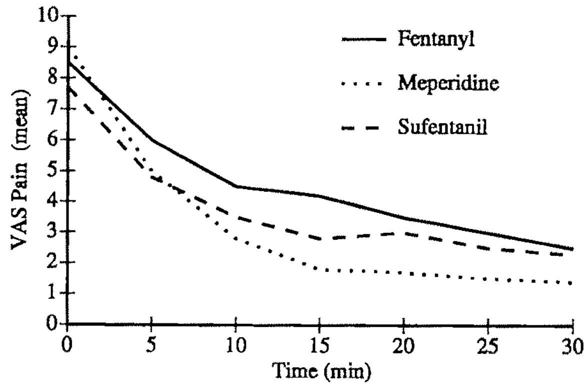

Figure 2. Pain visual analogue scale (VAS) for each opioid during the first 30 min after injection.

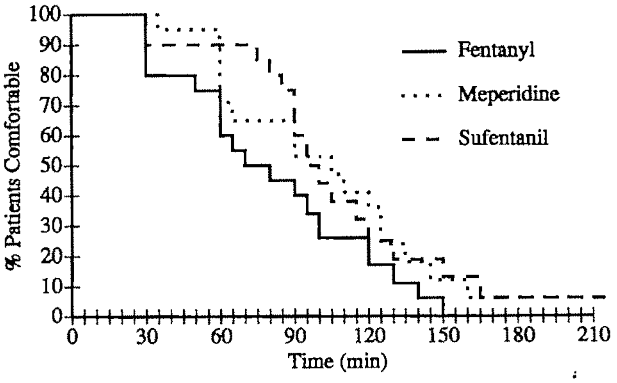

Figure 3. Step graph depicting the duration of analgesia provided by the first opioid injection. The graph steps down when patients requested additional analgesia or received bupivacaine for opioid failure. Some patients in the meperidine and sufentanil groups delivered without requesting supplemental analgesia; therefore, these lines do not intersect with the x-axis.

The groups did not differ in demographic attributes, time to delivery, method of delivery, or cervical dilation at baseline (Table 1). The average first dose to make a patient comfortable, the duration of the first dose of opioid analgesia, and the duration of effective opioid analgesia for each group are presented in Table 2. The groups did not differ in onset of analgesia (Figure 2), duration of the first dose of opioid analgesia (Figure 3), or duration of effective opioid analgesia (Figure 4). Two fentanyl-, zero meperidine-, and two sufentanil-group patients had inadequate analgesia at 30 min and required bupivacaine. Meperidine-group patients had significantly lower VAS pain scores once cervical dilation reached 6 cm and beyond (Figure 5). The percent of patients in each group who underwent vaginal delivery without intrathecal bupivacaine was 33% (fentanyl), 75% (meperidine), and 36% (sufentanil).

Patients in each group noted a similar small but significant increase in pruritus over time. Meperidine-group patients experienced more nausea, yet nausea scores in all groups were very low (Figure 6). All three groups had a slight decrease in BP from baseline (none <95 mm Hg systolic or >15%). There was transient sensory change in temperature in each group. No patient developed a detectable motor block.

We noted no significant intergroup differences in the FHR variables (Table 3). In both the fentanyl and meperidine groups, there was an increase in the number of variable decelerations after intrathecal drug injection. There was no change in the incidence of early or late decelerations (Table 3). Although

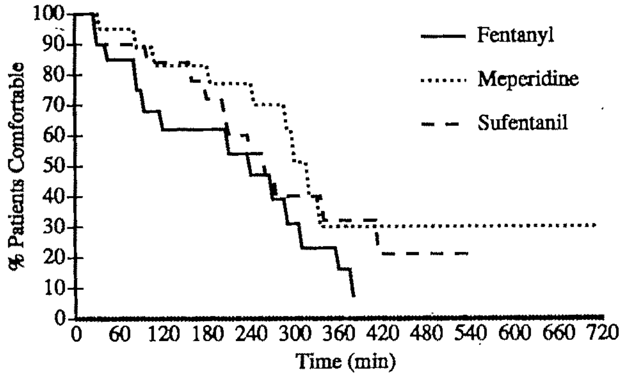

Figure 4. Step graph depicting the duration of effective opioid analgesia. The graph steps down when patients required injection of bupivacaine for adequate pain relief. The denominator changes when patients received bupivacaine for delivery. Some patients in each opioid group delivered without requiring bupivacaine analgesia; therefore, these lines do not intersect with the x-axis.

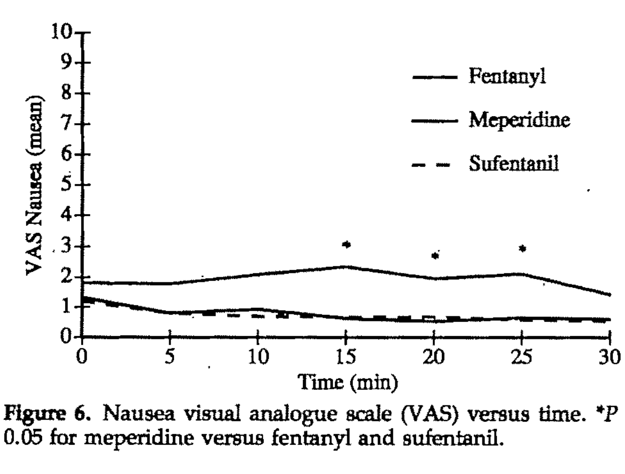

Figure 6. Nausea visual analogue scale (VAS) versus time. *$P < 0.05$ for meperidine versus fentanyl and sufentanil.

drawn selectively by the obstetrician, there were no intergroup differences in the umbilical cord blood gas tensions. No neonate had a 5-min Apgar score of <7.

The incidence of postdural puncture headache was 8.2%. Postdural puncture headache did not correlate with the opioid (Table 1) but did correlate with the type of needle used. We performed dural puncture with a 22-gauge Levi point needle in five parturients. Postdural puncture headache occurred in four of them. Of the remaining 56 patients (22-gauge ramped Sprotte needle), 1 developed a headache. In the Levi point needle group, one patient experienced a severe headache, requiring an epidural blood patch. The four other parturients with postdural puncture headache responded to conservative therapy.

Discussion

Several investigators have recently described the intrathecal use of the more lipid-soluble opioids for labor analgesia. Although the effect is not as long lasting as morphine analgesia, the reported incidence, duration, and severity of side effects are also less (6,7,10–14).

The present study examined the efficacy of intermittent intrathecal opioid injection in providing pain relief for the first stage of labor. Initially, intrathecal fentanyl, sufentanil, and meperidine produced similar analgesia with minimal side effects. After cervical dilation exceeded 6 cm, meperidine-group patients consistently reported lower VAS pain scores.

As labor advances, the nature of pain becomes increasingly somatic. Although all three opioids studied possess local anesthetic activity in vitro (15,16), only meperidine can function as a spinal anesthetic in clinical practice (17). This local anesthetic action may explain the greater degree of patient comfort in the meperidine group.

An alternative explanation for the increasing pain scores throughout labor is the occurrence of tachyphylaxis. We noted that in many patients, the duration of a given dose of opioid decreased with each successive injection. This phenomenon has been described in another study of intrathecal fentanyl used for labor analgesia (14). It is extremely difficult in a clinical study to differentiate between the changing nature of labor pain and tachyphylaxis. Either occurrence, or a combination of both, could explain the clinical results.

All three opioids caused minimal side effects. Although intrathecal meperidine was associated with more nausea than the other two agents, episodes were brief. Intrathecal administration of all three opioids did not produce any significant decreases in BP. There were no instances of motor block, but discernible sensory changes, consistent with the local anesthetic properties, occurred in all groups. It appears that short-acting spinal opioids offer a safe alternative to epidural local anesthetics, especially in patients whose hemodynamic stability is of particular concern.

Table 3. Fetal Heart Rate

[a] $P < 0.05$ compared with predose.

Evaluation of the FHR tracings before and after intrathecal opioid injections, as well as determination of acid-base status and Apgar scores, revealed no intergroup differences. As shown in Table 3, in the fentanyl and meperidine groups, the number of fetuses with variable decelerations postdose increased significantly. Yet, without significant changes in the baseline FHR, short-term variability, or number of fetuses manifesting late decelerations, it is unlikely that this single finding is of clinical significance.

There are no studies delineating intrathecal opioid potency ratios in parturients. Systemic opioid potencies, which correlate directly with opioid lipophilicity, reflect the need for the drug to cross the blood-brain barrier to gain access to the receptor site. Because intrathecally injected drugs bypass the blood-brain barrier, systemic opioid potencies do not predict intrathecal potency. In an animal model, intrathecal drug potency is inversely related to lipid solubility (18). It is possible that nonspecific binding of the highly lipid-soluble drugs by perineural tissue leaves less drug available for opioid receptor binding (18).

The design of the present study considered patient comfort as the endpoint for further opioid administration. Although we cannot accurately comment on potency ratios, our data appear to agree with the finding that intrathecal potency varies inversely with lipid solubility. Sufentanil (octanol/water partition coefficient 1778) is considered 10 times as potent as fentanyl (octanol/water partition coefficient 813) when systematically administered (19). In contrast, our data suggest that after intrathecal injection, sufentanil is only twice as potent as fentanyl.

Postdural puncture headache occurs frequently in parturients. In this study, we found no correlation between headache and opioid administered. There was an 80% incidence of postdural puncture headache with the use of the 22-gauge Levi point needle, in contrast to the 1.7% incidence with the 22-gauge Sprotte needle. Because a large-gauge spinal needle is necessary to thread a catheter, it is important to select a needle with an atraumatic bevel, particularly for use during parturition.

Currently, there is much concern about cauda equina syndrome and the continuous spinal technique. All cases reported to date were associated with hyperbaric local anesthetic solutions (20). In this study, we administered local anesthetics only if the patient perceived the opioid analgesia as inadequate, or at the request of the obstetrician, or for cesarean section anesthesia. If analgesia was not achieved with a specific dose range of local anesthetic, we assumed that the spinal catheter was not functioning and removed it. The following doses were used: during labor, a total of 5 mg of 0.25% bupivacaine; for vaginal delivery, a total of 7.5 mg of 0.75% bupivacaine with 8.25% dextrose; for cesarean section, 15 mg of 0.75% bupivacaine with 8.25% dextrose. When using hyperbaric bupivacaine, a sensory block of inadequate dermatomal spread was treated by modifying the patient's position or adding a small dose of isobaric or hypobaric local anesthetic. After this protocol, no patient experienced adverse neurologic sequelae.

In conclusion, we have shown that an intermittent injection spinal technique with fentanyl, meperidine, or sufentanil provides adequate first-stage labor analgesia. There is a small incidence of mild side effects associated with this technique. Meperidine may have advantages over the other two opioids, because it provides more reliable analgesia as the first stage of labor progresses.

Epidural Patient-Controlled Analgesia: Influence of Bupivacaine and Hydromorphone Basal Infusion on Pain Control After Cesarean Delivery

Robert K. Parker, DO, Yuko Sawaki, MD, and Paul F. White, PhD, MD, FFARACS

Department of Anesthesiology, Washington University School of Medicine, St. Louis, Missouri, and Department of Anesthesiology and Pain Management, University of Texas Southwestern Medical Center, Dallas, Texas

Epidural administration of hydromorphone was evaluated using a patient-controlled analgesia (PCA) delivery system in 170 healthy women undergoing elective cesarean delivery with epidural bupivacaine who were randomly assigned to one of four epidural PCA treatment groups: group I, hydromorphone alone by bolus administration; group II, hydromorphone, with a continuous (basal) infusion; group III, hydromorphone in combination with 0.08% bupivacaine by bolus administration; or group IV, hydromorphone and bupivacaine, with a concurrent infusion of both drugs. Patients in group I required significantly less opioid medication (2.1 ± 1.1 mg [mean ± SD]) during the first 24 h than patients in group II (3.3 ± 1.3 mg). Similarly, patients in group III self-administered significantly less hydromorphone (2.0 ± 1.0 mg) and bupivacaine (23.3 ± 11.4 mg) during the first 24 h of PCA therapy, compared with patients in group IV (hydromorphone [2.7 ± 1.1 mg] and bupivacaine [31.5 ± 11.6 mg]). The concomitant use of a local anesthetic or basal opioid infusion with hydromorphone via epidural PCA did not decrease the number of PCA demands or delivered doses. In addition, patients in all four groups had similar pain, sedation, discomfort, fatigue, and anxiety scores. The frequency of awakening at night to self-administer analgesic medication was not decreased when a basal infusion was used. Although only 5% of patients receiving hydromorphone alone complained of nausea, 25% of the patients receiving the opioid-local anesthetic combination (group III) reported PCA-related nausea ($P < 0.05$). Although the overall incidence of pruritus did not differ among treatment groups (55%–72%), 42% of patients in group IV required antipruritic therapy compared with 22% in group I ($P < 0.05$). Minimal hemoglobin oxygen saturation values at night were 94% (±2%) in all four groups. Persistent lower extremity paresthesias were noted in 22% of patients receiving the opioid-local anesthetic infusion (group IV), with 20% requiring discontinuation of the infusion secondary to difficulty ambulating. In the opioid-local anesthetic combination (vs opioid alone) group, significantly more patients required recatheterization, owing to urinary retention. Times to recovery of bowel function, ambulation, resumption of a solid diet, discontinuation of PCA therapy, and hospital discharge were similar in all four groups. In conclusion, the efficacy of epidural PCA with hydromorphone was not improved by adding 0.08% bupivacaine or a basal hydromorphone infusion (0.0375 mg/h) after cesarean delivery.

(Anesth Analg 1992;75:740–6)

Epidural administration of opioids and local anesthetics is becoming increasingly popular in the management of acute postoperative pain. Recent reports have described epidural patient-controlled analgesia (PCA) with opioids (1–5) and opioid-local anesthetic combinations with continuous (basal) infusions (6–9). However, the influence of local anesthetics on epidural opioid analgesia with or without a continuous infusion has not been studied.

Most of the clinical studies comparing epidural opioids versus opioid-local anesthetic combinations have utilized the highly lipid-soluble opioids (6–9). However, the use of fentanyl and sufentanil has been questioned because of their lack of a dose-sparing effect compared with intravenous administration (10–13). When epidural hydromorphone was administered with a PCA delivery system, a marked dose-sparing effect was reported compared with intravenous PCA with hydromorphone (5).

This investigation was supported in part by a grant from Knoll Pharmaceuticals, Whippany, New Jersey.

Presented in part at the Annual Meeting of the International Anesthesia Research Society, Honolulu, Hawaii, March 1990.

0003-2999/92/$5.00

We designed a prospective, double-blind study to evaluate the influence of a dilute local anesthetic solution (0.08% bupivacaine) and a basal opioid infusion (hydromorphone [0.0375 mg/h]) during epidural PCA with hydromorphone. In addition to determining the opioid and local anesthetic analgesic requirements, we assessed quality of pain relief, patient satisfaction, side-effect profiles, and recovery times after elective cesarean delivery.

Methods

After approval of the study protocol by the Washington University Human Studies Committee, 170 consenting, healthy women scheduled to undergo elective cesarean delivery were randomly assigned to one of four epidural PCA treatment groups. The theoretical basis for PCA therapy and the operational aspects of the PCA device were explained at the time of the preoperative visit and were reviewed with each patient before initiating PCA therapy in the postanesthesia care unit. Patients with evidence of bacteremia or coagulopathy, as well as those who were reluctant to have an epidural catheter remain in place after their operation, were excluded.

All patients received 0.5% bupivacaine (15–25 mL) via a percutaneous lumbar epidural catheter for surgical anesthesia. Approximately 2–3 h after epidural bupivacaine administration for surgical anesthesia, a Bard Ambulatory PCA device was connected to each patient's epidural catheter. Group I (control) received a 3-mL initial dose of hydromorphone (0.075 mg/mL), with supplemental 2-mL bolus doses at a minimal lockout interval of 30 min. Group II received the same regimen as the control group, with the addition of a continuous (basal) infusion of hydromorphone (0.5 mL/h [0.0375 mg/h]). Group III received a combination of hydromorphone (0.075 mg/mL) and 0.08% bupivacaine (0.8 mg/mL) by intermittent bolus injection, as described previously for group I. Finally, group IV received the same opioid-local anesthetic combination as described for group III, with the addition of a basal infusion at 0.5 mL/h (bupivacaine [0.04 mg/h] and hydromorphone [0.0375 mg/h]). The number of delivered bolus doses and patient demands (button presses) for supplemental medication and total drug dosages were recorded for up to 48 h after the operation. The patients, nurse observers, and surgeons were all unaware of the content of the PCA solution and the presence or absence of the basal infusion.

Evaluation of postoperative respiratory function included determination of respiratory rate (which was recorded every 2 h by the ward nurses) and measurement of hemoglobin oxygen saturation with the Nellcor Oxinet telemetry system when patients were at bed rest. An alarm would sound at the nursing station when the hemoglobin oxygen saturation decreased to <85% for >1 min. Other postoperative assessments included determination of recovery times from completion of the operation to unassisted ambulation, return of bowel sounds, resumption of solid diet, and hospital discharge.

Patients assessed pain (no pain to worst pain imaginable), sedation (wide awake to nearly asleep), fatigue (well rested to completely exhausted), discomfort (comfortable to very uncomfortable), and anxiety (relaxed to anxious) levels at 8-h intervals using 100-mm linear visual analogue scales (0 = none to 100 = maximal) (14). All patients were evaluated by the primary care nurse at 2-h intervals, and all side effects (e.g., nausea, vomiting, pruritus, lower extremity paresthesia or weakness, urinary hesitancy) were noted. The Foley catheter was routinely removed on the morning after surgery. Urinary hesitancy was defined as difficulty in voiding 6 h after removal of the Foley catheter.

The incidence of side effects was considered to be the percentage of patients experiencing the side effects out of the total number of patients in the group, regardless of the number of times the side effects were noted for any individual patient. A standardized protocol was used to treat side effects if the symptoms were present on successive nursing visits or if the patient complained of persistent symptoms. The PCA therapy was discontinued when patients were able to tolerate a clear liquid diet. Postoperative PCA assessment questionnaires were completed by the patients, as well as their surgeons and primary care nurses, after completion of PCA therapy.

Opioid and local anesthetic usage, visual analogue scale scores, and recovery times were analyzed using one-way analysis of variance, with a Bartlett's post hoc test to determine differences among groups; χ^2 testing was used to analyze discrete variables. The Wilcoxon rank-sum (nonparametric) test was used to compare median values for visual analogue scale scores and number of bolus doses in the four PCA treatment groups. Changes in opioid or local anesthetic usage over time within each treatment group were evaluated with repeated measures of analysis of variance and Student's *t*-test with Bonferroni's correction. A *P* value <0.05 was considered statistically significant. Data are reported as median (and interquartile ranges) or mean ± SD (in tables) and ±SEM (in figures).

Results

From November 1988 to December 1990, 170 women were enrolled in this epidural PCA study. The four treatment groups were comparable with respect to

PCA, patient-controlled analgesia.
Values are mean ± SD or numbers.

demographic variables (Table 1). The duration of surgery and total intraoperative epidural local anesthetic dosages were also similar in the four groups. The epidural catheter became dislodged, and PCA therapy was changed to intravenous PCA in three patients in group I (control) and in two patients in group III. Eight patients (20%) in the opioid-local anesthetic infusion group (group IV) required discontinuation of the infusion secondary to complaints of lower extremity weakness or paresthesia, or both. In addition, two patients in group I, two in group II, one in group III, and four in group IV requested discontinuation of their epidural PCA therapy because of persistent side effects. Patient data were excluded from further analysis at the time of these protocol violations.

The number of PCA demands and supplemental bolus doses was similar among all four treatment groups throughout the study period (Figure 1). The ratio of delivered doses-to-demands remained stable in all groups during the study period. Patients in the hydromorphone PCA plus basal infusion group (group II) received significantly more hydromorphone in the first 24 h of therapy (3.3 ± 1.3 mg [mean ± SD]) than the hydromorphone PCA alone group (2.1 ± 1.1 mg; $P < 0.01$). Similarly, the opioid-local anesthetic infusion group (group IV) received significantly more hydromorphone in the first 24 h (2.7 ± 1.1 mg) than the opioid-local anesthetic combination PCA group (group III) (2.0 ± 1.0 mg; $P < 0.01$). During each 4-h period after initiation of PCA therapy, more hydromorphone was administered to patients receiving a continuous opioid infusion (group II) compared with patients receiving the opioid on an intermittent PCA basis (group III) (Figure 2). Although a similar overall difference was seen between group III (opioid-local anesthetic combination without basal infusion) and group IV (opioid-local anesthetic with infusion), this difference was not as consistent. Similarly, patients in the opioid-local anesthetic infusion group (group IV) received significantly more ($P < 0.05$) bupivacaine in the first 24 h (31.5 ± 11.6 mg) than those receiving only intermittent bolus administration (23.3 ± 11.4 mg). A comparison of opioid alone without infusion versus the opioid-local anesthetic combination without infusion (i.e., group I vs. group III) revealed no significant differences in the delivered bolus dose-to-demand ratio or in the 24-h hydromorphone utilization.

Pain scores were similar at the time of initiation of PCA therapy and throughout the study in all groups (unreported data). When asked their expectations preoperatively, 33% of patients in each group anticipated severe or very severe pain after the operation. However, on the follow-up questionnaire, 95% of the patients in each group (except group III) reported experiencing only mild or moderate pain. In the opioid-local anesthetic combination group (group III), 16% of patients reported having experienced moderate to severe pain after the operation ($P < 0.05$). Overall, 94%–100% of patients reported receiving adequate postoperative pain therapy. Similarly, the nurses reported that 98% of the patients had satisfactory pain relief. Of the patients with a previous cesarean delivery ($n = 97$), 85% stated they had experienced either similar or less pain after this operation than they had previously experienced. Additionally, 80% of the patients stated they had been more active physically during the first 48 h after this cesarean delivery compared with their previous experience.

Visual analogue scale scores for sedation, discomfort, fatigue, and anxiety revealed no differences among groups during the study period (unreported data). Only 6%–12% of patients in each group reported feeling drowsy after their operation, whereas 60%–77% felt wide awake to slightly sleepy after surgery. A majority of patients in each group (56%–75%) stated they had slept well after their operation, and no differences were noted in the number of

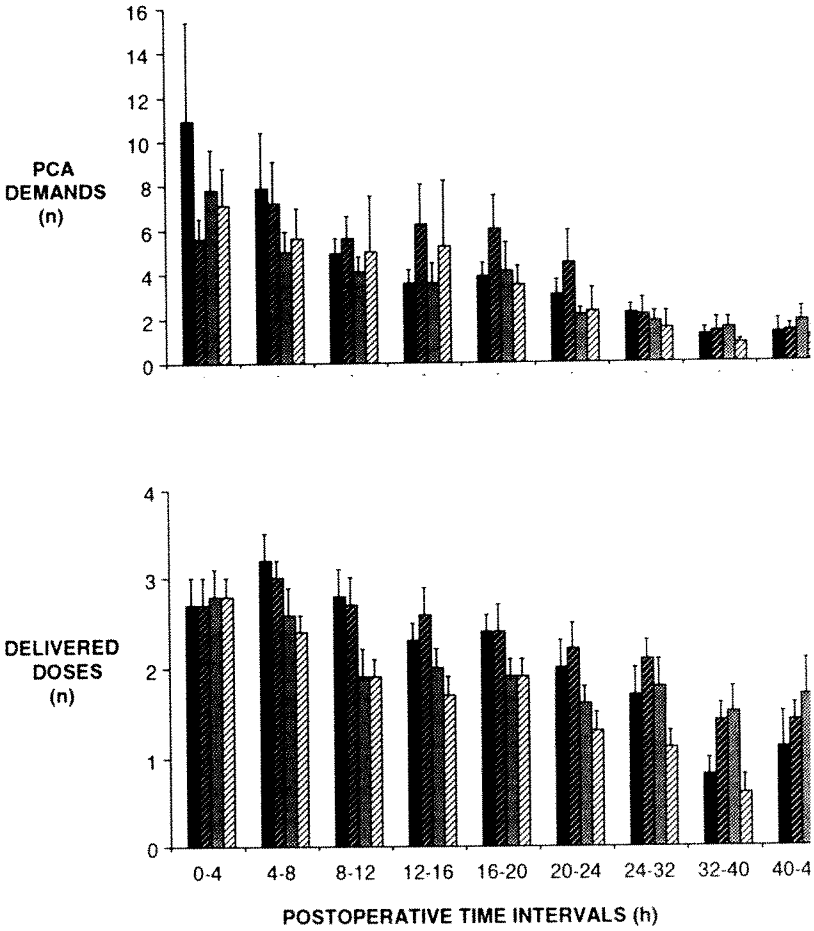

Figure 1. **(Top)** Postoperative patient-controlled analgesia (PCA) demands per 4 h. **(Bottom)** Postoperative PCA doses delivered per 4 h. *Solid bar,* opioid alone; *dark hatched bar,* opioid with basal infusion; *stippled bar,* opioid-local anesthetic; *light hatched bar,* opioid-local anesthetic with basal infusion. Values are mean ± SEM.

awakenings to self-administer pain medication among the four treatment groups. Overall, 35% of patients found it necessary to awaken so as to self-administer supplemental PCA doses. Only 18% of patients reported difficulty in sleeping due to pain. Activity in the room was the most common reason cited as the cause of difficulty in sleeping.

On the follow-up questionnaire, only 5% of patients receiving hydromorphone PCA (group I) thought that their PCA medication had contributed to postoperative nausea, whereas 25% of patients in group IV reported nausea associated with PCA administration ($P < 0.05$). In groups II and III, 16% of patients reported PCA-related nausea. This was similar to the incidence of nausea reported by the ward nurses (Table 2). Antinausea therapy was required in all groups, except in group I (opioid alone). Pruritus occurred in 55%–72% of patients, with a significantly higher incidence of intractable itching requiring antipruritic therapy in group IV (Table 2). Urinary hesitancy (Table 2) was seen in only two patients (one requiring catheter replacement) in group I. However, there was a significantly higher incidence of urinary hesitancy and catheter replacement in groups II–IV. Lower extremity paresthesia (i.e., numbness persi ing 8 h after surgery) was noted in 22% of patients group IV and resulted in discontinuation of t epidural infusion in 20% of patients in this group (because of lower extremity weakness and difficu with ambulation). No patient had a postoperat respiratory rate of <12 breaths/min. Additionally, patients had hemoglobin oxygen saturation valu <91%. All patients were able to ambulate on th own (with the exception of three in group IV hav leg weakness) within 16 ± 6 h after surgery. T times to resumption of bowel sounds (20 ± 10 solid diet (54 ± 18 h), and hospital discharge (97 19 h) were similar for all groups. According to surgeons' questionnaires, the return of bladder a bowel function was longer than expected in 25% opioid-local anesthetic infusion group patie (group IV) compared with only 8% of patients rece ing the opioid alone (group I) ($P < 0.05$). Al according to the surgeons, 33% of patients were a to ambulate earlier than expected, and 22% w ready for hospital discharge earlier than expect Ambulation and readiness for hospital discha were noted by the surgeons to be later than expec

in six patients, all of whom were in the opioid-local anesthetic infusion group (group IV). Overall, the surgeons reported being satisfied with the pain relief regimen in 96% of patients.

Discussion

Epidural analgesic techniques for managing postoperative pain have involved the use of both opioid analgesics and local anesthetics via either intermittent or continuous dosing methods. Unfortunately, the clinical usefulness of these studies is often limited because of problems with the study design (e.g., retrospective studies [15,16], historical controls [4], comparisons of different opioids [1], small patient populations with multiple surgical procedures [1], and comparisons of different drugs and modes of delivery [12,17–20]).

In 1988, Gambling et al. (21) reported on the role of continuous epidural infusion (vs epidural PCA) for administering bupivacaine during labor. These investigators noted that patients controlling their own drug delivery administered less medication than when a continuous infusion was used. Similarly, Marlowe et al. (2) found a decrease in the opioid requirement with epidural PCA versus epidural infusion for postoperative analgesia. Recently, Ferrante et al. (8) reported decreased bupivacaine consumption when a bupivacaine-fentanyl mixture was administered via epidural PCA compared with continuous epidural infusion of these drugs during labor. The addition of low-dose bupivacaine did not improve postoperative epidural fentanyl analgesia after knee surgery and may increase morbidity (22). Finally, Boudreault et al. (7) reported that patients utilizing epidural PCA with fentanyl to supplement a continuous infusion of epidural bupivacaine required less fentanyl than patients receiving a continuous epidural infusion of fentanyl and bupivacaine after laparotomy procedures.

Our data suggest that satisfactory postoperative pain relief after cesarean delivery can be obtained with less opioid medication when patients self-administer bolus doses of hydromorphone via epidural PCA, either alone or in combination with bupivacaine, compared to PCA with a continuous basal infusion. However, we were unable to demonstrate any advantage in combining local anesthetic with hydromorphone compared with hydromorphone alone in this postsurgical population. In addition, the administration of a hydromorphone-bupivacaine mixture with a basal infusion resulted in more nausea and difficulty with voiding and ambulation than the other epidural analgesic techniques. The use of a basal infusion, with or without local anesthetic, led to higher opioid usage without decreasing the pain scores or the number of patient demands for analgesic medication. These data confirm our previous findings involving intravenous PCA with or without a basal infusion (23). Analogous to the findings in our recent study in which a nighttime intravenous infusion was combined with PCA (24), we were unable to demonstrate any improvement in the patients' ability to sleep when an epidural infusion was utilized. Moreover, none of the patients receiving epidural PCA alone (groups I and III) required the addition of a basal infusion to optimize their postoperative pain management.

In this study, all women were able to achieve satisfactory pain relief without excessive sedation or evidence of respiratory depression. With the exception of 17 patients (12 in group IV), all patients successfully completed the study protocol without side effects necessitating changes in their initial PCA prescription. The use of a more dilute solution of bupivacaine (e.g., 0.015%) (9) might have decreased the number of patients in group IV requiring discontinuation of their PCA therapy. However, the use of more dilute bupivacaine solutions may not produce the desired local anesthetic effect. In preliminary dose-ranging studies, we found that 0.125% bupivacaine (6.25 mg/h) interfered with early ambulation in all patients and that 0.02% bupivacaine (1 mg/h) had no clinically apparent effect.

Although there was no evidence of intravascular, subdural, or subarachnoid catheter migration, the catheter became dislodged in 5 of the first 27 patients enrolled in the study. This problem was avoided in the remaining patients by using a more secure method of taping the catheter in place (5). Nevertheless, catheter migration or dislodgment, or both, is a potential problem in using epidural catheter techniques for postoperative analgesia (25–28). In addition, subarachnoid infection has been reported in patients receiving epidural analgesia after cesarean section (29). Finally, a programming error when utilizing the basal infusion mode may have greater consequences than with the conventional intermittent dosing technique (30).

One limitation of this double-blind study is the inability to extrapolate our results to other postsurgical populations. Future studies should include both men and women undergoing upper abdominal, thoracic, and major joint replacement procedures to further define the role of epidural PCA. A second criticism relates to the apparently arbitrarily chosen bolus doses (and drug concentrations), lockout intervals, and basal infusion rates. However, these PCA variables were determined to provide adequate analgesia in preliminary dose-ranging studies. More importantly, because patients were able to self-administer additional medication using the PCA device, these factors should not have significantly affected our findings.

In conclusion, epidural PCA with hydromorphone is a safe and effective method of providing pain relief after elective cesarean delivery. The addition of 0.08% bupivacaine or a basal hydromorphone infusion, or both, increased side effects without improving the patients' pain relief.

The authors thank Linda Kratz, RN, for her valuable assistance with data collection; Bard MedSystems Division (C. R. Bard, Inc., North Reading, Mass.) for the use of the Ambulatory PCA devices; and Nellcor Inc. (Hayward, Calif.) for use of the Oxinet telemetry system. Finally, the cooperation of our anesthesia, obstetric, nursing, and pharmacy colleagues at Barnes Hospital was greatly appreciated.

Nalbuphine Is Better Than Naloxone for Treatment of Side Effects After Epidural Morphine

Sheila E. Cohen, MBChB, FFARCS, Emily F. Ratner, MD, Ted R. Kreitzman, MD,
John H. Archer, MD, and Linda R. Mignano, MD

---

This study compared naloxone and nalbuphine when administered for treatment of side effects after epidural morphine, 5 mg, given for postcesarean analgesia. Patients requesting treatment for pruritus or nausea randomly received, in a double-blind fashion, up to three intravenous doses of either naloxone 0.2 mg (group 1; $n = 20$) or nalbuphine 5 mg (group 2; $n = 20$). The incidence of vomiting, the severity of nausea and pruritus, and the degree of sedation and pain were assessed before and 30 min after each dose. The first dose of nalbuphine decreased the incidence of vomiting ($P < 0.005$) and the severity of nausea and pruritus ($P < 0.01$), whereas naloxone caused no significant changes. Sedation scores increased after nalbuphine ($P < 0.05$) and remained unchanged after naloxone, whereas pain scores increased after naloxone ($P < 0.01$) and were unchanged after nalbuphine. Eighteen patients in group 1 and 12 in group 2 received a second dose, and 8 and 4 patients, respectively, a third dose. Other than decreased pruritus after the second dose with both drugs, no further changes occurred. We conclude that nalbuphine is superior to naloxone for the treatment of side effects after epidural morphine. However, persistent symptoms may require supplemental therapy, as repeated doses proved less effective than the initial dose.

(Anesth Analg 1992;75:747–52)

Epidural morphine provides excellent postoperative analgesia but is associated with a high incidence of troublesome side effects such as pruritus, nausea, and vomiting (1–7). In a previous study of women receiving epidural morphine for postcesarean section pain in our institution, 85% complained of pruritus and 59% of nausea (1). Prophylactic administration of naloxone or nalbuphine has been recommended to prevent these side effects (8,9). However, because only about 50% of patients require treatment (1), many would receive drug therapy unnecessarily. In addition to possible side effects from the drugs themselves, routine prophylactic injections of naloxone or nalbuphine to all women receiving epidural morphine after cesarean delivery would result in increased costs and added nursing workload. The current study was designed to compare the efficacy and adverse effects of nalbuphine and naloxone administered therapeutically to patients requesting treatment for side effects caused by epidural morphine given during cesarean section.

Methods

After approval of the study by the Human Subjects Committee, written informed consent was obtained from healthy women undergoing nonemergency cesarean section with epidural anesthesia. The majority of patients were having scheduled cesarean sections; the remainder were in labor, some with an epidural catheter already in place. Patients were excluded from the study if they had received opioids other than epidural fentanyl, 50–100 μg, either alone or in combination with dilute bupivacaine for labor analgesia. Antiemetics were not administered routinely, although metoclopramide, 10 mg IV, occasionally was given intraoperatively for treatment of nausea or vomiting. Patients could receive intravenous midazolam, 0.5–1 mg, or fentanyl 50–100 μg, intravenously or epidurally, for anxiety or discomfort during operation.

Immediately after delivery, all potential subjects received preservative-free epidural morphine, 5 mg in 10 mL, via the epidural catheter. Approximately 45% of patients subsequently requested treatment for pruritus, nausea, or vomiting. These individuals were entered into the study and randomly received in a double-blind manner either naloxone, 0.2 mg IV (group 1; $n = 20$) or nalbuphine, 5 mg IV (group 2;

n = 20). Study drugs were prepared by an anesthesiologist not involved in the study. If symptoms persisted, up to two additional doses of the same drug could be given at no less than 30-min intervals. The patient was asked to state which symptom was her primary reason for requesting treatment. Before, and 30 min after injection of each dose of study drug, the following assessments were made: presence and severity of nausea or pruritus (rated by the patient as none, mild, moderate, or severe and assigned scores of 0–3); whether vomiting had occurred; and the degrees of sedation and pain. The latter were quantified by the patient using a verbal pain scale (VPS) where 0 = no pain and 10 = worst pain imaginable, and a verbal sedation scale (VSS) where 0 = completely awake and 10 = almost asleep. These scales are comparable to visual numerical rating (10) or visual analogue pain and sedation scales (11) previously described. The study was terminated after three doses of the study drug had been given, or earlier at the patient's request. Continuing side effects were treated with further doses of naloxone or nalbuphine, or with metoclopramide for nausea and diphenhydramine for pruritus. Pain during the study period was treated with small (12.5–25 mg) doses of intravenous meperidine. Overall pain relief and efficacy of treatment for side effects were evaluated by the patient on the day after delivery as poor, fair, good, or excellent.

Data were analyzed using Student's t-test for continuous data, Mann-Whitney and Wilcoxon signed rank test for nonparametric data (pruritus and nausea scores, VPS, and VSS), and χ^2 or Fisher's exact test for categorical data. $P < 0.05$ was considered significant.

Results

The groups were similar with respect to age, weight, height (Table 1), and the incidence of elective cesarean sections (group 1: 51%, group 2: 49%). One patient in group 1 and three in group 2 had received epidural fentanyl during labor. With the exception of one patient in each group who received 0.5% bupivacaine, 2% lidocaine with 1:200,000 epinephrine was used to provide surgical anesthesia. Two patients in each group experienced intraoperative nausea and vomiting for which three of the four received metoclopramide.

The times from epidural morphine administration to the first dose of study drug are shown in Table 1, and the symptoms for which patients requested treatment in Table 2. More patients in group 2 than in group 1 complained of both nausea and pruritus (Table 2; $P < 0.05$) and more had vomited (65% vs 25%, $P < 0.05$). Before treatment, the severity of nausea and pruritus was similar in both groups (Tables 3 and 4). The first dose of nalbuphine decreased the incidence of vomiting ($P < 0.005$) and the severity of both nausea and pruritus ($P < 0.005$;

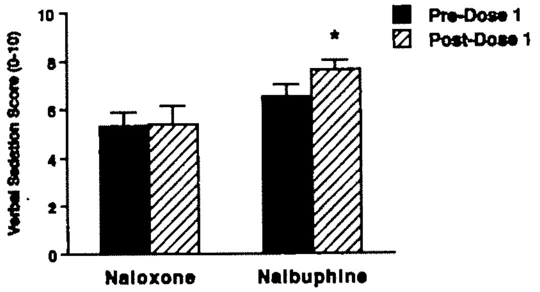

Figure 1. Verbal sedation scores (mean ± SEM) before, and 30 min after, administration of the first dose of naloxone or nalbuphine. *$P < 0.05$ versus predose score (Wilcoxon signed rank test).

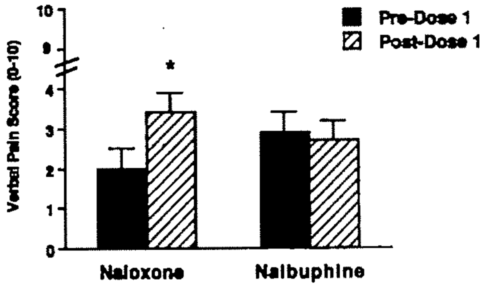

Figure 2. Verbal pain scores (mean ± SEM) before, and 30 min after, administration of the first dose of naloxone or nalbuphine. *$P < 0.05$ versus predose score (Wilcoxon signed rank test).

Tables 3 and 4), while naloxone caused no change in vomiting or the severity of nausea (Table 3), and a decrease in the severity of pruritus that just failed to reach statistical significance ($P = 0.06$; Table 4). Nalbuphine completely abolished nausea in 69% of patients with this symptom, compared with only 20% for naloxone ($P < 0.05$). Pruritus was abolished in 25% of patients after nalbuphine and none after naloxone ($P = 0.1$). Sedation scores increased after the first dose of nalbuphine ($P < 0.05$) and remained unchanged after naloxone (Figure 1), whereas pain scores increased after naloxone ($P < 0.01$) and remained unchanged after nalbuphine (Figure 2). (Mean scores are shown in these figures as the authors believe they illustrate central tendency in the groups better than median values; statistical comparisons were performed with appropriate nonparametric tests.)

Eighteen patients in group 1 and 12 in group 2 received a second dose, and 8 and 4, respectively, a third dose of study drug (NS). As with the first dose, the times from morphine administration to subsequent doses were similar in both groups (Table 1). Dose 2 of nalbuphine abolished nausea and pruritus in 43% and 45% of patients, respectively, compared with 0% and 34% for these symptoms with naloxone (NS between groups). The severity of pruritus decreased significantly after the second dose of both drugs ($P < 0.05$ vs predose scores). However, there were no statistically significant changes in the severity of nausea, although scores tended to improve after nalbuphine ($P = 0.1$). The third dose of study drug failed to improve symptoms in either group. Sedation and pain scores did not change significantly after the second or third dose of either drug.

Neither cardiovascular changes nor respiratory depression (respiratory rate ≤10 breaths/min) were observed during the study. Overall pain relief scores were similar in both groups, with 89% of patients in group 1 and 85% in group 2 rating their pain relief as good or excellent. Requirements for supplemental analgesia were similar in both groups, with seven patients in each group receiving intravenous meperidine during the study period (average cumulative doses of 22 ± 9 mg in group 1, and 27 ± 7 mg in group 2; NS). Three patients in group 1 and two in group 2 received meperidine in the period between the first and second doses of study drug (NS). Fifty percent of patients in group 2 rated their relief of side effects as good or excellent, compared with only 26% in group 1; however, this difference was not statistically significant.

Discussion

Side effects with intraspinal opioids, particularly hydrophilic agents such as morphine, occur with great frequency in the obstetric population (1–7). Among patients receiving epidural morphine 2–5 mg after cesarean section, 53%–93% complain of pruritus, and 34%–59% of nausea and vomiting (1–7). Although this therapy produces better pain relief after cesarean delivery than do systemic opioids (1,4), the associated side effects can prove incapacitating. Patients at our institution cited nausea as the most common reason for delay in walking after epidural morphine, whereas pain was the most common reason in patients receiving systemic opioids (1).

Various approaches have been explored to prevent or treat these side effects. Phenothiazines have been used as antipruritics, and metoclopramide, droperidol, and transdermal scopolamine as antiemetics (12,13). Because these drugs often treat only one symptom, multiple drug therapy may be necessary. Another drawback of these agents is their potential for causing sedation, thereby increasing the risk for respiratory depression (6,12). To avoid these problems, specific opioid antagonists have been used with the goal of counteracting all the side effects of intraspinal opiates with one drug. Naloxone, a predominantly μ-receptor antagonist, and nalbuphine, a drug with mixed μ-antagonist and κ-agonist effect, both have been used for this purpose. In the current study we found that nalbuphine was clearly superior to naloxone for the treatment of nausea and pruritus. In most previous studies these drugs have been administered prophylactically rather than therapeutically, with inconsistent results regarding their efficacy and their effect on analgesia.

In surgical patients, Rawal et al. (14) observed reversal of epidural morphine-induced respiratory depression by naloxone infused at 5 or 10 $\mu g \cdot kg^{-1} \cdot h^{-1}$. Other side effects were minimally affected and, as in another study in which 0.4–4 $\mu g \cdot kg^{-1} \cdot h^{-1}$ was infused (15), the higher naloxone dose adversely affected analgesia. Korbon et al. (8) gave intermittent intramuscular naloxone injections to cesarean section patients who had received epidural morphine, demonstrating reversal of respiratory depression, insignificant decreases in pruritus and nausea, and no effect on analgesia. In a similar population, Daly et al. (16) infused naloxone at 0, 0.05, 0.1, and 0.2 mg/h, reporting no differences in analgesia but significantly decreased pruritus scores with the highest dose; a tendency for dose-related decreases in pruritus and nausea was claimed. In contrast, Ramanathan et al. (17) found no differences in side effects but increased pain scores when naloxone 0.1 mg/h was infused after cesarean section at which epidural morphine was given. In a similar study, Thind et al. (18) found the benefits of naloxone infusion limited to a decreased severity of pruritus. Although some of these investigators advocate use of prophylactic naloxone to prevent nonrespiratory side effects, their recommendations often are based on findings that failed to reach statistical significance (8,16).

Prophylactic nalbuphine administration also has proved controversial. In surgical patients, nalbuphine boluses of 0.3 mg/kg (9), or 200 $\mu g/kg$ followed by an infusion of 50 $\mu g \cdot kg^{-1} \cdot h^{-1}$ (19), reversed respiratory depression after epidural morphine without affecting analgesia. Decreased pruritus was noted after 0.1 mg/kg of the bolus had been injected (9). In contrast, Morgan et al. (20) found that three prophylactic doses of intravenous nalbuphine given at 0, 6, and 12 h after epidural morphine administered at cesarean section failed to prevent decreases in respiratory rate or oxyhemoglobin saturation and had no effect on pruritus. However, the authors comment that because respiratory monitoring was intermittent and because patients often received intraoperative and postoperative sedatives or phenothiazines, firm conclusions could not be drawn regarding the effect of nalbuphine on respiration. Although our finding that nalbuphine decreased pruritus appears to contradict those of Morgan et al. (20), this may relate to differences in study design and methodology. Because we administered nalbuphine only to patients requesting treatment for side effects, whereas Morgan et al. (20) gave the drug prophylactically to all patients, our study might be more sensitive in demonstrating an effect. Also, we measured decreases in the severity of pruritus 30 min after injection of nalbuphine in symptomatic patients, whereas they recorded the average maximum pruritus score noted during the entire 18-h study period. Our data probably reflect the benefit associated with peak drug concentrations, whereas theirs may reflect the severity of symptoms occurring when nalbuphine concentrations were at their lowest.

We believe that prophylactic administration of naloxone or nalbuphine to prevent side effects of epidural morphine is not justified, and that treatment should be administered only to patients who develop symptoms. As we were unaware of other investigations comparing therapeutic administration of these drugs, we designed this study to determine their relative benefits and side effects. Our findings that nalbuphine more effectively relieved side effects while preserving analgesia supports its use in preference to naloxone. Although reversal of analgesia with naloxone might not have occurred had we given smaller doses, we selected relatively large boluses of each drug to maximize both beneficial and adverse effects. The 0.2-mg naloxone and 5-mg nalbuphine doses we used are in the ratio of 1:25, which approximates the 1:34 antagonist potency ratio for these drugs quoted by Schmidt et al. (21) and the 1:31 ratio for reversal of fentanyl-induced respiratory depression reported by Bailey et al. (22).

Nalbuphine potentially might improve analgesia via its agonist effect at the κ-receptor, or diminish it by antagonism at the μ-receptor. Indeed, studies in rats suggest a complex analgesic interaction between intraspinal morphine and systemic nalbuphine, depending on the relative doses of each, the time after nalbuphine administration, and the nature of the nociceptive stimulus (23). Reversal of epidural morphine analgesia by nalbuphine has not been described in humans (9,19), although decreased analgesia has occurred after nalbuphine administration to counteract respiratory depression after high (22,24,25) but not lower (26) doses of intravenous fentanyl. The degree of reversal of analgesia noted in these studies appears to be less than that found with naloxone, particularly when small doses of nalbuphine were used (22,24). One case report has described improved analgesia and reversal of side effects by nalbuphine in a patient who had received epidural morphine after cesarean section (27).

In the current study, we found no change in analgesia after nalbuphine, whereas pain scores increased significantly after naloxone. Although this did not result in different meperidine utilization in the two groups, we believe that increased pain scores are more sensitive indicators of patient discomfort than is systemic opioid dosage; pain scores were carefully evaluated by the investigators, whereas meperidine was administered at the discretion of the postpartum nurse. Any supplemental analgesic given to treat pain conceivably could have affected some of the outcome variables measured (e.g., nausea or pruritus). We selected meperidine because it lacks opioid antagonist effect and, in small boluses, causes minimal nausea or pruritus. As both groups received similar doses of meperidine, it is unlikely to have significantly modified our results.

In common with other investigators (9,19,20), we found increased sedation after the first nalbuphine injection, which did not worsen with subsequent doses (19). In spite of this, overt respiratory depression did not occur in any patient. Most studies in which arterial blood gases have been measured indicate that nalbuphine reverses respiratory depression from epidural morphine, despite causing increased sedation (9,19). Although, Morgan et al. (20) described several cases of respiratory depression in patients who had received nalbuphine, problems also occurred in the control group, and sedation by other depressant drugs probably was contributory. Close respiratory monitoring is advisable if drugs such as phenothiazines or systemic opioids are administered to patients who are sedated following nalbuphine given after intraspinal opioids. Although we found nalbuphine more satisfactory than naloxone for relieving pruritus and nausea, the duration of effect was limited. Some patients experienced persistent symptoms for which repeated treatment with the study drug proved less effective. Because fewer patients received second and third doses, analysis of these data is less reliable. Lack of a prolonged effect is not surprising, however, as the duration of both drugs is shorter than the usual duration of side effects. In a study comparing naloxone and nalbuphine given prophylactically as a basal infusion with additional self-administered doses, Kendrick et al. (28) also found nalbuphine more effective in preventing pruritus after epidural morphine. However, differences were apparent only during the first 8 h, with pruritus generally declining thereafter in both groups. If treatment of symptomatic patients is initiated with a nalbuphine bolus, supplemental therapy may be necessary for continuing symptoms. Whether a nalbuphine infusion is preferable to using conventional antipruritics or antiemetics in this circumstance has not been investigated.

In conclusion, we found that nalbuphine was better than naloxone for the initial treatment of pruritus and nausea caused by epidural morphine given during cesarean section. In addition to proving ineffective, naloxone partially reversed analgesia. Nalbuphine caused increased sedation but this had no obvious detrimental effects.

To develop a regimen that would provide good analgesia after cesarean section with minimal side effects in the setting of prolonged (>24 h) epidural infusion, buprenorphine or fentanyl was combined with 0.03% bupivacaine in a double-blind study of 23 parturients. Patients were randomly assigned to two groups: group I (n = 12), patient-controlled analgesia by epidural infusion of buprenorphine (3 μg/mL) with 0.03% bupivacaine; group II (n = 11), patient-controlled analgesia by epidural infusion of fentanyl (2 μg/mL) with 0.03% bupivacaine. Plasma for determination of opioid concentrations was obtained at intermittent intervals. Pain relief was similar and satisfactory in both groups. The median overall satisfaction score was higher (10.0 vs 7.5; $P < 0.03$) for group II. Pruritus was mild in most patients. Nausea and vomiting, which were most disturbing to t patients, were seen only with buprenorphine. I patient had a respiratory rate of <12 breaths/mi Mean plasma opioid concentrations did not exce 1 ng/mL during the study. However, four patie (33%) in group I and six patients (55%) in group experienced sensory loss in the lower extremiti which made ambulation difficult. One patient in ea group developed extensive pressure blisters on bo heels. These complications led us to terminate t study. We conclude that 0.03% bupivacaine used combination with an opioid in prolonged epidu infusions produces a high incidence of sensory loss the lower extremities and is unsuitable for situatio in which early ambulation is desired.

(Anesth Analg 1992;75:753-

Epidural use of local anesthetics for postoperative analgesia has been associated with adverse effects, such as hypotension, lower extremity sensory loss, pressure sores, and difficulty with ambulation (1–8). Epidural administration of fentanyl to provide postoperative analgesia is popular because of low incidence of side effects, such as nausea, vomiting, respiratory depression, and urinary retention (9). Buprenorphine, an opioid agonist/antagonist with a very high lipid solubility and affinity for the opioid receptor, has been reported to provide satisfactory postoperative analgesia with few serious side effects when administered epidurally (10,11) and might be superior to fentanyl for this purpose. Opioids have been administered epidurally in combination with local anesthetics to reduce the effective concentration of either drug and thus minimize side effect 14).

The objective of this investigation was to de regimen associated with minimal opioid- anesthetic-induced side effects in the settir prolonged (>24 h) epidural infusion after c section. Fentanyl combined with 0.03% bupi and buprenorphine combined with 0.03% acaine, at doses of these opioids found in our to be equipotent, were compared with re quality of analgesia, ease of ambulation, ar dence of side effects. In addition, we dete plasma concentrations of both opioids dur infusion to determine whether either drug a lates in plasma.

Methods

The study was approved by the Institutional Board of the Albert Einstein College of Medici written, informed consent was obtained fro patient. Twenty-three ASA physical status I–I rients at term, scheduled for elective cesarean under epidural anesthesia, were included. I

known to use sedatives or analgesics were excluded. After the subjects received 30 mL of 0.3 M sodium citrate and an infusion of 1.5–2 L of lactated Ringer's solution, continuous lumbar epidural anesthesia to achieve a T4-6 sensory level was established by injecting 3 mL of 3% 2-chloroprocaine with 5 μg/mL of epinephrine followed by 0.5% bupivacaine with epinephrine (2 μg/mL) via a catheter placed at the L3-4 interspace. The epidural catheter was directed cephalad 3 cm into the epidural space. No opiates were administered before or during the surgical procedure.

On arrival in the postanesthesia care unit, patients were randomly allocated to one of two groups: group I ($n = 12$) received continuous epidural patient-controlled analgesia (PCA) infusion of buprenorphine (3 μg/mL) with 0.03% bupivacaine diluted in saline. Group II ($n = 11$) received continuous epidural PCA infusion of fentanyl (2 μg/mL) with 0.03% bupivacaine diluted in saline.

The solutions used were placed in coded bottles, and neither the investigator nor the patient was aware of their contents. The epidural catheter was connected to a portable Pancreatec 5500-mini infuser (Pancreatec Inc., San Diego, Calif.), and each patient received an initial infusion at the rate of 10 mL/h, with self-administered 10-mL bolus doses every 2 h as desired.

Every 4 h or sooner, if requested, an investigator evaluated the patient for side effects and quality of analgesia. When required, he also altered the infusion rate and administered additional 10-mL bolus doses to achieve adequate analgesia. No patient received systemic opioids or sedatives during this treatment. The decision that the infusion was no longer necessary was made by the patient, but in no case was the duration of the infusion <24 h. Pain intensity was evaluated by using a 10-point visual analogue scale in which progressive changes in facial expression indicated degree of pain (0 = no pain; 10 = most severe pain). Overall satisfaction with the infusion was assessed by using a 10-point scale (0 = no satisfaction; 10 = best satisfaction). The patients were rated for side effects using a three-point scale (1 = mild; 2 = moderate; 3 = severe). Vital signs were monitored every 1–2 h by a nurse. Assisted by a nurse, patients started to ambulate 12–24 h after initiation of the study. On each occasion, heart rate and arterial blood pressure were measured at the start of ambulation. All of the patients had a urethral catheter inserted before and removed 12–24 h after surgery.

Plasma levels of fentanyl and buprenorphine were determined at 0, 1, 4, 8, 12, 36, and 48 h from the onset of epidural PCA infusion. Venous blood samples were obtained from an antecubital vein and, after centrifugation, plasma was separated and stored at −20°C until analysis. Plasma concentrations of fentanyl were determined using a radioimmunoassay kit (Research Diagnostics, Flanders, N.J.) (15). Plasma concentrations of buprenorphine were determined by Hazelton Laboratories Corp. (Vienna, Va.) using radioimmunoassay (16). The fentanyl assay has a limit of detection of 0.1 ng/mL and a coefficient of variation of 6.0%; the corresponding values for the buprenorphine assay are 0.1 ng/mL and 7.6%, respectively. Data were analyzed using repeated measures analysis of variance, Fisher's exact test, and Wilcoxon rank sum tests where appropriate; $P < 0.05$ was considered significant.

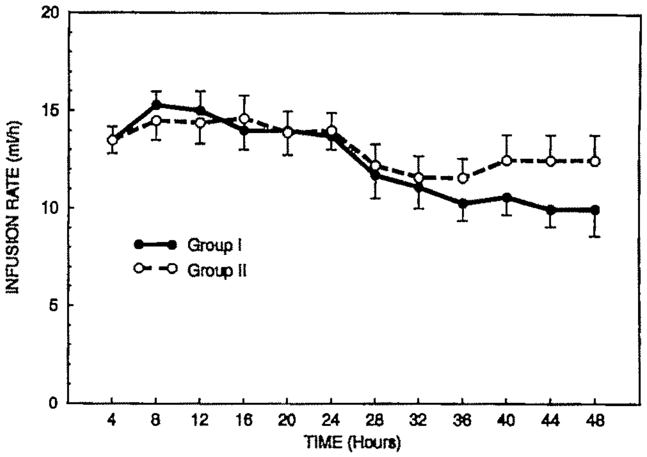

Figure 1. Patient-controlled analgesia epidural infusion rates. Values are mean ± SE. Data were analyzed by repeated measures analysis of variance. There were no differences between groups I and II.

Results

There were no differences between the groups with respect to age, height, weight, or parity. The durations of infusions for groups I and II were 34.2 ± 2.5 h (mean ± SE) and 39.0 ± 3.2 h, respectively. There were no differences in infusion rates (Figure 1) and the volume received as bolus doses between the two groups throughout the study (analysis of variance). Pain relief was satisfactory and similar (Table 1). The median overall satisfaction score was 7.5 for group I and 10 for group II ($P < 0.03$, Wilcoxon rank sums). The total incidence of pruritus for patients in group I (50%) did not differ significantly from that in group II (73%) (Fisher's exact test). Pruritus severe enough to require treatment occurred in only one patient in group I. Sedation was common, 58% in group I and 55% in group II. Sedation was never more than mild and occasioned no patient complaints. Nausea and vomiting were seen only in patients treated with buprenorphine, 33% and 25%, respectively. No pa-

Table 1. Pain Scores[a]

Time of study (h)	Group I		Group II	
	Mean (SE)	*n*	Mean (SE)	*n*
1	2.8 (0.9)	12	1.3 (0.7)	11
4	2.9 (0.8)	12	2.5 (0.7)	11
8	2.3 (0.4)	12	2.0 (1.0)	11
24	2.4 (0.6)	12	1.8 (0.9)	11
36	2.1 (0.4)	7	0.8 (0.4)	9
48	2.3 (0.5)	2	1.2 (0.4)	4

Data were analyzed by repeated measures analysis of variance. There were no significant differences between the groups.

[a] Pain scale: 0 = no pain; 10 = most severe pain.

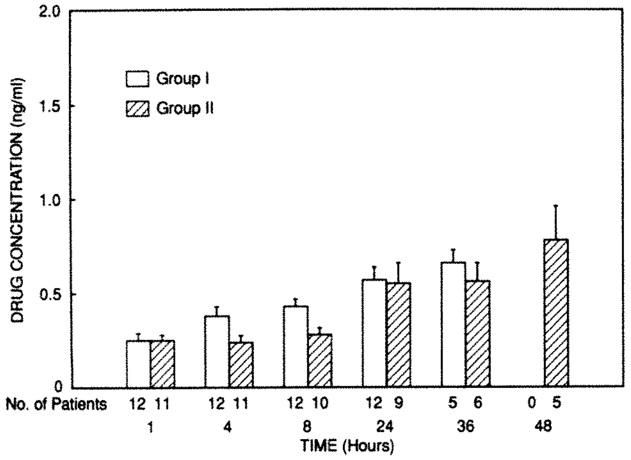

Figure 2. Plasma concentrations of buprenorphine (group I) and fentanyl (group II) are shown as mean ± SE at intervals throughout the study. No samples were obtained from group I patients at the 48-h time.

tient had a respiratory rate of <12 breaths/min or developed urinary retention. Four patients in group I (33%) and six in group II (55%) experienced sensory loss in the lower extremities, which made ambulation difficult. One patient in each group developed pressure blisters on the heels. The total bupivacaine dose over time for patients who developed numbness compared with those who did not was 4.2 ± 1.0 mg/h (mean ± SD) versus 4.2 ± 0.4 mg/h, respectively, in group I and 4.0 ± 0.9 mg/h versus 4.1 ± 0.9 mg/h, respectively, in group II. These differences were not significant. Mean plasma opioid concentrations remained <1 ng/mL throughout the infusion (Figure 2).

Discussion

The goal of this study, to develop a regimen that would provide satisfactory analgesia with minimal side effects and would not interfere with ambulation during a prolonged epidural PCA infusion after cesarean section, was only partially attained. Both infusion regimens were associated with low pain scores and high overall satisfaction scores and were without serious side effects. However, the occurrence of sensory loss in the lower extremities in 43% of our patients made ambulation difficult and in some individuals led to the development of heel blisters. This caused us to terminate the study midway.

Motor block and sensory loss in the lower extremities as well as heel sores have been reported in patients receiving postoperative analgesia with epidural infusions of 0.1% bupivacaine (3–5) or greater (6–8) in combination with opioids. Fischer et al. (4) reported a 61% incidence of numbness in the buttocks and a 74% incidence of leg weakness during epidural infusion of an opioid (fentanyl or morphine) with 0.1% bupivacaine for 24 h after cesarean section. In their report, 39% of the patients could not ambulate. In a previously published study (17), we avoided this problem by using 0.015% bupivacaine, a very much lower concentration. Although patient satisfaction was very high in general, the opioid-induced side effects of nausea, vomiting, and pruritus were bothersome to some. It was hoped that in this study, increasing the concentration of epidural bupivacaine to 0.03% would reduce the use of opioid and, consequently, the frequency of side effects. Indeed, the total dose of fentanyl used in this study was 30% lower. However, prolonged epidural infusion of 0.03% bupivacaine, in combination with fentanyl or buprenorphine, resulted in a frequent occurrence of sensory loss in the lower extremities without a reduction in the incidence of nausea, vomiting, and pruritus. We conclude that epidural 0.03% bupivacaine is unsuitable for prolonged postoperative analgesia because its use interferes with early ambulation.

We thank Michael Parides for his help with the statistical analysis and Barbara Viets for preparation of this manuscript.

American University of Beirut, Beirut, Lebanon

The influence of preoxygenation in the supine (n = 10) versus the 45° head-up (n = 10) position on the duration of apnea leading to a decrease in arterial oxygen saturation to 95%, as monitored by pulse oximetry, was investigated in 20 women undergoing elective cesarean section at term of pregnancy. The results were compared with those obtained in a control group of 20 nonpregnant women. In the supine position, the average time to desaturation to 95% was significantly shorter in the pregnant group (173 ± 4.8 s [mean ± SD]) than in the control group of nonpregnant women (243 ± 7.4 s). Using the head-up position resulted in an increase in the desaturation time in the nonpregnant group (331 ± 7.2 s) but had no significant effect in the pregnant group (156 ± 2.8 s). We conclude that pregnant women desaturate their arterial blood of oxygen more rapidly than do nonpregnant women. Furthermore, the head-up position extends the duration of apnea that can take place before desaturation occurs in nonpregnant patients.

(Anesth Analg 1992;75:757–9)

Preoxygenation is mandatory before "rapid-sequence" induction of general anesthesia in pregnant women (1,2), because they are at high risk for regurgitation and aspiration of gastric contents. Preoxygenation results in denitrogenation of the lungs (3), leading to an increase in oxygen reserve and delayed onset of hypoxia during apnea.

During pregnancy, the functional residual capacity of the lungs (FRC) is decreased, with further reduction occurring in the supine position (4). This decrease of FRC is compounded by the increase in oxygen consumption (5). As a result, the reduction in arterial oxygen tension during apnea is significantly greater in pregnant than in nonpregnant women (1).

Raising the awake pregnant woman to the upright position increases FRC (3) and Pa_{O_2} and reduces Pa_{CO_2} while breathing room air (6). Thus, it is speculated that arterial desaturation during apnea may be delayed in the pregnant patient if induction of anesthesia is accomplished in the head-up position (7,8).

We therefore investigated, in parturients about to undergo cesarean section, the effects of the supine versus the 45° head-up position on the duration of apnea, which would lead to a decrease in arterial oxygen saturation to 95%. The results were compared with those obtained in a control group of nonpregnant women.

Methods

The investigation was approved by the Institutional Research Committee, and informed consent was obtained from all patients. Twenty term-pregnant patients about to undergo elective cesarean section under general anesthesia were enrolled in the investigation. Patients with a history of hypertension, preeclampsia, anemia, diabetes, chronic smoking, or other conditions that might influence respiratory function or oxygen delivery were excluded. Patients with signs of fetal distress or abnormality were also excluded. Preoxygenation, rapid-sequence induction of anesthesia, and tracheal intubation were accomplished in the supine position in 10 patients and in the 45° head-up position in the remaining 10.

In all cases, arterial oxygen saturation was monitored continuously, with a pulse oximeter applied to the thumb, beginning while patients were breathing room air. They were then given oxygen (8 L/min) via

[b]Significantly different from supine group.

the circle system of an anesthesia machine and a tight-fitting face mask over a period of 3 min. A rapid-sequence induction of anesthesia was accomplished after application of cricoid pressure using ketamine (1.5 mg/kg). Succinylcholine (1.5 mg/kg) was injected intravenously and the trachea intubated. Thereafter, the tracheal tube was left open to room air, and a succinylcholine infusion was administered to maintain apnea.

Monitoring of arterial oxygen saturation was continued throughout the period of apnea, and the time to reach 95% saturation (desaturation time) was recorded. For reasons of safety, an arterial oxygen saturation of 95% was considered our endpoint. The endotracheal tube was then connected to the anesthesia circuit and the patient's lungs were ventilated with 100% oxygen until an arterial oxygen saturation of 100% was restored. Thereafter, all patients were placed in the supine position for surgery. Anesthesia was maintained after delivery with nitrous oxide-oxygen (2:1), supplemented with vecuronium. Apgar scores of the newborns were recorded at 1 and 5 min.

Oximetry results were compared with those obtained in a control group of 20 nonpregnant women undergoing gynecologic procedures, such as hysterectomy or tubal ligation, using similar preoxygenation and anesthetic techniques. Ten of the nonpregnant control patients were studied in the supine position; the other 10 were in the 45° head-up position. (As in the pregnant group, all patients having any disease that might influence respiratory function or oxygen delivery were excluded.)

The control oxygen saturation while breathing room air, the peak saturation obtained after preoxygenation, and the mean times of apnea at which 95% saturation were reached were compared. All values were expressed as mean ± SD. The Student's *t*-test was used for statistical analysis; $P < 0.05$ was considered significant.

Results

Demographic Data

The two groups of patients were similar in age, but the mean body weight of the pregnant patients was significantly greater (Table 1). The control arterial oxygen saturation while breathing room air was not significantly different in pregnant and nonpregnant patients. After the 3 min of preoxygenation, the oxygen saturation increased to 100% in all subjects.

During apnea in the supine position, the average time to desaturation to 95% was significantly shorter in the pregnant than in the nonpregnant control patients. Use of the head-up position resulted in a significant increase in the desaturation time in the nonpregnant but not the pregnant women (Table 1). In all patients, subsequent ventilation with 100% oxygen was followed by a transient decrease in saturation to 93%–94% for 5–10 s, with a rapid increase to 100% saturation thereafter.

In the cesarean section group, all newborns had an Apgar score ≥7 at 1 min and ≥8 at 5 min.

Discussion

The present study shows that desaturation after preoxygenation occurred more rapidly in apneic pregnant than in nonpregnant women, whether positioned in the supine or the 45° head-up tilt position. In the cesarean section group, the mean desaturation time to 95% was 173 ± 4.8 s in the supine position and 156 ± 2.8 s in the head-up position, a nonsignificant difference. In contrast, the desaturation time in the nonpregnant women increased from 243 ± 7.4 s in the supine position to 331 ± 7.2 s in the head-up position.

During pregnancy, the decrease in FRC (4) results in a reduction in oxygen reserve that is compounded by the increased oxygen consumption (5). During apnea, the oxygen reserve in the FRC will be exhausted more quickly in the pregnant than in the nonpregnant woman. Similarly, in obese patients arterial desaturation is significantly faster than in normal patients, with a linear correlation between time to desaturation and degree of obesity (9,10). In obese patients, the FRC is further reduced in the supine position (11).

Our data also show that preoxygenation in the head-up position resulted in an increase of the safe duration of apnea in nonpregnant patients but was not associated with any significant change in pregnant patients. These results were unexpected, because a change from the supine to the sitting position has been shown to increase the FRC in both the pregnant (4) and nonpregnant patient (12). It is possible that adopting the 45° head-up rather than the sitting position may not significantly increase the FRC in the pregnant patient at term. In contrast, the FRC may significantly increase with position change in the nonpregnant woman, because most of the alteration in FRC takes place between the horizontal and 60° head-up tilt position (12).

In conclusion, the present study shows that after 3 min of preoxygenation, desaturation during subsequent apnea, as monitored by pulse oximetry, is more rapid in pregnant than in nonpregnant patients. Changing from the supine to the 45° head-up position prolongs the desaturation time in the nonpregnant patient but has no effect in the pregnant woman.

Metoclopramide-Enhanced Analgesia for Prostaglandin-Induced Termination of Pregnancy

William H. Rosenblatt, MD, Ann Marie Cioffi, RN, Raymond Sinatra, MD, PhD, and David G. Silverman, MD

Department of Anesthesiology, Yale University School of Medicine, New Haven, Connecticut

We previously determined that a single dose of metoclopramide could significantly reduce the patient-controlled analgesia (PCA) morphine requirements of women undergoing prostaglandin-induced termination of pregnancy. In the present study, we evaluated whether repeated doses of metoclopramide would further reduce pain and accelerate expulsion of the fetus. After intraamnionic injection of prostaglandin, patients were randomly allocated to receive either 10 mg of intravenous metoclopramide (n = 17) or saline (n = 15), concurrent with the initiation of PCA. A second, identical dose was administered 4 h later. Data included visual analogue scale scores for pain 45 min after each administration of metoclopramide or saline and visual analogue scale and sedation scores every 2 h for the first 10 h, amount of morphine delivered by PCA pump, time of fetal and placental passage, and hospital discharge. Metoclopramide-treated patients experienced significantly earlier fetal and placental passage ($P < 0.05$). This was associated with a 66% reduction in PCA morphine received by the time of fetal delivery ($P < 0.05$). In addition, patients in the metoclopramide group were discharged from the hospital significantly sooner ($P < 0.05$). This difference included fewer second-day hospital stays ($P < 0.05$). Visual analogue scale scores measured 45 min after each infusion of the study agent were reduced from baseline in the metoclopramide group only ($P < 0.05$). No significant intergroup differences were noted with respect to pain or interval morphine usage. We conclude that repeated doses of metoclopramide significantly reduce the duration of induced labor and therefore the total PCA morphine requirements. This effected an earlier hospital discharge for patients undergoing prostaglandin-induced labor. The analgesic potentiating effect of metoclopramide is demonstrable within 45 min of administration.

(Anesth Analg 1992;75:760–3)

In a preliminary trial, we determined that the intravenous administration of metoclopramide significantly reduced the intravenous patient-controlled analgesia (PCA) opioid requirements and early pain scores of women undergoing induced labor for termination of pregnancy (1). In addition, the time interval between the intraamnionic injection of prostaglandin $F_{2\alpha}$ and fetal passage was significantly shortened.

Our use of metoclopramide for the purpose of reducing pain in this patient population was prompted by reports that metoclopramide provides effective analgesia for renal colic and improves analgesia when used for the treatment of opioid-induced nausea during labor (2–4). The effect of metoclopramide in the genitourinary tract may be attributed in part to its antagonism of the dopamine receptor and to its cholinergic activity, reducing smooth muscle spasm and increasing effective peristaltic action (5). Dopamine has also been demonstrated to depress the peristaltic activity of the fallopian tubes in an animal model (6). In addition, intravenous metoclopramide is capable of stimulating the neuroendocrine axis (7–9).

We repeated our trial with the use of two intravenous doses of metoclopramide, separated by 4 h, to determine whether by maintaining the level of metoclopramide we could extend the period of improved analgesia, promote passage of the placenta, and accelerate hospital discharge.

Methods

The study was approved by our Human Investigation Committee, and informed, written consent was obtained from 37 adult women, ASA physical status II, who had elected to have their second-trimester preg-

nancies terminated by an intrauterine injection of prostaglandin $F_{2\alpha}$ (Hemabate). Subjects were instructed in the use of a PCA device (Abbott Life Care II) and in the use of a visual analogue scale (VAS) for pain (0 = no pain; 10 = worst possible pain). They were randomly allocated in a double-blind fashion to receive either intravenous metoclopramide (10 mg) or an equivalent volume of normal saline when a VAS score of >5 was achieved. Patient-controlled analgesia (1 mg of morphine every 6 min on demand and a constant infusion of 1 mg/h) was begun 10 min after the study agent was administered. The dose of metoclopramide or saline was repeated 4 h later. Antiemetic medication (droperidol) and prostaglandin E suppositories needed to enhance labor were administered as per established hospital protocol.

The following data were collected by a nurse-investigator: VAS scores 45 min after each intravenous administration of metoclopramide or normal saline and VAS and sedation scores (graded from 1 = alert and oriented to 5 = stupor) every 2 h for the first 10 h, amount of PCA morphine delivered, time of fetal and placental passage, and hospital discharge. Differences between the groups with respect to VAS scores were analyzed using the Wilcoxon rank sum test. Differences in morphine consumption were analyzed with unpaired *t*-test and two-factor analysis of variance for repeated measures. Summary variables, including demographics, were analyzed using unpaired *t*-test and Fisher's exact test. A *P* value <0.05 was considered statistically significant.

Results

Of the 37 patients studied, 5 were not included in the analysis because of incomplete PCA data. Of the remaining subjects, 17 received metoclopramide and 15 normal saline. The two groups were similar with regard to age, weight, parity, surgical history, gestational age, reason for choosing termination of pregnancy, and baseline pain. After intravenous drug administration, interval sedation scores, doses of antiemetic medication, and number of prostaglandin E suppositories needed to enhance labor did not differ between groups. There were no untoward effects noted.

Forty-five minutes after each injection of metoclopramide or saline, only the metoclopramide-treated patients reported a significant reduction in the VAS score for pain ($P < 0.05$) (Figure 1). Two-hourly VAS scores for pain did not differ significantly between groups.

Likewise, interval morphine use did not differ significantly between groups. However, patients in the metoclopramide group received 66% less total morphine until passage of the fetus (12.2 ± 8.5 vs 27.6 ± 20.3 mg [mean ± SD]) ($P < 0.05$). This reduce total morphine requirement reflects significantly ea lier fetal expulsion (3.12 ± 2.8 vs 6.63 ± 5.7 h) ($P <$ 0.05) (Figure 2). Placental passage occurred signif cantly earlier in the metoclopramide-treated grou (4.56 ± 3.3 vs 8.74 ± 5.7 h) ($P < 0.05$) (Figure 2).

Moreover, patients treated with metoclopramid experienced earlier hospital discharge (12.0 ± 7.5 v 21.25 ± 6.2 h) ($P < 0.05$) (Figure 2). This differenc

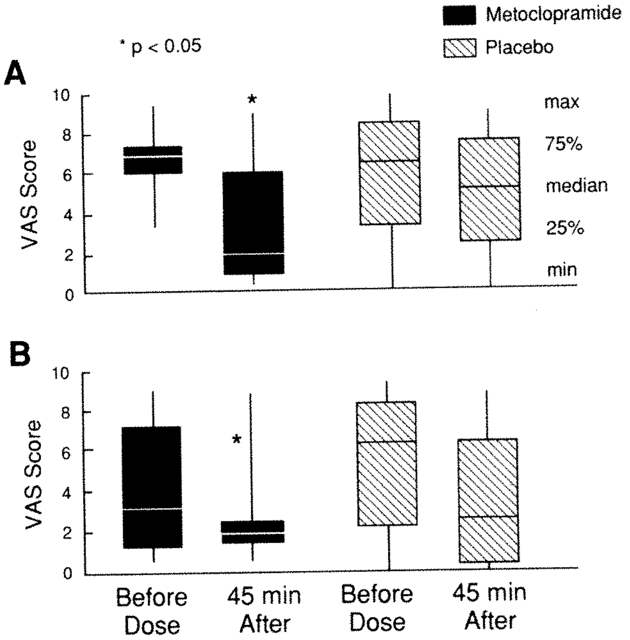

Figure 1. Visual analogue scale (VAS) scores before and 45 min after the first (**A**) and second (**B**) administration of metoclopramide or normal saline. *Significant intragroup change in VAS.

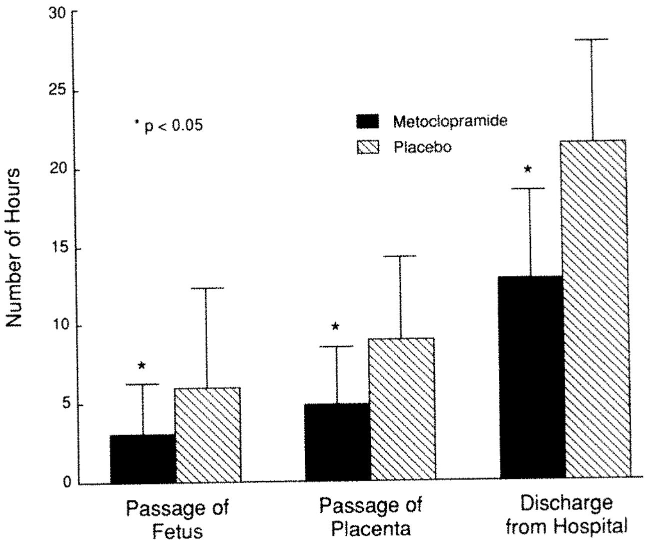

Figure 2. Time from first dose of metoclopramide or normal salin (and start of patient-controlled analgesia) to events of fetal an placental expulsion and hospital discharge.

included significantly fewer second-day hospitalizations (5 vs 11 in the saline-treated group) ($P < 0.05$). Sedation scores were not significantly different, but placebo-treated patients tended to be more sedated at the latest hour of observation ($P = 0.1$).

Discussion

These data are consistent with findings in our preliminary study in that metoclopramide treatment was associated with a reduction in the duration of induced labor and hence total demand-analgesic requirements. In addition, we now have demonstrated a sharp reduction in pain scores, accelerated fetal and placental passage, and earlier hospital discharge. Although sedation scores did not differ significantly, higher scores did occur in the tenth hour of study in the placebo-treated patients. This may in part explain the later hospital discharge of this group, owing to the sedative effects of their greater total morphine intake and exhaustion due to a prolonged labor. Exact discharge criteria were based on the "home-ready" evaluation by the gynecology nursing staff.

Metoclopramide is a central and peripheral dopamine antagonist with peripheral cholinergic properties. It has been noted to oppose the gastrointestinal inhibitory effects of the specific dopamine agonist, apomorphine, and to accelerate gastric emptying and intestinal peristalsis (10). Recently, metoclopramide has been found to have investigative and therapeutic applications in urology (2,3,5).

In the present study, metoclopramide was associated with a significant but short-lived reduction in the pain associated with prostaglandin-induced labor. Furthermore, there was an accelerated delivery of the abortus.

We speculate that the cramping pain of prostaglandin-induced labor may be due to incoordinate muscular contraction of the fallopian tubes (i.e., spasm). As in the gastrointestinal and urinary tracts, metoclopramide may restore normal peristaltic function to this smooth muscle system, thereby reducing the discomfort at its source and providing an improved expulsive force. There is evidence to suggest such a role for dopamine receptor antagonism in this setting: (a) dopamine receptors have been identified along the length of the human fallopian tube, and the in vitro application of dopamine in the sow oviduct has been shown to depress normal peristaltic activity (8,11); (b) metoclopramide stimulates human ureteral peristalsis and canine detrusor and urethral sphincter activity (3,12); (c) clinically, metoclopramide is efficacious in the treatment of renal colic (2,5); and (d) a previously reported incidental finding of Vella et al. (4) was that patients receiving meperidine and metoclopramide (for antiemetic therapy) during spontaneous labor had significantly lower pain scores than those receiving meperidine and promethazine.

The shortening of the time to passage of the fetus in the metoclopramide-treated group may have a central neuroendocrine mechanism. Metoclopramide (10 mg) is capable of stimulating the neuroendocrine axis, as is noted in human studies in which prolactin and vasopressin release are increased (8). It is possible that, like other dopamine antagonists, metoclopramide facilitates oxytocin release, thus enhancing uterine activity (13). However, the effect of dopamine and dopamine agonists is not consistent throughout the course of pregnancy, and one can only speculate as to the application of this effect to term labor.

It should be noted that the present study differs from our previous one not only in that the current protocol included a second dose of metoclopramide, but also in the course of the control patients: although the interval from intraamniotic injection of prostaglandin $F_{2\alpha}$ to onset of significant cramping pain was similar in both study populations (2–2.5 h), all patients in the current study had significantly higher baseline VAS scores before receiving metoclopramide or saline compared with the earlier study (6.4 vs 4.8) ($P < 0.05$). In addition, the current control patients expelled the fetus significantly earlier than their control counterparts in the earlier study (9.1 vs 15.7 h) ($P < 0.05$). This is not immediately explainable, in that there were no apparent differences between the two study groups with regard to the protocol for induction of labor. These baseline differences confound any attempt at close comparison of the two study populations.

In conclusion, the present data indicate that two doses of metoclopramide administered at an interval of 4 h effectively shortened the duration of induced labor (and hence reduced total PCA morphine consumption) and duration of hospitalization. In addition, acute relief of pain was noted. However, the decrease in pain was not sustained in that the metoclopramide-treated and control populations experienced similar overall VAS scores. By reducing overall cumulative morphine consumption, metoclopramide may have reduced sedation and allowed earlier hospital discharge.

We thank Theresa Z. O'Connor, MPH, for her assistance with statistical analysis, and Tracy Carafeno, RN, DeAwngellice Gore, RN, and Krys Dobranowski, RN, for their excellent nursing care.

Comparison of Methods for the Detection of Myocardial schemia During Noncardiac Surgery: Automated T-Segment Analysis Systems, Electrocardiography, and ransesophageal Echocardiography

hn E. Ellis, MD, Manish N. Shah, BA, Joan E. Briller, MD, Michael F. Roizen, MD,
olomon Aronson, MD, and Steven B. Feinstein, MD

epartment of Anesthesia and Critical Care and Department of Internal Medicine, The University of Chicago,
hicago, Illinois

Clinicians often fail to detect intraoperative ischemic electrocardiographic (ECG) changes when viewing oscilloscopes. Automated ST-segment monitors promise to increase the detection of such ECG changes. We investigated the capacity of two commercially available ST-segment monitors to detect intraoperative myocardial ischemia in patients at high risk for developing intraoperative myocardial ischemia during vascular and other noncardiac procedures. The ST-segment monitors were compared with two reference monitors: (a) printed eight-lead ECGs, as interpreted by a cardiologist, and (b) the presence of segmental wall motion abnormalities and thickening abnormalities detected by transesophageal echocardiography (TEE). We also examined the capacity of the printed ECG to diagnose myocardial ischemia when compared with TEE. We studied 44 patients who underwent TEE, printed multilead ECG, oscilloscope monitoring of leads V_5 and II, and measurement of ST-segment deviation from the baseline using an automated Hewlett Packard ST-segment device. The sensitivities for the Hewlett Packard system were 40% for TEE-diagnosed myocardial ischemia and 75% for ECG-diagnosed ischemia. Comparison of the printed ECG with TEE revealed that ST-segment changes in the printed ECG, as analyzed by a cardiologist, were 25% sensitive and 62% specific for the detection of TEE-diagnosed myocardial ischemia. When T-wave inversions were added to ST-segment depression as a criterion for the diagnosis of myocardial ischemia by the printed ECG, the sensitivity of ECG for the detection of intraoperative myocardial ischemia, as determined by TEE, was 40% and specificity was 58%. Twenty-three of the 44 patients were simultaneously monitored in leads I, II, and V_5 with an automated Marquette ST-segment monitor. In the 23 patients monitored with both Hewlett Packard and Marquette systems, the sensitivities (80% vs 100%, respectively) and specificities (67% vs 50%, respectively) were similar for ECG-diagnosed myocardial ischemia. Monitors of intraoperative myocardial ischemia often do not agree with each other; however, automated ST-segment monitors predict most ischemic changes seen on the printed ECG and can be used as an alarm to alert the clinician to examine the ECG.

(Anesth Analg 1992;75:764–72)

Recent work has documented the high incidence of perioperative ischemia in patients with peripheral vascular disease (1) and in those with nown coronary artery disease (2). In patients undering coronary artery bypass grafting procedures, rioperative myocardial ischemia has been associed with an increased risk of perioperative myocardial infarction (3). In patients undergoing noncardiac surgery, ST-segment depression detected by Holter monitoring after surgery predicts a ninefold increase in the risk of ischemic postoperative events (4). Because myocardial ischemia is often not detected by clinicians when viewing oscilloscopes (5), automated vigilance of the ST segments of the electrocardiogram (ECG) has been proposed as a method to alert clinicians to changes in the ECG (6,7).

Several instruments that continuously monitor deviation of the ST segment at a defined point in the cardiac cycle are now available. Although this technology has been used to define demographic predic-

tors of intraoperative myocardial ischemia (8), ST-segment monitors have not been compared directly with other established techniques for the detection of intraoperative myocardial ischemia.

The goal of this study was to assess this new ST-segment monitoring technology. Accordingly, we tested the hypothesis that ST-segment trend analysis could detect intraoperative ischemia as well as two commonly used techniques: (a) analysis of printed multilead ECG by a cardiologist, and (b) the detection of abnormalities in wall motion using two-dimensional transesophageal echocardiography (TEE). We compared two ST-segment trend monitors with ECG and TEE detection of intraoperative myocardial ischemia to determine sensitivity, specificity, positive predictive rate, and negative predictive rate for the two ST-segment trend monitors. In determining these rates, printed ECG and TEE were considered as standard reference monitors.

The need for determining these four rates when assessing new technology has been recently highlighted by Cooper et al. (9) who, in decrying the poor quality of early evaluations of magnetic resonance imaging, noted that "sound and scientifically rigorous evaluation of new technologies is necessary to insure quality of care and cost-effective use of resources." Rigorous technology assessment is crucial, for an unproved technology may not only prove costly, but may also delude the clinician into believing a sick patient normal or into initiating treatment when none is needed.

Methods

Patient Selection and Measurement Periods

After Institutional Review Board approval and patient consent, we studied 44 patients whose mean (±SD) age was 64 ± 12 yr. Of these 44, 35 underwent vascular reconstructive surgery (16 aortic, 12 carotid, and 7 femoral artery procedures). Nine other patients with significant risk factors for coronary artery disease undergoing other types of noncardiac surgery were also studied. Five were studied during laparotomy, and the remaining four underwent miscellaneous procedures. Those included in our study had at least two of the following risk factors: (a) age >70 yr, (b) history of hypertension, (c) history of peripheral vascular disease, (d) history of diabetes, (e) chronic renal failure, or (f) known coronary artery disease. The only exclusion criteria used were the presence of left bundle branch block pattern, a ventricular paced rhythm, or cardiac surgery. Left ventricular hypertrophy with "strain pattern" on ECG was not considered an exclusion. The ECGs were printed and ST-segment data recorded at 5 min before and after induction of anesthesia and at 5 min after tracheal intubation. Complete measurements (ECG, ST segments, and TEE) were carried out for 15 s before and after incision and 5 min before and after vascular occlusion and reperfusion during major vascular surgery, whenever any of the monitors suggested myocardial ischemia or whenever major hemodynamic perturbations (≥40% change from baseline in heart rate or mean arterial blood pressure) occurred.

ST-Segment Trend Monitors

To each patient we applied the leads of one or both of two ST-segment monitors. The Hewlett Packard (HP) (Hewlett Packard, Waltham, Mass.) 78534C monitor was used in all 44 patients. This monitor measured the deviation of the ST segment at a point 120 ms after the R wave from a baseline defined at 80 ms before the R wave. Paced beats were discarded and the median value during a 15-s epoch displayed. These recordings were made in the diagnostic mode, within the frequency 0.05–100 Hz. The value of ST-segment deviation was measured in leads II and V_5; the absolute values of ST-segment variation in these two leads were summed and displayed by the monitor.

The ST-segment monitors display a total that represents the sum of the absolute values of ST-segment change in the monitored leads. Therefore, we prospectively defined myocardial ischemia as the increase of 1.0 mm in the sum of the absolute value of ST-segment score over the lowest absolute value (closest to no deviation) measured during the operative procedure. We assumed that most ischemic changes would be in one vascular bed and, therefore, in one lead at a time. The definition of myocardial ischemia as 1 mm or greater change in the summated leads is not standard. However, we chose this definition in an attempt to improve sensitivity and also because this summed presentation is the usual manner in which the monitor displays data to the clinician.

A second monitor, the Marquette (MQ) (Marquette, Milwaukee, Wis.) 7000 ST-segment trend monitor, was applied simultaneously to 23 of the patients in the HP group. This monitor became available after we began our studies with the HP system. The MQ monitor measured the ST segment at 80 ms after the J point in leads I, II, and V_5, and summed the absolute values of ST-segment deviation from the baseline in the three leads. The monitor was used in a diagnostic mode, with a frequency response of 0.05–40 Hz. We prospectively defined myocardial ischemia as the increase of 1.0 mm over the lowest ST-segment sum during the case. When two ECG onitors (HP and MQ) were applied, the electrodes ere cut and attached so as to make them adjacent to ch other for the same lead on different machines. e were aware that results obtained from the HP and Q monitors might vary, because the HP monitor d not use a J-point reference. In addition, the MQ stem used an additional lead (I). Neither of the -segment systems tested allowed adjustment of the int in the cardiac cycle at which the isoelectric seline or the ST segment was measured.

wo-Dimensional Transesophageal Echocardiography

TEE probe was placed in each of the 44 patients ortly after induction of anesthesia. Short-axis views the midpapillary muscle level were recorded for s simultaneously with ST-segment trend and ECG ta, except for the period preceding tracheal intuba- n, when TEE was unavailable. The echocardio- ams were read by a single cardiologist unaware of e clinical condition; wall motion in each of four adrants was graded as 1 = normal, 2 = mild pokinesis and thickening abnormality, 3 = moder- e hypokinesis and thickening abnormality, 4 = inesis and lack of thickening, 5 = dyskinesis. An crease in the wall motion score of 2 or greater was e definition of myocardial ischemia as detected by E. The baseline for each quadrant was considered be the lowest score noted during TEE monitoring, t necessarily the initial TEE recorded after induc- n.

lectrocardiograms

e ECGs of all 44 patients were monitored with a ve-cable system that allowed printing of the six limb ads (I, II, III, aVR, aVL, aVF), the V_5 lead, and the CL_1 lead. These eight leads were printed at the me time that TEE images were recorded on video- pe: (a) on arrival in the operating room, (b) before d after intubation (when TEE was unavailable),) before and after vessel occlusion and reperfusion long with TEE), (d) whenever any of the modalities ggested myocardial ischemia (along with TEE), and) when there were hemodynamic perturbations as eviously defined (along with TEE). These ECGs ere reviewed by a second, independent cardiologist r the presence of myocardial ischemia; she was aware of clinical conditions. Our prospective defi- tion of myocardial ischemia on the printed ECG as 1.0 mm of downsloping ST-segment depression ver the minimal value in any one lead or T-wave versions occurring in more than one lead, or both. he ECG tracings for all 44 patients were available for alysis.

Table 1. Definitions of Rates Used in Technology Assessment

Technology in question (test)	Reference standard (disease) +	Reference standard (disease) −
+	A	B
−	C	D

Sensitivity = Positive test in disease = A/(A+C).
Specificity = Negative test in health = D/(B+D).
Positive predictive value = Disease with a positive test = A/(A+B).
Negative predictive value = Healthy with a negative test = D/(C+D).

Statistical Considerations

To determine the efficacy of the new technology, we compared it with accepted technologies and definitions of the disease state. To define sensitivity (how often the test is positive when the reference standard says the patient has the disease) and specificity (how often the test is negative when the reference standard says the patient does not have the disease), we first needed to define a reference standard. The TEE and eight-lead ECGs were used as two clinically available, separate arbitrary reference standards for the definition of intraoperative myocardial ischemia.

We pooled all periods of time for each patient so that any reading of myocardial ischemia detected during the patient's procedure resulted in that patient being considered to have had an ischemic event. Normal readings at all time periods were taken to indicate the absence of ischemia. Therefore, we determined how well the different ischemia-detection monitors predicted ischemia during an operation, not at each episode. Furthermore, we believe that pooling was necessary because of the different time frames after an ischemic episode in which each monitor is capable of revealing ischemia (10). However, we did note the incidence of ischemic ECG changes that occurred before placement of the TEE probe (i.e., during the stresses of induction, laryngoscopy, and tracheal intubation).

In addition, the positive predictive rate (the percentage of patients with an abnormal test who truly have the disease) and the negative predictive rate (the percentage of patients with a negative test who are truly healthy) were computed (Table 1).

Results

Hewlett Packard ST-Segment Monitors Versus Transesophageal Echocardiography as the Reference Standard

Forty-four patients had both HP ST-segment scores and TEE images available for comparison of the two

modalities. When TEE was used as the reference standard of myocardial ischemia, the sensitivity of the HP system was found to be 40%. In the 20 patients with TEE ischemia, only 8 (40%) had an ST-segment score change of ≥1.0 mm. The specificity of the HP system was 63%; of 24 patients without a significant wall motion abnormality, 15 were without a 1.0-mm increase in their ST-segment score. The positive predictive rate was 47%; of 17 patients with a ≥1.0-mm change in their ST-segment score, 8 had significant wall motion abnormalities by TEE. Finally, the negative predictive rate was 56%; of the 27 patients without ischemia by ST-segment analysis, 15 were without significant wall motion abnormality.

ST-Segment Monitors Versus Electrocardiography as the Reference Standard

In all 44 patients with ECG strips, the HP ST-segment device was compared with the reference standard of ST-segment changes on the printed ECG interpreted by a cardiologist. The sensitivity of the HP ST-segment monitor was 75% (6 of 8), the specificity 69% (25 of 36), the positive predictive rate 35%, and the negative predictive rate 93% compared with the printed ECG.

In the 23 patients in whom both the MQ and HP monitors were simultaneously applied, we also used the cardiologist's interpretation of the ST segments from the printed ECG as the reference standard for ischemia. Our results showed that the HP system was 80% (4 of 5) sensitive and 67% (12 of 18) specific, with a positive predictive rate of 40% (4 of 10) and a negative predictive rate of 92% (12 of 13). The MQ system demonstrated a sensitivity of 100% (5 of 5) and specificity of 50% (9 of 18), with a positive predictive rate of 36% (5 of 14) and a negative predictive rate of 100% (9 of 9) (Table 2).

Printed Electrocardiography Versus Transesophageal Echocardiography as the Reference Standard

In the group of 44 patients, we determined the sensitivity of the printed ECG using TEE as our reference standard for ischemia detection. We examined ST-segment changes, both with and without T-wave inversions, in addition to the presence of isolated T-wave changes, to compute sensitivities and other indices of accuracy. When TEE was considered the comparison standard, sensitivity of ST-segment changes in the printed ECG was 25% (5 of 20), specificity 62% (15 of 24), positive predictive value 62% (5 of 8), and negative predictive rate 58% (21 of 36) (Table 2). When T-wave criteria were added to the definition of ischemia on the printed ECG, sensitivity increased to 40% (8 of 20), whereas specificity was 58% (14 of 24) (Table 2). For an isolated T-wave change, compared with TEE, the positive predictive value was 75% (i.e., three of four patients with isolated T-wave inversions had an ischemic TEE).

Timing of Ischemic Episodes

We also examined how often ECG changes occurred before insertion of the TEE probe. Three patients developed ischemia, as detected by ST-segment changes in the printed ECG before placement of the TEE probe; all three demonstrated subsequent evidence of ischemia as detected by TEE.

Myocardial ischemia occurred most commonly during defined periods of expected stress, such as intubation, incision, and vascular occlusion. Thirty-

Table 3. Comparison of the Incidence of Ischemic ST-Segment Changes in Patients With and Without Left Ventricular Hypertrophy on Preoperative Electrocardiogram

$\chi^2 = 0.380$; 10% critical value = 2.706 (no significant difference).

two of the patients demonstrated myocardial ischemia by one or more of the modalities. Thirty of these 32 patients (94%) demonstrated ischemia during the defined sampling periods, whereas 15 of the 30 also had ischemia during additional time periods. Only two patients had ischemia only during the additional time periods in which measurements were made during abnormal hemodynamics, without manifesting ischemia during expected periods of stress. In these two patients, ischemia was detected by TEE and T-wave inversions in one and by ST-segment changes in the other.

Effects of Left Ventricular Hypertrophy on Incidence of Ischemia Diagnosed by Printed Electrocardiography

We did not exclude patients who had left ventricular hypertrophy (LVH) from this study, although the presence of LVH with repolarization changes ("strain") may make the diagnosis of myocardial ischemia by ECG difficult. The preoperative ECGs of all 44 patients were reviewed for the presence of LVH. Thirty-five patients did not have LVH, seven patients had LVH by voltage criteria without repolarization changes, and only two had LVH with repolarization changes. Neither of the patients with LVH with strain had intraoperative ST-segment changes of >1 mm. A comparison of the incidence of ischemic ST-segment changes in patients with and without LVH appears in Table 3; there was no significant difference.

Intraobserver Variability of Transesophageal Echocardiographic Readings

The videotaped echocardiographic recordings of 16 patients were analyzed 1 yr later by the same reviewer to establish intraobserver variability. In 10 of 16 (62%) patients reviewed, the observer agreed with his previous determination of the presence or absence of intraoperative myocardial ischemia. Five of the six patients who had discordant determinations had small disagreements: (a) a change from normal to moderate hypokinesia read originally was later called a change to mild hypokinesis (four patients; all changed from a two-grade change to a one-grade change); and (b) a change from normal to moderate hypokinesia read originally was later called no change (one patient; a two-grade change). In one patient with baseline segmental wall motion abnormalities (SWMAs), the original reading detected no decrease in function, whereas repeat reading detected a change from moderate hypokinesia to dyskinesia (two-grade change). In 68 of the 88 (77%) episodes reviewed in these 16 patients, the observer agreed with the diagnosis of a normal or ischemic episode.

Discussion

Recent work has highlighted the common and deleterious, yet often unrecognized, nature of perioperative myocardial ischemia (4). Printed ECG and TEE may be used, but they are discontinuous and require physician attention. The use of automated ST-segment monitors has been reported to assist in the vigilance of anesthesiologists (5–7). Although such monitors have been used to document ischemia occurring during reported cases (5) and to define demographic risk factors for the development of intraoperative ischemia during cardiac surgery (7), ST-segment analysis has not been compared with other methods of detecting intraoperative myocardial ischemia.

Limitations of This Study

We used intermittent, brief recordings of TEE and printed ECG in this study. Therefore, it is possible that we missed other periods of ischemia. However, we studied patients during periods of operative stress, such as tracheal intubation and aortic occlusion, and during hemodynamic stress when we believed that ischemia would be the most likely to occur. When we sampled data at times other than the defined perioperative events (during hemodynamic abnormalities or suspected myocardial ischemia), it added little to the detection of ischemia: only two patients, for example, had ischemia detected during periods other than the defined perioperative events. The 18% incidence of myocardial ischemia (detected by ST-segment changes in intermittent printed ECG) in our patients is similar to that reported by other workers who have used continuous ECG monitoring during vascular surgery (11). We therefore believe that such an incidence of myocardial ischemia allows the comparison of the different detection modalities.

We decided to analyze our data by comparing the evidence of ischemia detected during an operation by each monitoring modality rather than by comparing corresponding episodes. We pooled our data because of the temporal dissociation of ECG and TEE in detecting intraoperative myocardial ischemia. This temporal dissociation of ECG and TEE in detecting intraoperative myocardial ischemia has recently been demonstrated by London et al. (12). In that study, although 19 patients had ischemia detected by both modalities, simultaneous ischemia was detected in only 5 patients (12).

Limitations of Transesophageal Echocardiography in Detecting Myocardial Ischemia

A major limitation of TEE is its inability to monitor patients during one of the most stressful parts of surgery—tracheal intubation. Although TEE may be used in awake patients, insertion of the probe before induction of anesthesia might be uncomfortable and might produce additional stress in the patient; it would certainly complicate airway management. Transesophageal echocardiography was not available to us during induction of anesthesia and intubation of the trachea; however, all three of the patients who had ST-segment changes on ECG as evidence of ischemia during this period subsequently developed an ischemic TEE study during surgery.

Transesophageal echocardiography has at least three other limitations in its capacity to detect intraoperative myocardial ischemia. First, although the short-axis view at the midpapillary muscle level does demonstrate the mechanical function of regions subserved by all three major coronary arteries, this view will not detect apical abnormalities. Chung et al. (13) reported a patient who had an anteroapical myocardial infarction (documented by transthoracic echocardiography) after aortocoronary bypass, who demonstrated ST-segment elevation during surgery but whose TEE remained unchanged. As a corollary, it is also possible that if a patient has an apical scar, and the echocardiographer is not careful to maintain a short-axis view at exactly the same level, moving the view in and out of the area of scar may cause the false diagnosis of myocardial ischemia to be made. Second, it has been suggested that changes in afterload, rather than myocardial ischemia, can produce regional wall motion abnormalities. Kavanaugh et al. (14) found in a dog model that the area of wall motion abnormality produced by coronary artery occlusion indeed was greater than was the area of hypoperfusion; however, in that study, pharmacologically induced changes in afterload did not alter segmental wall motion. Third, the normal heart does not have homogeneous contractility; in canine experiments, the apex of the heart has been shown to have greater systolic shortening than basal regions of the left ventricle (15). In those experiments, performed without coronary artery constriction, the differences in regional systolic shortening were statistically significant. However, it is not clear whether the regional heterogeneity was great enough that it would be confused with myocardial ischemia. For example, when dogs were anesthetized with 1% isoflurane, percent systolic shortening was 18% in the apex and 13% in the base; the addition of verapamil abolished the difference in percent systolic shortening, decreasing them to 10% and 9% respectively. It is unlikely that the change from 18% to 10% in the apex would be called hypokinetic relative to the change in the base (13% to 9%). Indeed, the apex is not routinely monitored with TEE. Lowenstein et al. (16), in a recent editorial, discussed animal work in which afterload was increased after a period of myocardial ischemia (17). They point out that although increased afterload does diminish systolic shortening in postischemic myocardium, the decrease does not appear to be of the magnitude that would be associated with a new SWMA. This lack of change would be even less likely to be considered a SWMA when thickening changes are also considered a criteria for SWMA diagnosis, as we believe necessary. Further work is clearly needed to define the sensitivity and specificity of TEE in detecting myocardial ischemia, particularly in the settings of "stunned" myocardium and varying afterload.

We found a disturbingly high intraobserver variability in the diagnosis of myocardial ischemia. In 16 patients in whom studies were reviewed twice, 1 yr apart, 5 patients had a change in diagnosis of intraoperative ischemia. Four of the five patients had a change from normal to moderate hypokinesis, later called a change to mild hypokinesis. We now believe that a change to moderate hypokinesis, which we prospectively defined as change that might represent myocardial ischemia, may not be so significant a change. Tischler et al. (18), using dipyridamole echocardiography to evaluate patients before vascular surgery, scored segments as normal, hypokinetic, akinetic, or dyskinetic; they required a change of one grade to diagnose ischemia. London et al. (12) scored segments as normal, mild hypokinesis, severe hypokinesis, akinesis, or dyskinesis; they required a change of two grades (i.e., from normal to severe hypokinesis) to define a SWMA as representative of myocardial ischemia. Even with these more stringent criteria, the detection of new severe hypokinesis did not appear to herald adverse outcome. The changes that we detected from normal to moderate hypokinesis may represent trivial episodes of myocardial ischemia, or not even myocardial ischemia at all.

ST-Segment Devices

When the HP ST-segment monitor results were compared with analysis of ST-segment changes in the printed ECG for each of the 44 patients, reasonable correlations were seen. The predictive negative rate was an impressive 93%; that is, when the ST-segment monitor never increased its score by ≥1.0 mm, only 7% of the patients developed intraoperative myocardial ischemia, as indicated by printed ECG ST-segment changes. In the smaller group of 23 patients monitored with both MQ and HP monitors, the additional use of lead I in the MQ system was associated with a somewhat greater sensitivity (100% vs 80%) and somewhat lower specificity (50% vs 67%). This finding is surprising, because the extra lead used by the MQ, lead I, is rarely associated with intraoperative ischemic changes, as has been demonstrated by London et al. (19). The lower positive predictive values of both devices suggest that they detect ST-segment change more often than does a cardiologist's interpretation, for potential reasons that are discussed later. Although it would be possible to compare the individual leads used to calculate the ST-segment sum with other standards for diagnosing ischemia, such would not be an appropriate technology assessment, because it is the sum of changes that the clinician is presented with to make decisions. Thus, we believed that the appropriate technology assessment utilized sums for comparisons.

Limitations of ST-Segment Devices

The automated ST-segment monitors have various technical limitations that may produce erroneous results. They do not adjust the isoelectric point or the point in the ST segment at which ischemic changes are measured during tachycardia, nor do they distinguish upsloping or downsloping ST segments. Although the isoelectric baseline of the HP device was always chosen at 80 ms before the R wave, the MQ algorithm was not available to us. The difference between the detection algorithms of HP and MQ might be highlighted by tachycardia, which may produce erroneous determinations of ST-segment changes. Tachycardia is associated with a shortened PR interval, a taller P wave, and deflection of the PQ segment below the isoelectric line (20). Using fixed (relative to the QRS complex) points for the isoelectric point may either cause the isoelectric point to be measured in the P wave, causing a normal ST segment to appear falsely depressed in comparison, or to be measured during a PR segment that is deflected below the isoelectric line.

False-positive determinations of myocardial ischemia by automated ST-segment devices may also be due to inaccurate measurement of the ST segment. It is not clear how the HP system's lack of a J-point reference affects results. For both systems, however, tachycardia may shorten the ST segment (21); measuring the ST segment at a fixed time of 120 ms after the height of the R wave (as is done by the HP system) may result in the "ST segment" actually being measured during the T wave. The resultant inaccuracy will depend on the polarity of that T wave. Newer improvements (which were not available to us at the time of study) in both devices allow the clinician to view with a cursor at what point in the ECG the baseline and ST-segment measurements are being made and to alter the position of that cursor. This additional capacity may lessen artifacts due to tachycardia and abnormal isoelectric baselines; however, our study did not address this hypothesis.

A comparison of the patients who were monitored with the HP and MQ monitors revealed that 8 of 23 patients had discordant results. We do not have printouts from the MQ monitor to verify its algorithm, because we recorded the values displayed on the oscilloscope. In the eight patients with discordant results, we noted that MQ was positive in six patients and HP was positive in two. This is not surprising, given the higher sensitivity of the MQ system in detecting ECG ischemia. Even in these discordant cases, the differences between the maximal intraoperative change in absolute sums in the two systems were small. The differences ranged from 0.3 to 1.6 mm. Of note, three of these discordant results (MQ positive, HP negative) occurred because the change in the MQ was exactly 1.0 mm.

Others have shown that different operating room ECG systems may vary in their capacity to detect myocardial ischemia. Slogoff et al. (22) have recently demonstrated that ECG systems may vary in the amount of ST-segment change detected in patients undergoing coronary artery bypass graft surgery. Some of these differences appear to be due to the use of 0.5 Hz as the lower end of the frequency response range for many operating room monitors. In such cases, the use of the monitoring mode increases the incidence of myocardial ischemia (ST-segment changes of >1.0 mm) seen in coronary artery bypass graft surgery patients before cardiopulmonary bypass. Although 8.3% of patients demonstrated ischemia by these criteria in lead V_5 on a Holter monitor, and 12.8% of patients demonstrated ischemia by these criteria on a standard 12-lead ECG, the incidence of ischemia detected by an operating room monitor in that study was 27.5% (22). This high figure is probably due to artifactual ST-segment depression caused by the 0.5-Hz filter. In our study, the printed ECGs were all done using a frequency range of

0.05–100 Hz, using the diagnostic mode. Hence, we believe that it is valid to compare the values of ST-segment change in the patients in our study with the other ischemia detection devices.

Transesophageal Echocardiography Versus Printed Electrocardiography (Ischemia Defined by ST Segments or T Waves, or Both)

When data were examined for all periods during the operative procedures, we found that TEE and analysis of the ST segments of printed ECGs had the capacity to detect myocardial ischemia similar to previous series of high-risk patients undergoing noncardiac surgery. When TEE was taken as the reference standard, the sensitivity of the printed ECG was only 25% for ST-segment changes and 40% for ST-segment changes or T-wave inversions, or both. Smith et al. (23) reported that during aortic and coronary bypass surgery, TEE detected intraoperative myocardial ischemia in four times as many patients as did printed ECG, with ST-segment depression used as a criteria. We found that the addition of T-wave criteria for the detection of myocardial ischemia using the printed ECG increases the sensitivity of the printed ECG from 25% to 40% compared with the reference TEE. We had decided prospectively to examine the usefulness of adding T-wave inversions in the definition of myocardial ischemia. We did this because previous studies had shown a low sensitivity for ischemia detection by ST-segment change compared with TEE. We hypothesized that the addition of the T-wave criteria might enhance capacity to detect myocardial ischemia. Supporting this hypothesis is a study of patients with resting T-wave inversions who underwent exercise radionucleotide angiography stress testing (24). A significantly higher incidence (62% vs 28%) of new wall motion abnormalities was noted in patients in whom new T-wave inversions occurred compared with those without new T-wave inversion (24). T-wave changes were more sensitive, although less specific, than were ST-segment changes seen with stress ECG.

In reviewing data comparing mechanical, electrocardiographic, metabolic, and hemodynamic indicators of myocardial ischemia in patients with coronary artery disease undergoing vascular surgery, Haggmark et al. (1) suggested the possibility that "accepted criteria (ST segment changes only) for interpreting the ECG to indicate myocardial ischemia during anesthesia are too stringent." Our data concerning the association of T-wave changes with TEE ischemia might seem to confirm this, because three of four patients with isolated T-wave changes also developed new SWMA; however, the number of such patients was very small. Other workers have suggested that T-wave changes are benign. Breslow et al. (25) concluded that T-wave inversions in the recovery room did not predict perioperative morbidity and mortality. However, the patient population in that study had a low "pretest probability" of having coronary artery disease. Our data, which show that three of the four patients with T-wave inversions in the absence of ST-segment changes had wall motion abnormalities, lead us to conclude that T-wave changes in a high-risk population may be associated with an ischemic TEE examination. However, we do not know whether either T-wave inversions or SWMAs were associated with adverse outcome in this study. The T-wave changes or SWMAs, or both, may be such sensitive indicators of myocardial ischemia that they may have a low predictive value for cardiac complications. Indeed, London et al. (12) showed that SWMAs were only associated with a 6% incidence of cardiac complications.

Automated ST-segment analysis devices are probably better than the "naked eye" in detecting ischemia, but they may be misleading. Because its positive predictive value is only 36% for the MQ system and 35% for the HP system as detected by our reference standard of TEE, each episode of ST-segment sum change of 1 mm or greater represents only approximately a one-third chance that the patients will be found to have myocardial ischemia by TEE. Our view, however, is that an ST-segment trend monitor should be considered an alarm that causes the clinician to increase vigilance. Thus, although our data do not prove our hypothesis that ST-segment trend analysis detects the same incidence of intraoperative myocardial ischemia as does printed multilead ECG or TEE, the two ST-segment trend monitors evaluated may prove useful to indicate the need for the anesthesiologist to examine the patients' ECG carefully. The indicators are useful because intraoperative ischemic episodes tend to be brief and therefore unrecognized by clinicians (12). Brief intraoperative ischemic episodes may herald longer postoperative episodes. If this were true, recognition of intraoperative ischemia may identify patients who might benefit from aggressive postoperative antianginal therapy; however, this is a hypothesis that remains unproved.

Further studies are needed to provide the clinician with reliable, inexpensive, and simple monitors for detecting intraoperative myocardial ischemia. In high-risk patients, ST-segment trend monitors may be used as an alarm, in conjunction with the review of printed ECG strips during surgery, potentially improving the detection of myocardial ischemia. However, these ECG modalities may not predict the presence of wall motion and thickening changes as seen in TEE. Further study is necessary to determine which intraoperative monitoring devices are best for predicting patient outcome.

The lack of concordance of monitors of intraoperative myocardial ischemia leaves us unable to define a reference standard for its detection. The myocardial ischemia detected in this study was often not severe, which may explain the discordance of the different modalities and the relatively low intraobserver variability of TEE readings. The use of more stringent criteria may be needed to predict adverse patient outcome. However, because our study did not follow patients to determine the incidence of postoperative cardiac complications, we cannot compare the capacity of the different intraoperative monitors to predict adverse events. Both TEE and printed ECG appear from other studies to have low positive predictive values for postoperative complications. Changes in either monitor probably need to be severe and long-lasting to predict adverse outcome. The recent demonstration that postoperative myocardial ischemia occurs more frequently than intraoperative or preoperative ischemia (4) suggests that the capacity to diagnose intraoperative myocardial ischemia may be of limited value in predicting patient outcome.

We thank Ronald Thisted, PhD, for statistical assistance, and Suzanne Pierson and Jaimie Israel for editorial assistance.

Lung Traction Causes an Increase in Plasma Prostacyclin Concentration and Decrease in Mean Arterial Blood Pressure

Mishiya Matsumoto, MD, Kenji Ohki, MD, Ikuo Nagai, MD, and Takao Oshibuchi, MD

Department of Anesthesiology, University of California at San Diego, La Jolla, California, and Division of Anesthesiology, Saiseikai Shimonoseki General Hospital, Yamaguchi, Japan

The effects of lung traction on arterial blood pressure and plasma prostacyclin concentrations were studied in five patients undergoing partial pneumonectomy or lobectomy. After manual traction of a lung segment, mean arterial blood pressure decreased from 77 ± 5 mm Hg (mean ± SEM, before lung traction) to 59 ± 5 mm Hg. The concentrations of 6-keto prostaglandin $F_{1\alpha}$ (a stable breakdown product of prostacyclin) increased significantly from 46 ± 6 pg/mL (mean ± SEM, before thoracotomy) to 593 ± 91 pg/mL. Four of five patients showed facial flushing and palmar erythema. Arterial blood pressure returned to pretraction value, and both the facial flushing and palmar erythema disappeared within 30 min after lung traction. These results suggest that traction of the lung stimulates release and/or production of prostacyclin, which results in facial flushing, palmar erythema, and decrease in arterial blood pressure.

(Anesth Analg 1992;75:773–6)

Prostacyclin (PGI_2), a potent vasodilator, is released after mesenteric traction in aortic surgery (1–3) and after closure of the peritoneum during cesarean section (4). In those situations, arterial blood pressure may decrease in association with facial flushing (1–4).

Prostacyclin is generated in the vascular wall (5,6). Distention of the vessel is thought to stimulate the release of PGI_2 (7). Recently, we observed a decrease in arterial blood pressure after lung traction during pneumonectomy. The patient showed facial flushing and palmar erythema that were similar to what we observed in a previous study in which we demonstrated the release of PGI_2 during cesarean section (4). Mechanical manipulation of the lung (8) or hyperventilation (7) causes release of PGI_2, which may affect the pulmonary circulation. It is well-known that systemic administration of PGI_2 decreases arterial blood pressure; however, it is not known whether PGI_2 released from the lung causes decreased arterial blood pressure. The purpose of this study was to determine whether the decrease in arterial blood pressure after lung traction is associated with an increased plasma concentration of PGI_2.

Methods

After receiving institutional approval, five (male and female) patients, ASA physical status I or II, aged 14–71 yr, who were undergoing partial pneumonectomy or lobectomy because of pneumothorax or lung cancer, were studied. Informed consent was obtained from each patient. Patients had no history of cardiovascular disease. All patients received atropine (0.5 mg IM) and hydroxidine (50 mg IM) 30 min before induction of anesthesia. For postoperative pain management, an epidural catheter was inserted in all patients. Except for a test dose of 2 mL of 2% lidocaine, no additional lidocaine was administered during the study period. Anesthesia was induced with thiopental (4 mg/kg IV), followed by vecuronium (0.08 mg/kg) to facilitate endotracheal intubation. A radial artery was cannulated for the measurement of arterial blood pressure and sampling of blood. Anesthesia was maintained with enflurane (1%–2%) and nitrous oxide (60%–66%) in oxygen. The concentration of enflurane was maintained as constant as possible during the study period. After thoracotomy, the lung segment to be resected was grasped in the surgeon's hands, and manual traction

Table 1. Changes in Mean Arterial Pressure and Heart Rate in Five Patients Undergoing Partial Pneumonectomy or Lobectomy

Pt No./ Gender	Mean arterial pressure (mm Hg)			Heart rate (beats/min)		
	Before traction	5 Min after traction	30 Min after traction	Before traction	5 Min after traction	30 Min after traction
1/M	87	67	88	85	109	83
2/M	73	45	82	80	75	70
3/M	63	56	82	52	52	60
4/F	87	73	83	90	90	75
5/M	77	55	83	78	78	82
Mean ± SEM	77 ± 5	59 ± 5[a]	84 ± 1	77 ± 7	81 ± 9	74 ± 4

Pt, patient.
[a] $P < 0.05$, significantly different from baseline.

was applied for 30 s. This traction was performed in a standardized fashion by the same surgeon in all five patients.

Mean arterial pressure (MAP) and heart rate (HR) were measured before traction and 5 and 30 min after traction. Blood samples for prostanoid analysis were collected before thoracotomy and 5 and 30 min after traction. To avoid artifactual release of prostanoids, the blood samples were slowly withdrawn into disposable plastic syringes and transferred into ice-chilled plastic tubes containing ethylenediaminetetraacetate (1 mg/1 mL blood) and indomethacin (0.036 mg/1 mL blood). The blood samples were placed on ice immediately and centrifuged at 4°C. After centrifugation, plasma was frozen and stored at −80°C. The concentrations of plasma 6-keto prostaglandin $F_{1\alpha}$ (6-keto $PGF_{1\alpha}$), a stable breakdown product of PGI_2, and thromboxane B_2 (TXB_2), a stable breakdown product of thromboxane A_2, were measured by the radioimmunoassay method. Radioimmunoassay for 6-keto $PGF_{1\alpha}$ was performed on the incubation mixture, which consisted of 0.8 mL of sample or standard (Ono Pharmaceutical Co., Osaka, Japan), 0.1 mL of [^{3}H]6-keto $PGF_{1\alpha}$ (specific activity 130.0 Ci/mmol; New England Nuclear Co., Boston, Mass.), and 0.1 mL of anti-6-keto $PGF_{1\alpha}$ serum (final dilution 1:3000; Advanced Magnetics Co., Cambridge, England). The interassay and intraassay coefficients of variation of 6-keto $PGF_{1\alpha}$ were 8.6% and 10.5%, respectively. Radioimmunoassay of TXB_2 was performed as described for 6-keto $PGF_{1\alpha}$ using standard TXB_2 (Ono Pharmaceutical), [^{3}H]TXB_2 (specific activity 196.8 Ci/mmol; New England Nuclear), and anti-TXB_2 (final dilution 1:16,000; Ono Pharmaceutical). The interassay and intraassay coefficients of variation of TXB_2 were 7.2% and 8.3%, respectively. The detection limit of 6-keto $PGF_{1\alpha}$ and TXB_2 in this method was 20 pg/mL.

Data were statistically analyzed by the Kruskal-Wallis one-way analysis of variance, followed by the Mann-Whitney rank sum test. A value of $P < 0.05$ was considered significant.

Results

Traction of the lung was associated with a significant reduction in MAP (Table 1), and a significant increase in 6-keto $PGF_{1\alpha}$ at 5 min (Table 2) after traction was applied. Facial flushing and palmar erythema were observed in four patients within the 5-min period after lung traction. By 30 min, MAP returned to pretraction values, and both flushing and erythema disappeared. We decreased the concentration of enflurane in one patient (patient 2) until MAP returned to 55 mm Hg because of hypotension after traction. The concentration of 6-keto $PGF_{1\alpha}$ remained elevated compared with prethoracotomy values at 30 min after traction. The concentrations of TXB_2 increased after traction in some patients, but there was no significant difference in the concentration of TXB_2 compared with baseline values in the group as a whole. There was no significant change in HR from baseline at any time (Table 1).

Discussion

In the current study, we demonstrated that traction of the lung is associated with a decrease in MAP and an increased plasma concentration of 6-keto $PGF_{1\alpha}$ (a stable breakdown product of PGI_2). Prostacyclin is continuously generated in the lung and acts as a circulating hormone (5). Endothelial cells lining blood vessels, including the pulmonary vessels, potentially produce PGI_2 (5,6). The production or release of PGI_2 is enhanced after mechanical stimulation, such as distention of the vessels (7). Several investigators have reported that abdominal mesenteric traction decreases MAP and increases HR, which is accompanied by an increased concentration of plasma 6-keto

Table 2. Changes in Concentrations of 6-keto $PGF_{1\alpha}$ and Thromboxane B_2, and Appearance of Facial Flushing in Five Study Patients

[b] $P < 0.05$, significantly different from the value at 5 min after traction.

$PGF_{1\alpha}$ (1–4). Both lung and mesentery contain vessels that may be distended by traction.

We did not measure plasma concentrations of 6-keto $PGF_{1\alpha}$ or TXB_2 immediately before traction of the lung. It is appropriate to ask whether surgical incision itself may increase the concentration of 6-keto $PGF_{1\alpha}$. Goto et al. (9) reported that laparotomy significantly stimulated the release of PGI_2 under general anesthesia. They showed that the concentration of 6-keto $PGF_{1\alpha}$ significantly increased from <10 to 55 pg/mL 20 min after start of surgery (9). However, there was no comment relating the elevation of 6-keto $PGF_{1\alpha}$ to surgical activity. The peak concentration of 6-keto $PGF_{1\alpha}$ in their study is less than that in ours, and there was an increase rather than a decrease in MAP associated with the increase in the concentration of 6-keto $PGF_{1\alpha}$ (9). In contrast, Seltzer et al. (1) did not find a significant change in the plasma concentration of 6-keto $PGF_{1\alpha}$ after laparotomy under general anesthesia. In our study, there was no flushing or palmar erythema before traction of the lung. Therefore, we think it unlikely that surgical incision itself increased the concentration of PGI_2 to the degree in which apparent vasodilation was observed in our study.

The concentrations of 6-keto $PGF_{1\alpha}$ after pulmonary traction were less than those reported after mesenteric traction (1–4). This may represent a difference in the amount of vascular bed that was involved in the traction or a difference in the intensity of the traction. In the current study, traction was performed as consistently as possible by the same surgeon. The peak concentration of 6-keto $PGF_{1\alpha}$ in one patient (patient 4) was low, and that patient did not show flushing or palmar erythema. The structure of the lung that was retracted in that patient was almost destroyed because of large bullae. It is possible that the manipulated part of the lung may have contained fewer vessels in this patient than in the others. This supports the hypothesis that distention of the vessels stimulates the production and/or the release of PGI_2.

The cyclooxygenase inhibitor ibuprofen (administered orally before anesthesia) has been demonstrated to prevent an increase in the concentration of 6-keto $PGF_{1\alpha}$ and a decrease in arterial blood pressure in the setting of mesenteric traction (1,3). Although cyclooxygenase inhibitors have side effects, such as inhibition of platelet function, they may be useful in preventing the abrupt decrease in arterial blood pressure in the setting of lung traction.

Hudson et al. (3) reported a late increase of TXB_2 after mesenteric traction in abdominal aortic surgery. They suggest that the late increase of TXB_2 represents the regulatory response to elevated PGI_2 synthesis and vasodilation (3). We also measured TXB_2 concentrations but did not find late elevations of TXB_2. In our study, HR did not increase significantly after traction. This may be due to the lesser degree of peak concentration of 6-keto $PGF_{1\alpha}$ that we observed. Also, the number of patients in our study was small. Further studies may be necessary to further elucidate the HR response or TXB_2 response, or both.

In conclusion, we demonstrated that lung traction is associated with an increased plasma concentration of 6-keto $PGF_{1\alpha}$ and a reduction in MAP. Although the hypotension may have been due to a mechanical effect in the lung (i.e., reduced venous return to the heart), PGI_2-induced vasodilation should now be a consideration in the differential diagnosis of this phenomenon.

Efficacy of Anticholinergic and β-Adrenergic Agonist Treatment of Maximal Cholinergic Bronchospasm in Tracheally Intubated Rabbits

Sai Chuen Wu, MBSc, Jacob Hildebrandt, PhD, Pamela D. Isner, BS, David J. Pierson, MD, and Michael J. Bishop, MD

Departments of Anesthesiology, Medicine (Pulmonary and Critical Care), and Physiology and Biophysics, University of Washington School of Medicine, Seattle, Washington, and the Department of Anesthesiology, Chang Gung Memorial Hospital and Chang Gung Medical School, Linkou Medical Center, Linkou, Taiwan, Republic of China

Cholinergically induced bronchoconstriction is thought to be a major cause of bronchospasm during anesthesia. We used tracheally intubated rabbits (4-mm endotracheal tube) stimulated with methacholine to assess the efficacy of β-adrenergic agonist and anticholinergic treatment in reversing the increases in respiratory system resistance. Four groups were compared: (a) inhaled metaproterenol, 20 puffs via metered dose inhaler (0.65 mg/puff); (b) inhaled ipratropium bromide, 20 puffs from a metered dose inhaler (18 μg/puff); (c) 2 mg of intravenous atropine; and (d) no treatment after methacholine challenge as a control group. Methacholine increased respiratory system resistance from 0.041 ± 0.001 (mean ± SEM) to 0.098 ± 0.006 cm $H_2O \cdot mL^{-1} \cdot s^{-1}$ ($P < 0.001$). Whereas β-adrenergic agonist treatment was ineffective in ameliorating bronchoconstriction, inhaled ipratropium bromide and atropine were highly effective, causing an 86%–88% reversal in the methacholine-induced increase in respiratory system resistance. Both these agents were also effective in improving dynamic compliance. We conclude that inhaled ipratropium bromide is effective in treating cholinergic bronchospasm even when administered via a small endotracheal tube and that the β-adrenergic agonist metaproterenol is ineffective in rabbits in the face of maximal cholinergic stimulation.

(Anesth Analg 1992;75:777–83)

During tracheal intubation and anesthesia, mechanical stimulation of receptors in the nose, larynx (1), or airways (2) may precipitate vagally mediated reflex bronchoconstriction and mucus secretion (3,4). The usual treatment of intraoperative bronchospasm includes deepening of anesthesia (5,6) and administration of a β-adrenergic agonist (7). Inhaled anesthetics attenuate pulmonary bronchoconstriction by blocking vagal reflexes and by direct smooth muscle relaxation (8–10); β-adrenergic agonists relieve bronchospasm by stimulating β-adrenergic receptors and inducing smooth muscle relaxation (11).

In the proposed study, we assessed the efficacy of inhaled bronchodilator treatment of methacholine-mediated bronchospasm using a rabbit model in which the trachea was intubated with a 4.0-mm inner diameter endotracheal tube (ETT). We produced maximal bronchoconstriction with methacholine and then compared treatments with the β-adrenergic agonist metaproterenol, inhaled ipratropium bromide (IB), or parenteral atropine. We attempted to answer the following questions: (a) Are inhaled bronchodilator agents effective when delivered via an ETT using a metered dose inhaler (MDI)? (b) How effective is inhaled anticholinergic therapy compared with parenteral therapy?

Methods

We performed a total of 28 studies in seven adult New Zealand White rabbits with a mean weight of 3.2 ± 0.1 kg (mean ± SEM) (range 2.7–4). Animals were anesthetized with pentobarbital sodium (30 mg/kg IV) and intubated orally with a 4.0-mm cuffed ETT. Each rabbit was then paralyzed with pancuronium bromide (0.3 mg IV) and ventilated with 100% oxygen by a piston-type ventilator (Harvard Apparatus, Millis, Mass.) set to deliver a tidal

volume of 15 mL/kg at a frequency of 25 breaths/min (Ttot = 2.4 s) and an inspiratory cycle of 0.33 (Ti = 0.8 s). The electrocardiogram was monitored, and anesthesia was maintained by an intravenous bolus dose of 20% of the initial dose of sodium pentobarbital and 0.1 mg of pancuronium every hour.

Tracheal flow was measured through a heated pneumotachograph head (Hewlett Packard, Waltham, Mass.) and a differential flow transducer (Hewlett Packard model 47303A) placed between the Y-piece of the ventilator circuit and the ETT tube. Flow signals were calibrated by timed volume accumulation in a 9-L respirometer. Airway pressure was measured at the mouth side of the pneumotachograph. All signals were amplified, filtered, and recorded by a 12-bit analogue-to-digital converter, sampled at a rate of 100 Hz, and stored on an IBM/AT compatible computer.

Dynamic compliance (Cdyn) of the respiratory system was calculated as tidal volume divided by change of airway pressure measured at the two points of zero flow. Respiratory system resistance (Rrs) was calculated using the isovolume technique (12) at a lung volume of 30 mL above functional residual capacity. Five minutes before each measurement, the trachea was suctioned, and three total lung capacity inflations (peak airway pressure 35 cm H_2O) were performed to standardize volume history.

During 11 separate studies in five of the rabbits, we also inserted a fluid-filled catheter to the point in the esophagus where end-expiratory pressure was minimal. During this series, we measured lung resistance (Rl) from transpulmonary pressures (airway minus esophageal pressure) at the isovolume points. We then confirmed that Rrs correlated closely with Rl in our anesthetized, paralyzed rabbits (Figure 1).

A dose-response curve to methacholine was obtained in three rabbits to determine the concentration of methacholine that assured maximal bronchomotor response. Each rabbit was challenged with normal saline solution and then increasing concentrations of methacholine (1.6–100 mg/mL in doubling concentrations) for 3 min at 20-min intervals. The medications were delivered as an aerosol generated by an ultrasonic nebulizer (Ultra-Neb, model 099HD, DeVilbiss) in line with the ventilator circuit. The "dose" of methacholine deposited on the airways is actually not known. Nevertheless, as ventilatory variables were uniform, the dose should be proportional to the concentration of active agent. Fifteen minutes after each challenge, pulmonary mechanics data were recorded and Rrs calculated. In all three rabbits, Rrs demonstrated a plateau at 25–50 mg/mL (change in Rrs of <20% after a response of >200% over baseline). Severe dysrhythmias but no increase in bronchoconstriction were noted when concentrations of 100 mg/mL of methacholine were used. Our finding that 50 mg/mL provided maximal response confirmed the data of Romero and Ludwig (13), who noted peak response at a concentration of methacholine between 32 and 64 mg/mL. Accordingly, we used 50 mg/mL of methacholine to obtain a plateau response for subsequent studies.

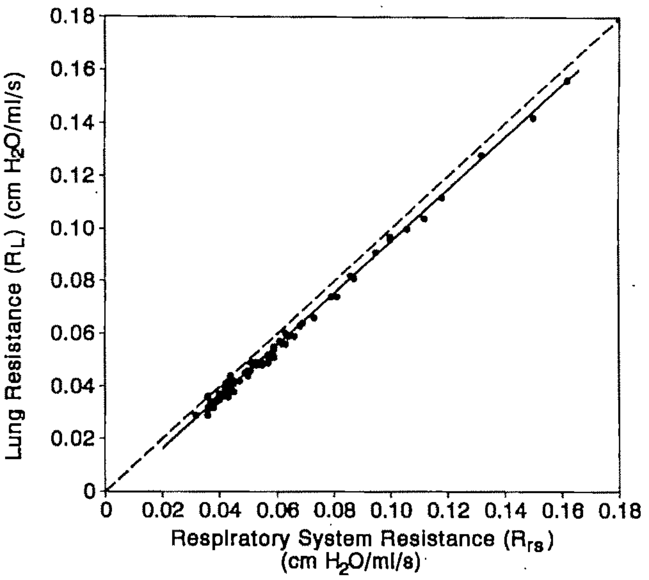

Figure 1. Correlation of Rl with Rrs: $r = 0.998$; $P < 0.001$; $n = 11$, Rl = 0.986 (Rrs) − 0.004. *Dashed line* is the line of identity. The constant of 0.004 for the difference between Rl and Rrs represents chest wall resistance.

After two baseline values of Rrs and Cdyn had been obtained 2 min apart, the rabbits were challenged with 3 min of 50 mg/mL of inhaled methacholine generated by the ultrasonic nebulizer. Pulmonary mechanics were recorded again at 15, 35, 55, and 75 min after commencing the challenge. Each rabbit received four different treatment regimens performed in random order 1–3 days apart. The treatment regimens were begun after the 15-min post-methacholine data collection point. The four treatments included

1. Inhaled metaproterenol, 20 puffs via MDI (0.65 mg/puff)
2. Inhaled ipratropium bromide (IB), as a single dose of 20 puffs via MDI (18 μg/puff)
3. Single dose of atropine (2 mg IV) administered at 30 min after methacholine challenge
4. No treatment as a control group

The MDI treatments were performed using at least five different inhalers per treatment to minimize any effect of variability among inhalers. Each MDI was shaken vigorously before use. Each puff of MDI was delivered with a 5-s inflation to an inspiratory pressure of 35 cm H_2O.

All treatment groups other than group 3 (IV atropine) received a single dose of atropine (2 mg IV) after data collection at the 75-min point to document that reversible bronchoconstriction still persisted. Pulmonary mechanics were measured 10 min later to record the efficacy of the atropine treatment. Treatment efficacy was assessed as a percent reversal of the response to methacholine. Thus,

$$\%\text{ Rrs reversal} = \frac{\text{Rrs(MC)} - \text{Rrs(Treatment)}}{\text{Rrs(MC)} - \text{Rs(Baseline)}} \times 100,$$

$$\%\text{Cdyn reversal} = \frac{\text{Cdyn(Treatment)} - \text{Cdyn(MC)}}{\text{Cdyn(Baseline)} - \text{Cdyn(MC)}} \times 100,$$

where Rrs(MC) and Cdyn(MC) represent Rrs and Cdyn, respectively, at 15 min after methacholine; Rrs(Baseline) and Cdyn(Baseline) represent the average value of the two sets of baseline data, and Rrs(Treatment) and Cdyn(Treatment) represent the values for subsequent treatments. Thus, a value of 0 would represent no improvement after treatment, and a value of 100 would represent a return to the baseline value.

Data were analyzed using one-way analysis of variance to determine the significance between group differences, followed by least-significant difference testing to determine differences between the control (methacholine alone) group and the various treatments (14).

Results

Methacholine inhalation more than doubled Rrs within 15 min from a mean of 0.041 ± 0.001 to a mean of 0.098 ± 0.006 cm $H_2O \cdot mL^{-1} \cdot s^{-1}$ ($P < 0.001$).

In the 11 studies in which we measured RL separately, we found that the effect of methacholine on chest wall resistance, Rcw = (Rrs − RL), was minimal. Although Rcw increased from a mean of 0.004 ± 0.001 to 0.006 ± 0.001 after methacholine, this effect was small compared with the overall increase in resistance (3.5% of the increase).

Significant reversal of the elevation in Rrs occurred only after treatment with inhaled IB or intravenous atropine (Figure 2). Reversal with IB was 86% ± 3% at 35 min after methacholine challenge and further increased to 96% ± 2% at 55 min after methacholine challenge. Atropine reversal was 88% ± 7% initially but then declined to 76% ± 12% at 55 min. In the absence of any treatment, spontaneous reversal of the increase in Rrs was 30% ± 4% at 35 min and 34% ± 5% at 55 min. Metaproterenol was not effective compared with the spontaneous reversal.

Methacholine decreased Cdyn of the respiratory system approximately 30% from a mean of 3.15 ± 0.07 to a mean of 2.19 ± 0.04 mL/cm H_2O ($P < 0.001$) at a respiratory rate of 25 breaths/min. Spontaneous reversal of this decrease in the untreated group was prolonged: 33% ± 8% at 35 min after challenge and 55% ± 7% at 55 min after challenge. Both atropine and IB were successful in substantially and rapidly reversing the initial decline in Cdyn, although only atropine had a persistent beneficial effect that was clearly different from the spontaneous improvement (Figure 3).

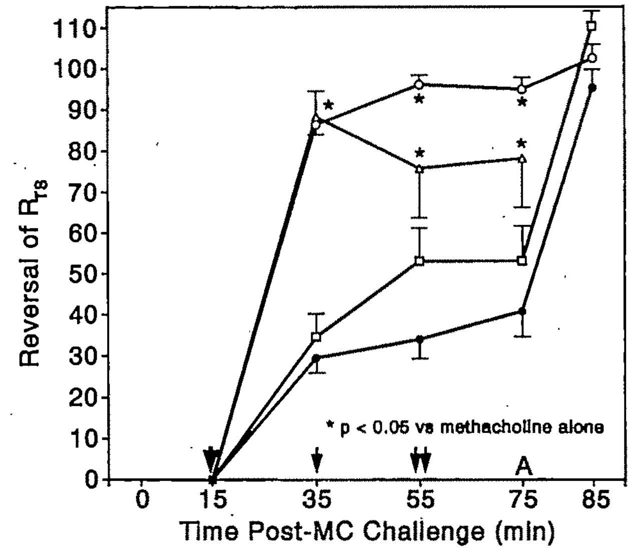

Figure 2. Percentage reversal in respiratory system resistance (Rrs) after treatment with anticholinergic and β-adrenergic agonists. The Rrs was raised approximately 150% above baseline by methacholine (MC) at t = 0. *Large arrow* is the time point of initial treatment at 15 min. No significant differences are noted between the β-adrenergic agonist and the untreated controls. ●——●, MC alone, no treatment; ○——○, IB, ipratropium bromide; □——□, MDI 20, single-dose 20 puffs of metaproterenol. △——△, atropine (2 mg IV) administered at 75 min, indicated by *A*, to all except the atropine group. Data are mean ± SE.

At the conclusion of this study, atropine (2 mg IV) significantly decreased resistance to within 15% of baseline in all groups (other than the original intravenous atropine group, which did not receive further atropine) (Figure 2). However, atropine administration did not lead to significant further improvement in Cdyn (Figure 3).

Methacholine significantly decreased heart rate both during the 3-min challenge and 5 min after the challenge (Figure 4). At 15 min after methacholine, heart rate recovered spontaneously in the control group and stabilized during the rest of the experiment. Heart rate for all treatment groups did not differ significantly from the control group. Intravenous atropine administered at the conclusion of the study had no additional effect on heart rate.

Discussion

In this study we compared the effectiveness of various strategies for reversing cholinergic bronchocon-

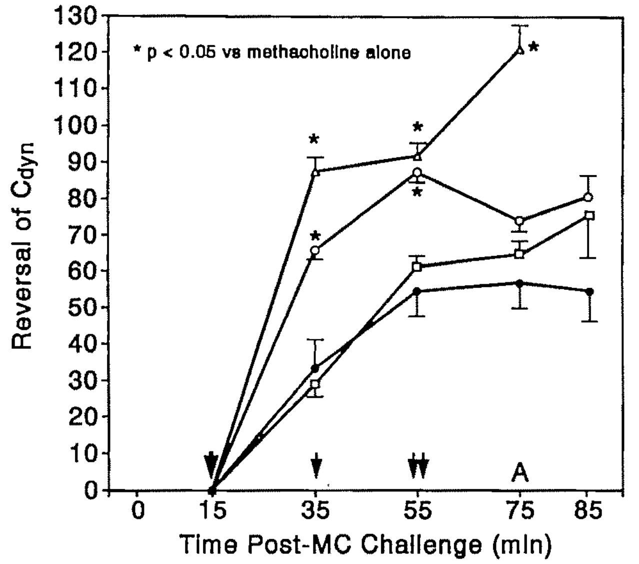

Figure 3. Percentage reversal of the methacholine (MC)-induced increase in Cdyn after treatment with anticholinergic and metaproterenol. *Large arrow* was time point of initial treatment. Abbreviations and symbols as in Figure 2.

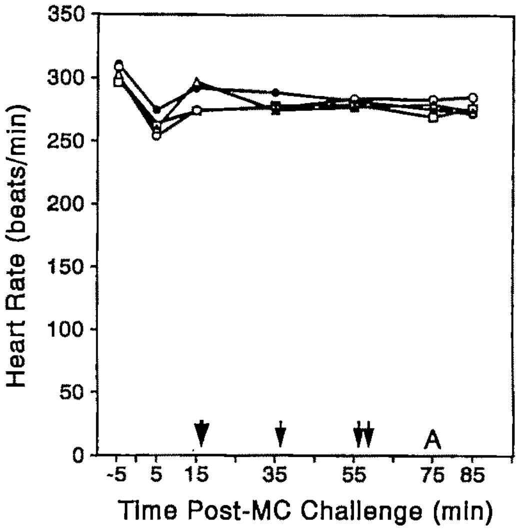

Figure 4. Mean heart rate after methacholine (MC) challenge and treatment with anticholinergic or β-adrenergic agent. Intravenous atropine (2 mg) was administered at 75 min, indicated by *A*. Pulse rate decreased significantly after methacholine challenge ($P < 0.001$). No significant differences were noted among the regimens. Standard errors were omitted for clarity in this figure. striction modeled by aerosol administration of methacholine to anesthetized, paralyzed rabbits. The important findings of this study are the following:

(a) Aerosol from an MDI can provide effective treatment via a small ETT, as demonstrated by the efficacy of IB.
(b) β-Agonist treatment of a maximal methacholine stimulus was not effective in this model.
(c) Inhaled anticholinergic therapy with IB provides therapeutic efficacy equal to that provided by complete parenteral parasympathetic blockade with atropine.

After tracheal intubation, only 2%–10% of the drug from an MDI reaches the airway, even if the proper technique is used (15). This amount may be even less in pediatric-sized ETTs such as those used in this study. We therefore tested an initial dose of 20 puffs of the metaproterenol to ensure that an adequate dose was delivered to the airways in order to compare the efficacy of the drugs.

The IB and metaproterenol were administered using identical delivery systems that produce a similar profile of droplet size. A significant portion of the droplets are in the appropriate range for airway deposition (1–5 μm) (16). Penetration of the aerosols into the lungs should therefore have been identical.

We chose IB as an inhaled drug to study its efficacy against a maximal cholinergically induced bronchial response, because it is a direct cholinergic antagonist and thus relieves bronchospasm via a mechanism different from the β-adrenergic agonist (17). We used parenteral atropine in a large dose as a positive control. The dose of atropine used was based on the uniform and complete reversal of methacholine bronchospasm previously reported by Romero and Ludwig (13). Metaproterenol is an effective β-adrenergic agonist in the treatment of obstructive lung disease (18,19) when used in doses far lower than those used in our study. The dose we used was approximately 200 times the usual per kilogram dose in adult humans.

The dose of IB chosen was high relative to human doses, raising the possibility that its effect was achieved by systemic absorption. However, unlike atropine, which undergoes complete and rapid absorption from the mucosa, IB is <1% absorbed and is thus unlikely to have been effective because of systemic absorption (17).

Rabbits were studied multiple times in a randomized order to control for the effects of repeated intubation and methacholine challenge. We chose a rabbit model because of the rabbits' relatively uniform bronchoconstrictive response to methacholine without airway hyperreactivity (13). Great caution must be taken in extrapolating our results to humans. These results are not intended to be a model of reactive airways disease but may reflect the effects seen with reflex cholinergic bronchoconstriction, a phenomenon thought to be responsible for some cases of intraoperative bronchospasm. The specific questions we addressed with regard to drug delivery cannot be answered for humans with absolute certainty other than in a human model. Although the rabbit provides a reliable model of cholinergic-induced increased airway resistance, there are differences between this model and human intraoperative bronchospasm.

Many cases of intraoperative bronchospasm involve patients with underlying obstructive lung disease and reactive airways. However, in a review of 14 consecutive cases of intraoperative bronchospasm at one author's institution, 50% of the patients had no history, signs, or symptoms of underlying reactive airways disease, and cholinergic reflexes have been hypothesized to be an underlying mechanism of such bronchospasm (20). Thus, we believe that there is validity in using cholinergic bronchospasm as a model.

We studied a maximal dose of methacholine. It is unknown whether in humans such a maximal cholinergic stimulus ever occurs. Hence, we are really studying a worst-case scenario. Additionally, even in reflex bronchospasm, a variety of other mediators may be released. Thus, our model must be viewed as having many differences from the clinical situation, and our conclusions must be viewed more as indications for further studies.

Rrs rather than RL was used to study the response because of its simplicity of measurement, requiring only airway pressure and flow data. Furthermore, technical difficulties due to esophageal secretions and catheter movement leading to artifacts can make measurements of RL less reproducible. Nevertheless, we documented close correlation between the two measurements in our totally paralyzed rabbits (Figure 1).

The measured changes in Rrs reflect a combination of changes in chest wall resistance (Rcw), airway resistance, and lung tissue viscosity (13). These components can be differentiated only by direct measurements of alveolar pressure. The Rcw changes were minimized by the use of neuromuscular paralysis. Mean Rcw was 0.004 cm $H_2O \cdot mL^{-1} \cdot s^{-1}$, or approximately 20% of Rrs exclusive of the ETT and did not change after methacholine administration. The overall effect on pulmonary mechanics does not differ whether changes in Rrs are due to changes in airway resistance or lung viscosity. It is of no consequence to the management of the clinical problem of increased Rrs to differentiate the source of the increase.

Our mean measured control Rrs of 0.041 cm $H_2O \cdot mL^{-1} \cdot s^{-1}$, when corrected for the resistance of the ETT, which we determined to be 0.020 cm $H_2O \cdot mL^{-1} \cdot s^{-1}$ at the flow rates used, corresponds closely to previously measured values in rabbits of 0.020 cm $H_2O \cdot mL^{-1} \cdot s^{-1}$ (13).

The β-adrenergic agonists reverse bronchoconstriction caused by a cholinergic stimulus (21). Cholinergic agonists induce increased tone by binding to smooth muscle cell surface receptors that operate via stimulatory G-proteins (Gs) and ultimately result in Ca^{2+} release from endoplasmic reticulum, resulting in muscle contraction. In addition, they can inhibit adenylate cyclase. β-Adrenergic agonists are thought to relax smooth muscle by binding to a different cell surface receptor and, via an inhibitory G-protein (Gi), increase adenylate cyclase activity and, ultimately, cyclic adenosine monophosphate, a smooth-muscle relaxant (22). Thus, β-adrenergic agonists should partially interfere with cholinergically induced spasm. Cholinergic antagonists act as direct competitors for the cholinergic receptor site.

Previous studies demonstrating the efficacy of β-adrenergic agonists in cholinergic bronchoconstriction have differed from ours in not assessing a maximal stimulus. Our results agree with another study that noted that bronchodilator potency of β-adrenergic agonists is reduced during marked bronchoconstriction, such as occurs in severe asthma or with the experimental administration of high doses of a constrictor agonist (23). We conclude that even though β-adrenergic agonists play a major role in relieving bronchoconstriction in a variety of circumstances, conventionally used doses may not reverse maximal cholinergic challenge. Although much larger doses might be effective, existing dose-response curves for β-adrenergic agonists suggest that most of their effects should occur at the concentrations we delivered. Thus, metaproterenol conceivably could shift the dose-response curve but did not prove effective at the maximal methacholine response.

Ipratropium bromide was as effective as atropine in treating the increase in Rrs at the first time point and had a more persistent effect. Intravenous atropine had a peak effect at the first time point, but then declined in efficacy, probably due to its short duration of action.

Reversal of Cdyn was significant in both the atropine and IB groups compared with the control and β-adrenergic agonist groups at the first point after treatment (35 min). However, as spontaneous recovery of compliance increased, inhaled IB failed to demonstrate any significant difference from the other groups, whereas the effect of intravenous atropine persisted. Because Cdyn is a function of more peripheral small airways, this difference may be explained by the differences in route of administration of the drugs. Previous studies in normal subjects have shown a greater bronchodilator effect in large central airways than in peripheral airways after inhaled but not intravenous atropine (24,25). This remains controversial, and other studies have failed to localize any degree of preferential bronchodilatory effect of the IB in normal subjects (26) or in patients with asthma (27). Inhaled IB is primarily deposited in larger airways and might theoretically produce greater bronchodilation in larger airways where it is best delivered. Changes in Rrs primarily reflect changes in more central airways, whereas changes in Cdyn typically reflect changes in the more peripheral airways. Thus, efficacy of the inhaled drug in reversing Cdyn might be less than the efficacy of a parenteral drug.

Reversible bronchoconstriction still existed at 75 min after methacholine administration, as demonstrated when atropine (2 mg IV) was given. The Rrs in all groups improved to within 15% of the original baseline value after atropine administration.

The trend in heart rate changes was not significantly different in treatment groups compared with the methacholine-only group. Neither atropine nor metaproterenol elicited an increase in heart rate, although a reversal of increased Rrs was noted. The lack of response of heart rate agrees with the observation by Holtzman et al. (28) in dogs; they noted that despite effective inhibition of muscarinic receptors in the airways by anticholinergic agents, response of cardiac muscarinic receptors was unchanged even at the highest dose of atropine. This differs from humans in whom cardiac muscarinic response is seen at doses of atropine required to produce bronchodilation (29). The relative safety of intravenous atropine in rabbits should not necessarily be extrapolated to humans.

One of the purposes of our study was to demonstrate the efficacy of drug delivery using an MDI via an ETT. Previous studies showed that 2%–10% of the weight of a puff from an MDI exits the end of the ETT, but no determination has been made as to whether the drug itself traversed the tube or whether carrier substances in the MDI solution were preferentially preserved at the exit. The response to IB demonstrated that drugs delivered using MDI technology can reach highly effective concentrations in the airways, even with a pediatric-sized ETT in place.

Our studies confirm that inhaled anticholinergic treatment is equally efficacious as total parenteral parasympathetic blockade in this rabbit model. Any extrapolation to the clinical situation must be made with great caution. Reflex bronchoconstriction in humans has a significant cholinergic component but also involves other locally released mediators. Clinical experience has also shown that β-adrenergic agonists are effective in the clinical care of irritant-induced spasm, and β-adrenergic agonists have been shown to be more effective in histamine-induced bronchospasm than in cholinergically induced spasm. Methacholine administration also differs from reflex vagal bronchoconstriction in reversability by β-adrenergic agonists in vitro (30). This may be due to prejunctional effects of the β-adrenergic agonist, which would not play a role during direct application of a cholinergic stimulus. Perhaps the only direct clinical conclusion to be drawn at this point is that addition of inhaled IB to the conventional treatments of bronchospasm during anesthesia might be useful. Given the lack of any toxicity of IB, such a trial seems reasonable.

In conclusion, this study demonstrates that (a) under maximal cholinergic stimulus in rabbits as a model of bronchospasm, both inhaled IB and intravenous atropine relieve bronchoconstriction; (b) the β-adrenergic agonist metaproterenol is ineffective in reversing bronchoconstriction in this model; and (c) effective aerosol doses of a drug (IB) do reach the airways when administered via a 4.0 ETT.

Comparison of Two Techniques to Inflate the Bronchial Cuff of the Univent Tube

Medhat S. Hannallah, MD, FFARCS, and Jonathan L. Benumof, MD

Department of Anesthesia, Georgetown University Medical Center, Washington, D.C., and Department of Anesthesiology, University of California, San Diego Medical Center, San Diego, California

The Univent tube is an endotracheal tube with a movable bronchial blocker. The blocker cuff reportedly exhibits high-pressure characteristics when inflated to seal any adult bronchus. This study was aimed at measuring the cuff volume that would seal the bronchus when two different techniques of cuff inflation were used. One technique is based on creating negative pressure and the other is based on creating positive pressure within the breathing system. In addition, we directly measured the compliance characteristics of the cuff. The study was performed in eight adult patients undergoing thoracotomy. The negative pressure technique of cuff inflation (NPT) was tested by applying −150 mm Hg of pressure to the blocker lumen, causing loss of volume in the breathing system as evidenced by deflation of the reservoir bag. The blocker cuff was then inflated until the bag ceased to deflate. In the positive pressure technique of cuff inflation (PPT), the blocker lumen was connected to a beaker of water while maintaining pressure of +30 mm Hg within the breathing system. The bronchial cuff was then inflated until air bubbles ceased to appear in the beaker. Direct measurement of compliance of the blocker cuff confirmed its high-pressure characteristics. Bronchial sealing volume ranged from 3 to 5 mL when measured with the NPT and from 4 to 6 mL when measured with the PPT. In most cases, the NPT could provide satisfactory lung collapse with equal or smaller cuff volume than that measured with the PPT, but the smaller cuff volume was associated with only a relatively small reduction in cuff pressure. The PPT provided more reliable bronchial seal against a known airway pressure. It should therefore provide better lung protection in the presence of bleeding or infection.

(Anesth Analg 1992;75:784–7)

The Univent tube is an endotracheal tube with a movable bronchial blocker that is available for one-lung ventilation (1). The blocker cuff exhibits high-pressure characteristics when inflated to seal any adult bronchus (2). It is important, therefore, to inflate the blocker cuff to the smallest volume that would seal the bronchus rather than use 6–7 mL of air to routinely inflate it, as recommended by the manufacturer (Univent; Fuji Systems Corporation, Tokyo, Japan).

Two techniques have been described for inflating the blocker cuff to the bronchial sealing volume. One is based on creating negative pressure within the breathing system (2). The other technique pressurizes the proximal airway to a certain level and then demonstrates that no air leaks from the endobronchial catheter, similar to the procedure used for a double-lumen tube (3). The purpose of this study was to measure the blocker sealing volume using the negative pressure technique (NPT) of cuff inflation and to compare it with the cuff volume that would produce bronchial seal using the positive pressure technique (PPT) of cuff inflation. Because previous description of the high-pressure characteristics of the blocker cuff was based only on measurement of its resting volume and diameter, this study also aimed at directly measuring the pressure-volume relationship of the cuff to document its compliance characteristics.

Methods

The study was approved by the Georgetown University Hospital Institutional Review Board. Eight adult patients undergoing thoracotomy were studied after giving informed consent. Patient characteristics are summarized in Table 1. After induction of general anesthesia, the Univent tube was placed in the trachea. Tubes with an internal diameter of 7 or 8 mm were used, depending on the patient's build. The size of the bronchial blocker is equal in both these tube sizes. After the trachea was intubated, the tube was

Table 1. Clinical Characteristics of Eight Patients Undergoing Thoracotomy

Age (yr)	64 ± 14
Male/female	4/4
Weight (kg)	80 ± 15
Height (cm)	179 ± 11
Side of thoracotomy (right/left)	4/4

Values are number of patients or mean ± SD.

rotated 90° to the side to be occluded, and the blocker was advanced into the corresponding mainstem bronchus. Fiberoptic bronchoscopy was used to guide the depth of insertion of the blocker, which was placed so that its cuff lay completely within the bronchus just beyond the carina. General anesthesia was maintained with high-dose fentanyl or sufentanil supplemented with 0.5%–1.5% isoflurane in oxygen. Arterial oxygen saturation was monitored continuously with a pulse oximeter.

Compliance of the blocker cuff was first studied. A three-way stopcock connected the inflating tube of the blocker cuff with a 3-mL syringe and a calibrated aneroid manometer. The cuff was inflated with air in 1-mL increments to a total volume of 7 mL. The manometer recorded the cuff pressure that corresponded to each cuff volume. This part of the study was performed in four patients only.

The cuff was then deflated, and the bronchial sealing volume, as measured by NPT, was tested (Figure 1). After the patient's lungs were ventilated several times with 100% oxygen, ventilation was discontinued, the overflow valve in the breathing system was opened fully, and fresh gas flow to the system was turned off. Oxygen was flushed into the system until the reservoir bag became distended. Suction pressure of −150 mm Hg was then applied to the blocker lumen with a 10F suction catheter. With the bronchial cuff deflated, the distal end of the lumen of the blocker was freely connected with the trachea, causing loss of volume in the breathing system, as evidenced by deflation of the reservoir bag. The blocker cuff was then inflated with air in 1-mL increments, and the reservoir bag was observed carefully until it ceased to deflate. This was considered an indication that sealing of the bronchus had been accomplished, and the corresponding cuff volume was recorded. If the reservoir bag was emptied before completion of the test, it was refilled by flushing more oxygen into the breathing system.

Bronchial seal at this point was tested with the PPT. The 10F suction catheter now connected the blocker lumen to a beaker of water (Figure 2). The breathing system attached to the Univent tube was pressurized to +30 mm Hg. Complete seal at that pressure was confirmed if no air bubbles appeared in the beaker. Incomplete seal, on the other hand, led the pressurized air to escape through the blocker lumen, and bubbles appeared in the beaker. In this case, the blocker cuff was inflated in 1-mL increments until air bubbles ceased to appear in the beaker, indicating bronchial seal, and the corresponding cuff volume was recorded.

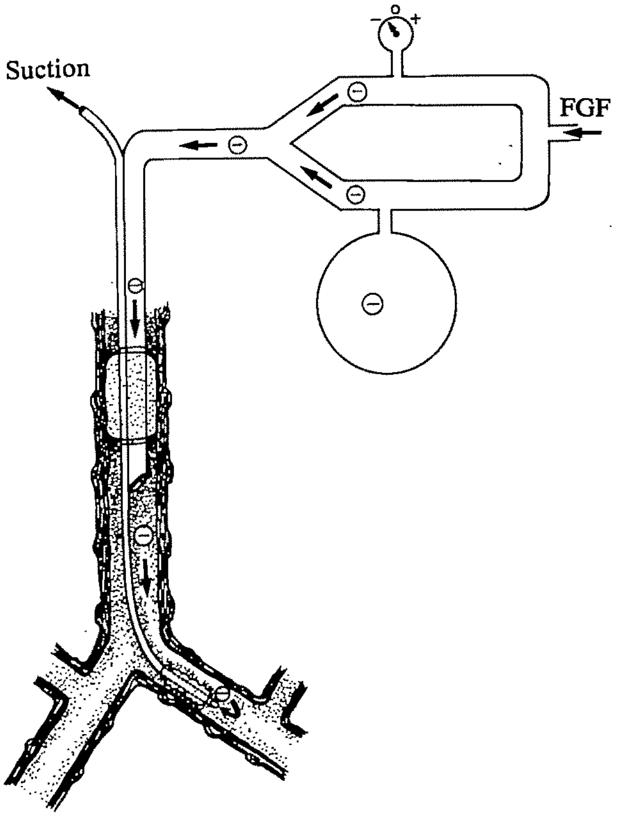

Figure 1. Negative pressure technique of bronchial cuff inflation. FGF, fresh gas flow. (Reproduced with permission from J. B. Lippincott Company; Hannallah M. The Univent® tube: bronchial cuff inflation. Anesthesiology 1991;75:165–6.)

Because the diameter of the blocker lumen is only 2 mm, spontaneous collapse of the blocked lung is very slow. To help lung collapse, suction through the blocker was maintained as long as the cuff was inflated regardless of whether the NPT or PPT was used.

Bronchial sealing volume as measured by NPT was used to inflate the blocker cuff, even if it was smaller than that measured by the PPT. After the chest was opened, the degree of collapse of the blocked lung was evaluated. If it was incomplete and the sealing volume as measured with the PPT was larger than that measured with the NPT, the cuff was inflated to the larger volume.

Fiberoptic confirmation of the position of the blocker was finally repeated to ensure that it remained completely within the bronchus after cuff

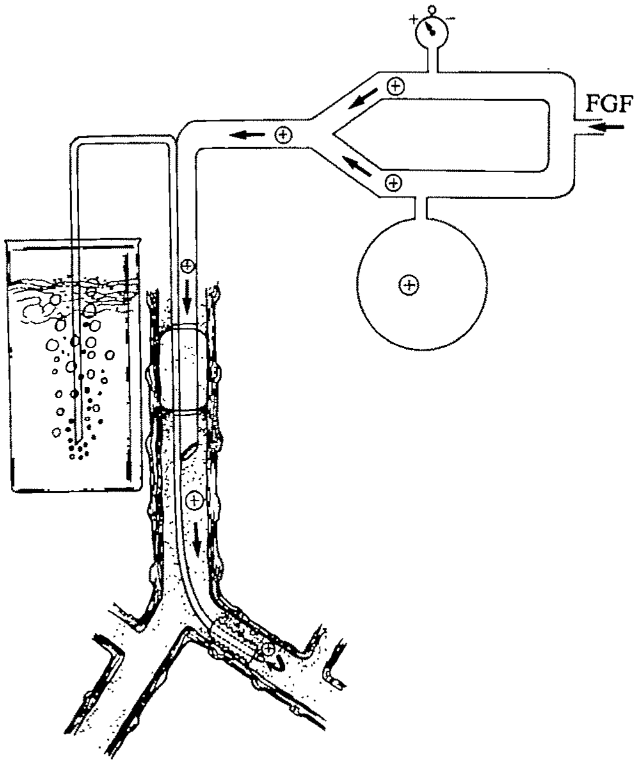

Figure 2. Positive pressure technique of bronchial cuff inflation. FGF, fresh gas flow.

inflation, because herniation of the cuff above the carina could compromise the seal and predispose to overinflation of the cuff.

Results

Figure 3 illustrates the relationship between cuff volume and mean cuff pressure in the four patients studied. The cuff was particularly noncompliant within the first 2 mL of inflation. At 2-mL volume, mean cuff pressure measured 178 mm Hg. For every 1-mL increase in cuff volume above 2 mL, mean cuff pressure increased by an average of 16 mm Hg.

Figure 4 illustrates the relationship between sealing volumes of the bronchial cuff as measured by both the NPT and PPT. The volume measured by the NPT ranged between 3 and 5 mL. When measured by the PPT, the volume range was 4–6 mL. The sealing volume measured by both techniques was equal in three patients. In the remaining five patients, the PPT failed to confirm bronchial seal when the cuff was inflated by the NPT. In these five patients, the cuff volume was increased by 1 mL before the PPT indicated bronchial seal.

In seven of the eight patients studied, complete collapse of the blocked lung was achieved when the bronchial cuff was inflated using the NPT. In the eighth patient, the sealing volume was 3 mL when measured by the NPT and 4 mL when measured by the PPT. The cuff was inflated to a volume of 3 mL initially. During thoracotomy, lung collapse was judged to be incomplete. When the cuff volume was increased to 4 mL, the lung became totally collapsed.

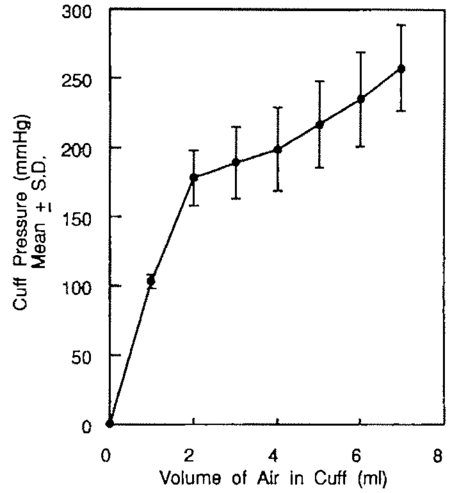

Figure 3. Compliance curve of the bronchial cuff of the Univent tube. Cuff pressure data are the mean ± SD in four patients.

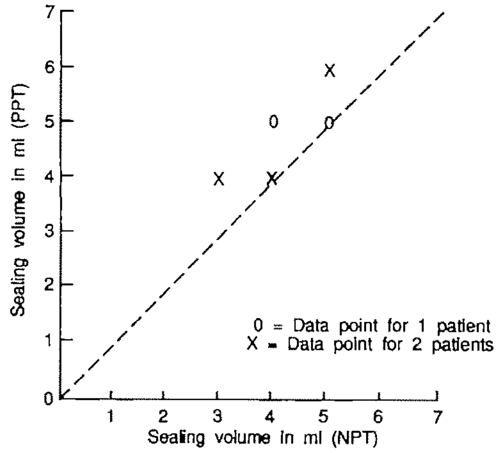

Figure 4. Relationship between sealing volumes of the bronchial cuff as measured by negative pressure technique (NPT) and positive pressure technique (PPT). *Dashed line* is line of identity.

Discussion

The high-pressure characteristics of the bronchial blocker cuff of the Univent tube was clearly demonstrated in this study. In a low-volume, high-pressure cuff, however, cuff pressure does not necessarily correlate to pressure exerted on the bronchial wall, because high pressure is needed to maintain cuff inflation itself (4,5). Nevertheless, intracuff pressure and pressure on the endobronchial wall can be expected to change in the same direction. In addition, more of the cuff pressure is likely to be transmitted to the endobronchial wall when contact between the two is complete, which takes place when a bronchial seal has been achieved. This emphasizes the importance of not inflating the cuff beyond its bronchial sealing volume.

Because no patient required a sealing volume of 7 mL, we tested the compliance curve of the blocker cuff in only four patients to avoid exposing more patients to unnecessarily higher cuff pressure than that which would produce bronchial seal.

Variable compliance at different cuff volumes could be explained by the fact that cuff pressure depends on the tension (T) in the cuff wall and on the cuff radius (R) at different cuff volumes, according to Laplace's law: $P = 2\,T/R$. The increase in cuff radius relative to the increase in wall tension must have been small at cuff volumes <2 mL, resulting in low compliance, and relatively larger at cuff volumes between 2 and 7 mL, resulting in better compliance. This is analogous to compliance and pressure changes of a reservoir bag in a breathing system that is progressively increasing in volume. The rate of rise in bag pressure decreases as its volume and diameter increase until the pressure inside the bag reaches a plateau of 40–50 cm H_2O as it continues to expand (6).

In this study, we sought to determine the optimal technique for inflating the cuff of the bronchial blocker of the Univent tube by comparing the two techniques that had been described for that purpose. We found that both techniques worked well and produced satisfactory lung collapse with the help of continuous suction through the blocker lumen. Complete collapse was well tolerated in the small group of patients studied. If hypoxemia results from the initiation of one-lung ventilation, suction can be discontinued, and constant positive airway pressure can be applied to the operative lung through the blocker lumen to correct it (7).

The NPT could achieve lung collapse with cuff volume that was sometimes 1 mL smaller than that measured by the PPT. That could possibly be explained by the fact that the endpoint for the PPT is more sensitive than that for the NPT. It is easier to see a few small bubbles under water than to detect a minor change in the volume of a 3-L reservoir bag. The difference in bronchial sealing volumes between the two techniques may also be due to a difference in lung volume and airway caliber at the time of bronchial cuff inflation. At that time, the lungs and airways are maximally expanded when the PPT is used and are in a neutral or partially collapsed position when the NPT is used. Reducing cuff volume by 1 mL reduces cuff pressure by 16 mm Hg on average. The value of this magnitude of pressure reduction when cuff pressure is already in the 200–250 mm Hg range is probably not significant.

The 1-mL incremental change in cuff volume was chosen in this study because it was considered a small but still clinically significant change. If cuff volume were increased in <1-mL increments, the differences between bronchial sealing volumes of the cuff as measured by the two techniques would probably be <1 mL.

In conclusion, the Univent tube bronchial blocker cuff is a high-pressure cuff that should be inflated carefully to the smallest bronchial sealing volume. Both the PPT and the NPT can be used satisfactorily for that purpose. The NPT is easier to perform, requires fewer tools, and usually uses a slightly smaller volume of air in the cuff. Gas-tight bronchial seal against known airway pressure is more reliably produced with the PPT, which may therefore provide better lung protection in the presence of bleeding or infection.

We thank Cherry Graziosi and Virginia Triay for their administrative assistance.

Tracheal Intubation Without the Use of Muscle Relaxants: A Technique Using Propofol and Varying Doses of Alfentanil

Mark S. Scheller, MD, Mark H. Zornow, MD, and Lawrence J. Saidman, MD

Department of Anesthesiology, UCSD School of Medicine, San Diego, California

We have noted that tracheal intubation can be accomplished in many patients after induction of anesthesia with propofol and alfentanil without the simultaneous use of muscle relaxants. This study was designed to evaluate airway and intubating conditions after administration of propofol and alfentanil in 75 ASA physical status I or II outpatients with Mallampati class I airways undergoing various surgical procedures. The patients were randomly assigned to one of five groups for induction of anesthesia. All patients received midazolam 1 mg IV before induction of anesthesia. Group I patients (n = 15) received d-tubocurarine 3 mg, thiamylal 4 mg/kg, and succinylcholine 1 mg/kg IV. Groups II–V patients (n = 15 each) received alfentanil 30, 40, 50, or 60 μg/kg followed by propofol 2 mg/kg IV. No muscle relaxants were given to patients in groups II–V. Airway management was performed by one of the authors who was blinded as to the dose of alfentanil administered. After loss of consciousness, patients' lungs were ventilated via face mask, and the ease of ventilation was recorded. Jaw mobility was also assessed. Ninety seconds after administration of the propofol or thiamylal, laryngoscopy was performed and exposure of the glottis and position of the vocal cords were noted. Intubation of the trachea was performed and patient response was noted. Heart rate and arterial blood pressure were also recorded before induction of anesthesia, after induction, and then again after intubation of the trachea. The lungs of all patients were easily ventilated via mask, and the jaw was judged to be relaxed in all patients. In group II (30 μg/kg alfentanil), 5 of 15 patients' tracheas could not be intubated because of poor exposure of the cords or the presence of closed vocal cords. In all other groups, vocal cord position was significantly more often favorable for tracheal intubation compared with the 30 μg/kg alfentanil group. In patients given alfentanil, the incidence of persistent coughing or movement after intubation of the trachea was most frequent with the 30-μg/kg dose of alfentanil. All patients receiving alfentanil had significant decreases in heart rate and arterial blood pressure after induction of anesthesia compared with preinduction values. However, there were no differences between the alfentanil groups. Patients who received thiamylal and succinylcholine had significant increases in heart rate after induction of anesthesia compared with preinduction values. Mean arterial pressure increased significantly after laryngoscopy and intubation of the trachea compared with postinduction values in patients receiving thiamylal and succinylcholine. We conclude that in premedicated outpatients with favorable airway anatomy receiving alfentanil (>30 μg/kg) and propofol for induction, ventilation via mask, jaw mobility, exposure of the vocal cords, position of the cords during laryngoscopy, and patient response to intubation of the trachea differs little from that achieved with thiamylal and succinylcholine.

(Anesth Analg 1992;75:788–93)

Induction of anesthesia using short-acting hypnotic drugs is frequently facilitated by the simultaneous administration of a depolarizing muscle relaxant such as succinylcholine. However, succinylcholine administration may be associated with side effects such as prolonged paralysis, postoperative myalgias, malignant hyperthermia, hyperkalemia, or increases in intracranial or intraocular pressure (1). These side effects have spurred research into the development of a nondepolarizing drug with a short onset of action. One of these, mivacurium, has recently been approved by the Food and Drug Administration and is now available for clinical use. However, even the use of nondepolarizing relaxants may be associated with undesirable effects, such as prolonged neuromuscular blockade, the need to reverse neuromuscular blockade, or the inability to reverse the paralysis quickly if airway management via mask or tracheal intubation is not possible. For these reasons, a method of providing good intubating conditions rapidly without using muscle relaxants has been sought by a number of investigators. Thiopental

alone in the dose of 4 mg/kg has been summarily judged to provide poor intubating conditions (2). Propofol, on the other hand, has been reported to depress pharyngeal and laryngeal reactivity to a greater extent than equipotent doses of thiopental (3). When either propofol or thiopental were combined with alfentanil (30 μg/kg) and lidocaine 1.5 mg/kg, jaw relaxation, visualization of the larynx, position of the vocal cords, ease of tracheal intubation, and tolerance of the endotracheal tube were observed to be favorable in the majority of patients (4). Nonetheless, the authors of this study recommended against routine use of this technique, because they believed it could not guarantee the excellent intubating conditions generally associated with the use of succinylcholine and thiopentone.

We too have noted that in outpatients given propofol and alfentanil for anesthetic induction, the lungs are easily ventilated via face mask, and laryngoscopy and tracheal intubation are easily performed without the need for concomitant neuromuscular blockade. The purpose of the present study was to characterize airway management, tracheal intubation, and hemodynamic responses in patients with favorable airway anatomy given varying doses of alfentanil in the presence of a fixed dose of propofol and to compare the results with those obtained with a standard thiamylal/succinylcholine induction sequence.

Methods

We studied 75 surgical patients undergoing same-day surgery for a variety of surgical procedures for which endotracheal anesthesia was planned. The study was approved by the institutional human studies review board. Patients were ASA physical status I or II, and all had Mallampati class I airway anatomy (5). Patients were excluded if they had a history of intravenous drug use, alcohol addiction, full stomach, coronary artery disease, or reactive airway disease.

Once in the operating room, intravenous access was established and all patients received 1 mg of midazolam intravenously. After midazolam administration, patients were asked to breathe oxygen via face mask while baseline vital signs (preinduction) were measured. Monitors included an automated blood pressure cuff, electrocardiogram, transcutaneous pulse oximeter, temperature, and end-tidal carbon dioxide. Patients were randomized to one of five groups by having an assistant pick one of five cards describing the induction sequence. Group I patients (n = 15) received *d*-tubocurarine 3 mg, thiamylal 4 mg/kg, and succinylcholine 1 mg/kg. Group II patients (n = 15) received alfentanil 30 μg/kg and propofol 2 mg/kg. Group III patients (n = 15) received alfentanil 40 μg/kg and propofol 2 mg/kg. Group IV patients (n = 15) received alfentanil 50 μg/kg and propofol 2 mg/kg. Group V patients (n = 15) received alfentanil 60 μg/kg and propofol 2 mg/kg. No muscle relaxants were given to patients in groups II–V. Ventilation via mask, laryngoscopy, and tracheal intubation were performed by an experienced anesthesiologist (one of the authors) who was unaware as to the dose of alfentanil the patient would be given. (Note that we were not able to be completely blinded as to group because we could generally distinguish the thiamylal/succinylcholine group from the others.) Alfentanil was delivered as a bolus infusion by a battery-powered pump (model AS20GH-2; Baxter Health Care Corporation, Hooksett, N.H.) which was programmed with the patient's weight and the dose of alfentanil. Methylene blue (0.1 mL) was added to the alfentanil as a marker to ensure the accurate delivery of alfentanil in all cases. The pump required approximately 80 s to deliver a 40-μg/kg bolus to a 60-kg patient. When the alfentanil bolus was finished, propofol (2 mg/kg) was given as a rapid intravenous bolus by hand-held syringe. Once the patient lost consciousness, ventilation via mask was attempted and the ease of ventilation was recorded as easy, difficult, or impossible. Vital signs were measured 45 s after the bolus dose of propofol was given (postinduction). Oral or nasal airways were inserted at the discretion of the anesthesiologist. Ninety seconds after the propofol was administered, laryngoscopy was attempted by one of three experienced anesthesiologists who was unaware of the dose of alfentanil given. During laryngoscopy and attempted intubation of the trachea, the intubating anesthesiologist assessed each patient for four variables: jaw relaxation, exposure of the vocal cords, position of the vocal cords, and patient movement during and within 1 min of attempted intubation of the trachea. The criteria used for ranking these variables are listed in Table 1. Patients whose tracheas could not be intubated after receiving the assigned induction drugs were so noted and succinylcholine (1 mg/kg IV) was administered. Tracheal intubation was then reattempted and exposure of the larynx and outcome of the intubation attempt were recorded. Once the trachea was intubated, the tracheal cuff was gently inflated. Vital signs were obtained immediately (postintubation) and recorded. Anesthesia was maintained at the discretion of the anesthesia care provider.

Mean arterial pressure and heart rate data were analyzed by one-way analysis of variance with post hoc paired *t*-testing where appropriate, comparing changes from preinduction values to postdrug and posttracheal intubation values within groups. Two-way analysis (group vs time) of variance was used to

test for differences in heart rate and mean arterial pressure between groups. Kruskal-Wallis and χ^2 analyses were used to determine differences between groups for nonparametric data.

Results

There were no significant differences between groups in terms of gender distribution, mean patient weight, mean patient age, or the percentage of smokers (Table 2). There were no significant preinduction differences between groups in heart rate or mean arterial blood pressure (Table 3). Mean arterial pressure and heart rate decreased significantly after induction compared with preinduction values in patients who received alfentanil (groups II–V) (Table 3). However, the magnitude of the postinduction decreases in heart rate and mean arterial blood pressure were not different between the various groups of patients who received alfentanil. Postintubation mean arterial pressure increased significantly compared with postinduction values in all of the groups receiving alfentanil. Group I patients (thiamylal/succinylcholine) had significant increases in heart rate after induction compared with preinduction values. Mean arterial pressure also increased significantly after intubation compared with postinduction values in group I patients (Table 3).

The ease with which ventilation via mask could be performed was not different between groups. In no patient was ventilation via mask judged to be impossible. In one patient in the 30-μg/kg group and in two patients in the 40-μg/kg group, the lungs were thought to be difficult to ventilate via mask. Jaw relaxation was thought to be good in all patients. No patient appeared to manifest signs of opioid-induced rigidity at any time. Exposure of the glottis was more often judged to be complete in groups I, III, IV, and V compared with group II (30 μg/kg alfentanil). However, these differences were not statistically significant. Exposure of the vocal cords was either complete (12/15) or partial (3/15) in all patients receiving thiamylal/succinylcholine. Complete or partial vocal cord exposure was judged to be absent in one patient in each of the alfentanil groups. However, the one patient receiving 60 μg/kg in whom the vocal cords could not be even partially visualized and in whom the initial attempt at tracheal intubation was unsuccessful then received succinylcholine 1 mg/kg. Repeat laryngoscopy was also not successful at exposing any part of the vocal cords, although the trachea was intubated by passing the tube blindly posterior to the epiglottis. In one patient receiving 50 μg/kg in whom the vocal cords could not be even partially visualized, the trachea was successfully intubated on the first attempt. No coughing or movement was observed in that patient after tracheal intubation and inflation of the endotracheal cuff.

The position of the vocal cords during laryngoscopy was significantly more often judged to be open or midposition in patients receiving 40, 50, or 60 μg/kg of alfentanil or thiamylal/succinylcholine compared with patients receiving 30 μg/kg (P = 0.023, 0.016, 0.029, and 0.018, respectively). In groups III, IV, and V (40–60 μg/kg alfentanil), there were no significant differences between groups with respect to vocal cord position (Table 4). One patient exhibited purposeful movement after intubation of the trachea. That patient received 40 μg/kg of alfentanil. The patient moved her hand but did not cough or otherwise object to the presence of the endotracheal tube in her trachea and had no recall of the event when questioned later. No patient in the 50- or 60-μg/kg alfentanil group or the thiamylal/succinylcholine group moved purposefully in the periinduction period. After intubation of the trachea and inflation of the tracheal cuff, a small number of patients in every group coughed persistently. Three patients in the 30-μg/kg alfentanil group, three in the

40-μg/kg alfentanil group, and one in the thiamylal/succinylcholine group had persistent coughing after tracheal intubation and inflation of the cuff. No patient in the 50-μg/kg alfentanil group or the 60-μg/kg alfentanil group had persistent coughing (Figure 1). A number of patients coughed once or twice after inflation of the tracheal cuff, but this was not drug or dose related. Of the 15 patients receiving thiamylal/succinylcholine for induction, four patients coughed once or twice after tracheal intubation and cuff inflation. The numbers of patients in groups II–V who coughed once or twice were 2, 4, 7, and 3, respectively (Figure 1). Significantly more patients (5 of 15) in group II (30 μg/kg) required succinylcholine for eventual tracheal intubation compared with all of the other alfentanil groups in which only 1 patient (60 μg/kg) required succinylcholine for tracheal intubation.

One patient who received thiamylal/succinylcholine had prolonged neuromuscular blockade lasting approximately 2.5 h after a 20-min laparoscopy. However, plasma cholinesterase levels and dibucaine number were in the normal range in this patient, leading us to suspect that this patient has a rare form of atypical acetylcholinesterase.

Discussion

These data demonstrate that tracheal intubation may be accomplished reliably in premedicated outpatients with favorable airway anatomy after intravenous induction without the simultaneous administration of muscle relaxants. Others have also reached similar, but not identical conclusions. For example, Kallar (3) was able to intubate the tracheas of 28 of 30 patients who were given 4 μg/kg of fentanyl, 1 mg/kg of lidocaine, and 2.5 mg/kg of propofol. This compared with 1 of 30 patients given fentanyl, lidocaine, and 4 mg/kg of thiopental and 0 of 30 patients given fentanyl, lidocaine, and 2 mg/kg of methohexital. Havorka et al. (4) studied 106 patients given 1.5 mg/kg of lidocaine and 30 μg/kg of alfentanil who

were then assigned to receive either propofol 2.5 mg/kg or thiopental 5 mg/kg for induction. They noted that tracheal intubation was more easily accomplished with thiopental than with propofol. Although Havorka et al. did not study a group of patients receiving succinylcholine, they concluded that intubating conditions were not reliably acceptable with either propofol or thiopental, and that succinylcholine or other muscle relaxants should be used routinely to ensure optimal intubating conditions. It should be pointed out, however, that Havorka et al. found that tracheal intubation was difficult in only 1 patient in 50 who received thiopental and 5 of 50 who received propofol.

Our study differed from that of Havorka et al. in that we included control groups of patients who received more than 30 µg/kg of alfentanil. Our results agree with those of Havorka et al. in that administration of thiamylal/succinylcholine was associated with better exposure of the vocal cords and a significantly reduced incidence of closed or midposition vocal cords compared with 30 µg/kg of alfentanil. In fact, we had a substantially higher percentage of patients (5 of 15) in the 30-µg/kg group who eventually required succinylcholine for tracheal intubation than Havorka et al. This may be attributable to methodologic differences in the two studies, as we did not include lidocaine in our premedication and our induction dose of propofol was 25% less. However, the results we obtained with higher doses of alfentanil were not objectively or subjectively different from those obtained using thiamylal/succinylcholine. Specifically, exposure of the vocal cords, position of the vocal cords during laryngoscopy, and patient movement during or after tracheal intubation were not different between the groups of patients receiving 40, 50, or 60 µg/kg of alfentanil and the group receiving thiamylal/succinylcholine. Similarly, in terms of intubation parameters, there were no differences between the 40-, 50-, and 60-µg/kg alfentanil groups, suggesting that doses of alfentanil above 40 µg/kg will not be associated with better intubating conditions.

No patient receiving alfentanil was thought to exhibit signs of opioid-induced muscular rigidity. The jaw was judged to be relaxed in all patients and the lungs of all but two patients could be easily ventilated via mask. In no patient was ventilation via mask deemed impossible. The ED_{50} for induction with alfentanil is approximately 110 µg/kg in healthy patients (6). That is, approximately 50% of patients will lose consciousness with that dose of alfentanil. In that study, chest wall rigidity was observed in 4 of 7 patients given 100 µg/kg of alfentanil, although no patient recalled any difficulty breathing. Because our dose range, 30–60 µg/kg, was well below the ED_{50} for induction for alfentanil, we did not expect rigidity to be a clinical problem. We also administered midazolam and propofol in combination with the alfentanil. There is evidence in animals and humans that benzodiazepines and barbiturates do prevent or attenuate alfentanil-induced muscular rigidity (7–9). Propofol may have similar properties, but this has not been studied as of yet. The slow rate of infusion of the alfentanil bolus dose may also have made opioid-induced rigidity less likely.

Arterial blood pressure and heart rate decreased significantly in patients given alfentanil (regardless of dose), whereas arterial blood pressure and heart rate increased in patients given thiamylal/succinylcholine. The administration of opioids was expected to be associated with lower arterial blood pressure and heart rate compared with thiamylal and succinylcholine. This has been observed by other investigators using a variety of induction techniques (10). Despite mean arterial pressures in the 50–60 mm Hg range in some patients after a propofol/alfentanil induction sequence, we did not administer ephedrine to any patient. Our experience has been that this relative hypotension is always associated with good peripheral perfusion, as evidenced by continuing digital pulse oximetry readings, and is short lived. Intubation of the trachea is almost always followed by an increase in arterial blood pressure (Table 3). However, our patient population was relatively young and healthy, and this technique may not be appropriate for some elderly or hypovolemic patients or for patients with some forms of cardiovascular or cerebrovascular disease.

Of concern to many anesthetists is the state of the patient immediately after the trachea has been intubated. Our observation period after intubation was only 1 min long, and in that period of time we noted very few patients moving purposefully or coughing persistently. It must be pointed out, though, that unless supplemental anesthesia is quickly administered, some patients will begin to cough or move within a few minutes, particularly in response to surgical positioning or preparation. Thus, when using this technique for tracheal intubation, additional anesthetic drugs such as nitrous oxide, isoflurane, propofol, or thiopental should be administered soon after induction to reliably prevent coughing or movement.

Along these lines, it must be pointed out that we waited 90 s after administering alfentanil before attempting laryngoscopy. We chose this period of time because of electrophysiologic data suggesting that the peak effect of alfentanil occurred at approximately 90 s after a bolus dose (11,12). Using a different waiting period might produce results different from those we observed.

We conclude that in premedicated healthy outpatients with favorable airway anatomy, tracheal intubation may be accomplished using a combination of 40 μg/kg of alfentanil and 2 mg/kg of propofol. The simultaneous administration of muscle relaxants may not be necessary to ensure acceptable jaw mobility, mask ventilation, vocal cord exposure, vocal cord position, or movement in response to tracheal intubation in this patient population. Because muscle relaxant administration may be associated with undesirable side effects, this technique may be of value in some patients.

Comparison of the Anesthetic Requirement for Tolerance of Laryngeal Mask Airway and Endotracheal Tube

Christopher J. Wilkins, MB, ChB, Paul G. W. Cramp, MB, ChB, James Staples, MD, and Wendell C. Stevens, MD

Department of Anesthesiology, Oregon Health Sciences University, Portland, Oregon

---

We tested the hypothesis that the laryngeal mask airway (LMA) is tolerated at lighter levels of anesthesia than an endotracheal tube (ET). We studied 20 unpremedicated, nonsmoking ASA physical status I or II patients aged 18–40 yr whose surgery lasted >1 h. Subjects were randomly assigned to receive either an ET or LMA. Anesthesia was induced with intravenous propofol and the LMA or ET was inserted. The ET-group patients received 1.5 mg/kg of succinylcholine, preceded by vecuronium (0.015 mg/kg IV). Maintenance of anesthesia was with only isoflurane and approximately 66% N_2O in O_2 by spontaneous ventilation. All gas concentrations were measured by a Raman spectrometer sampling from the breathing circuit end of the LMA or ET. Toward the end of the procedure, the end-tidal N_2O and isoflurane concentrations were allowed to decrease to <3 vol% and 0.8 ± 0.05 vol%, respectively. The end-tidal isoflurane concentration was then decreased in 0.1% ± 0.05% decrements, each stable value being held for 5 min. The patient was observed for signs of reaction to the presence of the LMA or ET. The mean (range) end-tidal isoflurane concentrations for reaction to ET and LMA were 0.55% (0.4–0.7) and 0.35% (0.2–0.51), respectively ($P < 0.001$). These data confirm the original hypothesis of the study.

(Anesth Analg 1992;75:794–7)

A major responsibility of the anesthesiologist in caring for the anesthetized patient is ensuring patency of the airway and adequacy of ventilation. Problems may occur during light anesthesia (coughing, breath holding, and airway obstruction from soft tissues, laryngeal spasm, and bronchospasm); during deep anesthesia (hypercarbia and hypoxia from respiratory depression); or at any level of anesthesia (all of the above plus inability to intubate the trachea and the presence of foreign material in the respiratory tract).

These problems may be overcome in a number of different ways. A novel approach to avoid, or better manage, some of them is the use of the laryngeal mask airway (LMA) developed by Brain (1,2). The LMA (Intavent International, The Netherlands) is inserted blindly through the mouth and forms an airtight seal against the perimeter of the larynx after inflation of the elliptical cuff within the hypopharynx (1,2). One of its specific advantages is its capacity to provide a clear airway in patients in whom conventional mask anesthesia is difficult or impossible and in whom tracheal intubation is either difficult or undesirable. Controlled ventilation through the LMA is usually successful (3), but the device does not protect the airway from aspiration of gastric contents.

Clinical experience suggests that the LMA is tolerated at much lighter levels of anesthesia than are required for the presence of an endotracheal tube (ET). This could be of twofold advantage: first, it might allow lighter levels of anesthesia to be used in some circumstances; second, it would circumvent the repetitive breath holding and coughing that sometimes occur when patients awaken with an ET in place. It is this putative advantage that we tested in this study.

Methods

Approval of the Oregon Health Sciences University Committee on Human Research was obtained, and all subjects gave written, informed consent before their inclusion in the study. Twenty (11 male, 9 female) ASA physical status I or II patients aged 18–40 yr were selected. All were of normal body weight and airway examination and were free from factors predisposing them to inhalation of gastric contents. Patients were nonsmokers, free from sub-

stance abuse, and were not on incidental drug therapy. The following criteria were also met:

1. An operation requiring the supine position
2. An operation allowing unrestricted access to the patient's head and neck throughout anesthesia
3. An operation not involving penetration of a serous cavity or the use of neuromuscular blocking drugs
4. An operation that could be performed with equal safety using inhaled anesthesia administered through either an LMA or ET
5. A procedure expected to last 1–2 h.

Such procedures included a variety of gynecologic, orthopedic, plastic, and general surgical procedures.

Patients were unpremedicated. Each was randomly assigned (on the basis of the last digit of the hospital registration number) to receive either an LMA (n = 10) or ET (n = 10). After institution of appropriate monitoring and breathing oxygen, anesthesia was induced with propofol (2.0–2.5 mg/kg IV) over approximately 30 s until the eyelash reflex was lost. Patients allocated to the ET group also received succinylcholine (1.5 mg/kg IV), preceded by vecuronium (0.015 mg/kg IV) to reduce muscle fasciculations. Patients in the LMA group did not receive any neuromuscular blocking drugs. The LMA or ET was then inserted in the usual way. Ventilation was assisted until the return of adequate spontaneous respiration. Anesthesia was maintained with isoflurane in approximately 66% N_2O in O_2 administered through a circle CO_2 absorption system at a total fresh gas inflow of 6 L/min, and the concentration of isoflurane was adjusted in response to clinical signs. No other drugs were administered.

At the end of the surgical procedure, the N_2O flow was discontinued, and anesthesia was maintained with isoflurane in O_2. The end-tidal N_2O concentration was allowed to decrease <3% for 5 min. The patient was left completely undisturbed during the following sequence.

The end-tidal isoflurane concentration was reduced in decrements by manipulation of the vaporizer setting. The initial value was 0.8% ± 0.05%, and each decrement was 0.1% ± 0.05%. Each concentration was maintained for 5 min after both (a) the end-tidal value had been reached, and (b) the difference between the inspired and end-tidal concentrations was <25% of the end-tidal concentration.

The patient was continuously observed for signs of reaction to the presence of the LMA or ET. Such signs were swallowing, coughing, gagging, sudden changes in the depth or regularity of respiration, movement of the head, or gross purposeful movement to remove the device. Shivering or extensor posturing were regarded as ambiguous signs, and the patient exhibiting these was excluded from analysis.

The occurrence of one or more of these signs was taken as the endpoint of the study, and the end-tidal isoflurane concentration at which it occurred was taken to be the value for intolerance of the airway device. The LMA or ET was then removed according to clinical judgment.

Monitoring of respired gas concentrations was with Raman gas analysis (Rascal, Albion Instruments, Salt Lake City, Utah), sampling continuously from the junction of the breathing attachment and the LMA or ET. This instrument provides values of inspired and expired concentrations of O_2, CO_2, N_2, N_2O, and volatile anesthetics. Values for volatile anesthetics are given to two decimal places. The calibration was checked, after the machine had been running for at least 1 h, against three reference standards (0.31% isoflurane in O_2; 2% isoflurane in 40% N_2O/balance O_2; and pure argon) before each procedure. A full calibration was performed if the error for isoflurane concentration was greater than ±0.01% against the 0.31% reference or >0.1% against the 2% reference value. During the emergence sequence, inspired and expired N_2 concentrations were recorded as a means of detecting atmospheric contamination (leak).

Statistical analysis was by Fisher's exact test, to test for bias in the distribution of ET and LMA between genders and to confirm randomization, and by Student's t-test for other data. The level of significance was taken at $P < 0.05$.

Results

Twenty patients participated in the study (11 male, 9 female). Ten received an LMA and 10 an ET. Two patients in the ET group were eliminated from the study, one because of shivering movements at the end of the procedure and one who received opiate analgesia during surgery. There were no significant differences between the groups for age, gender distribution, duration of N_2O exposure, propofol dosage, and time between attainment of the final end-tidal isoflurane concentration and the time of rejection of the LMA or ET (Table 1). There were no differences between the groups for end-tidal CO_2 values at both the beginning and end of the measurement period (Table 1). No bias in distribution of LMA or ET by hospital number was detected.

In all cases, the goal of obtaining the difference between the inspired and end-tidal isoflurane concentrations at <25% of the end-tidal value was bettered, the maximal deviation being 10% during the stepwise reduction of isoflurane concentration and 25% for the final values at the point of airway rejection. In all cases, this point was reached before the full 5-min stabilization period had been achieved.

Table 1. Clinical Characteristics of the 18 Study Patients

	LMA group	ET group
Age (yr)	30.8 (9.6)	26.1 (8.1)
Gender (M/F)	7/3	4/4
Propofol (mg/kg)	3.1 (1.4)	3.5 (0.88)
N_2O exposure (min)	84.7 (22.4)	99.7 (28.0)
Time at final isoflurane conc. (s)[a]	184 (47.1)	167 (36.7)
$P_{\mathrm{ET}}\mathrm{CO}_2$ (mm Hg)		
Start	45.4 (11.2)	43.7 (11.9)
End	40.8 (6.2)	41.4 (5.7)

LMA, laryngeal mask airway; ET, endotracheal tube; conc., concentration; $P_{\mathrm{ET}}\mathrm{CO}_2$, end-tidal CO_2.

Values are mean (SD); gender distribution by absolute numbers.

[a] Before rejection of the LMA or ET.

Table 2. Inspired and End-Tidal Concentrations of Isoflurane at the Time of Reaction to the LMA or ET

	LMA group	ET group
End-tidal conc. (%)	0.35 (0.11)	0.55 (0.09)[a]
Inspired conc. (%)	0.31 (0.12)	0.56 (0.07)[a]

LMA, laryngeal mask airway; ET, endotracheal tube; conc., concentration.

Values are mean (SD).

[a] ET > LMA ($P < 0.001$).

The signs indicating rejection of the airway device were always swallowing, coughing, or biting, sometimes accompanied by movements of the head rather than changes in the depth or regularity of respiration. Data for isoflurane concentrations were found to be normally distributed and are shown in Table 2.

Discussion

The LMA was introduced into clinical practice by Brain (1,2). Its use is well documented in the anesthetic literature (1–5). One of its claimed advantages is that its presence causes very little stimulation and that it is tolerated at light levels of anesthesia (LMA User's Manual, Intavent International). In contrast, the presence of an ET may necessitate a deeper level of anesthesia, which may cause hypoventilation in patients breathing spontaneously. This may alter the choice of anesthetic technique in favor of controlled ventilation in tracheally intubated patients. It is also likely that an airway device that is tolerated at light levels of anesthesia would provoke fewer episodes of coughing, breath holding, and bronchospasm during emergence than one requiring deeper levels of anesthesia. The use of lighter levels of anesthesia may also result in less cardiovascular depression and shorter recovery times.

All observations were made by a single observer who was aware of the nature of the airway device used. This is unlikely to cause bias, because the clinical signs used (coughing, biting, swallowing) were distinct and easy to observe.

The randomization was by last digit of hospital number. This method was used for simplicity but may have been a source of unrecognized bias. However, analysis of the distribution has not shown any such problem (Fisher's exact test).

The end-tidal isoflurane concentration was allowed to decrease in steps of 0.1%, and the point at which reaction to the presence of the airway device occurred was taken as the endpoint of the study. Each concentration was held constant for 5 min after the difference between the inspired and end-tidal concentrations was <25% of the end-tidal value. This favors equilibration of end-tidal, alveolar, and arterial concentrations and results in an error of <5% in the alveolar concentration as an estimate of the arterial value (6). Although each concentration was maintained for 5 min, it was clearly not possible to control the point of airway rejection, and therefore the time at the final concentration also could not be controlled. The "true" end-tidal concentration at which the patient would have reacted to the presence of the airway device is thus underestimated. Furthermore, because the equilibration time was only 5 min, the alveolar partial pressure of isoflurane as an estimate of brain tension will also be an underestimate (7). The 5-min period was chosen as a compromise between absolute accuracy and an unacceptable prolongation of the patient's anesthetic. The gas analyzer sampled from the junction of the breathing attachment and the LMA or ET. It is therefore possible that the samples were not truly end-tidal. For all these reasons, it was not considered meaningful to calculate MAC values for rejection of the airway devices. Nevertheless, the validity of the observed difference between the groups should not be affected by these factors.

Because the LMA may not form a gas-tight seal with the airway, it is possible that leakage of gas could have occurred. Contamination with air during inspiration would result in a lower concentration of isoflurane being delivered to the alveoli than the measured inspired value. We measured N_2 concentrations in the expired gas, and none was detected in any patient. A leak during inspiration is therefore unlikely.

Leakage during expiration, particularly if it occurred at the end of expiration, would produce a falsely low measured value, because anesthetic would be lost before it could be measured. Grouped data for inspired and end-tidal isoflurane concentrations are shown in Table 2. Inspired and end-tidal values are similar within the groups, and for the LMA group, the end-tidal concentration is greater than the inspired concentration. This suggests that significant leakage did not occur. This is further supported by the CO_2 concentrations, which were not significantly different between the groups (Table 1).

Propofol was chosen over thiopental as the drug used to induce anesthesia for two reasons. First, clinical experience suggests that passage of the LMA is smoother when propofol is used. Second, its shorter elimination half-life should make it less likely to affect anesthetic requirements during the measurement period >1 h after administration; however, this effect cannot be excluded.

The total propofol dosage was more than expected. This may reflect the fact that the patients were unpremedicated, and several appeared overtly anxious. Four patients in each group required supplemental propofol to prevent movement immediately after induction. Propofol dosage was not different between the groups.

N_2O was used during surgery but discontinued before the start of the observation sequence. Washout of N_2O from the brain is rapid (half-time 1.6 min) and will lag behind both the blood and alveolar compartments. To be certain that any residual anesthetic effect of N_2 had been minimized, the alveolar (end-tidal) concentration was allowed to decrease to <3% for 5 min.

Bench testing of the model of the type of Raman scattering detector that we used has shown the instrument to be capable of accuracy in measurement of volatile anesthetic concentrations of ±0.03% (8). An evaluation in the clinical setting has shown it to be as accurate in measuring volatile anesthetic concentrations as a dedicated mass spectrometer (9). The manufacturer quotes an accuracy for clinical use of only ±0.3% for volatile anesthetics. This is to allow for variation between instruments and drift from calibration that is only performed monthly, as well as for using the instrument before full warm-up. We used a single instrument for all cases and verified the accuracy of the instrument before each use after allowing a period for full warm-up. We accepted an accuracy of ±0.01% at 0.31% isoflurane and 0.1% at 2% isoflurane. Thus, although absolute accuracy of the concentrations cannot be guaranteed, the observed difference between the groups remains valid.

We conclude that the LMA is tolerated at lower concentrations of isoflurane anesthesia than an ET.

Total Intravenous Anesthesia: Effects of Opioid Versus Hypnotic Supplementation on Autonomic Responses and Recovery

Terri G. Monk, MD, Yifeng Ding, MD, and Paul F. White, PhD, MD, FFARACS

Division of Clinical Research, Department of Anesthesiology, Washington University School of Medicine, St. Louis, Missouri, and Department of Anesthesiology and Pain Management, University of Texas Southwestern Medical Center, Dallas, Texas

During radical prostatectomy procedures under total intravenous anesthesia, acute hemodynamic responses to retropubic dissection (30% ± 8% to 36% ± 12% [mean ± SD] increases in mean arterial pressure) were treated with supplemental doses of either an opioid analgesic (alfentanil) or a sedative-hypnotic (propofol) to return the mean arterial pressure to within 10% of the preincision value. Although both drugs were effective, control with propofol required 10.1 ± 2.5 min compared with 6.3 ± 2.6 min in the alfentanil group (mean ± SD; $P < 0.01$). Plasma stress hormone concentrations increased significantly in response to this surgical stimulus: epinephrine increased from 246% ± 169% to 283% ± 330%; norepinephrine increased from 44% ± 33% to 83% ± 104%; and antidiuretic hormone increased from 1300% ± 1591% to 1700% ± 1328%. Both alfentanil and propofol were equally effective in returning the catecholamine concentrations to their preincision levels. However, antidiuretic hormone levels remained above preincision values in both groups. Despite earlier awakening (3.4 ± 2.9 vs 9.1 ± 6.8 min; $P < 0.05$) in the alfentanil treatment group, there was no difference in time to spontaneous ventilation or tracheal extubation between the groups. In addition, 36% of the alfentanil-treated patients required antihypertensive therapy in the postanesthesia care unit compared with only 9% in the propofol group ($P < 0.05$). Postanesthesia care unit and hospital discharge times were similar in both treatment groups. We conclude that supplemental doses of alfentanil or propofol were equally effective in controlling acute hemodynamic and hormonal responses to surgical stimuli during total intravenous anesthesia.

(Anesth Analg 1992;75:798–804)

Total intravenous anesthesia (TIVA) involves the combined use of intravenous sedative-hypnotic, opioid analgesic, and muscle-relaxant drugs (1–4). Alfentanil and propofol are rapid, short-acting compounds with similar pharmacokinetic profiles. Although pharmacokinetic modeling suggests that sufentanil is an acceptable opioid analgesic to combine with propofol infusions during TIVA techniques lasting <6–8 h (5), most early studies involving TIVA techniques used concomitant infusions of alfentanil and propofol (6–9). While fixed-dosage regimens are frequently used, it is unclear whether it is preferable to vary the opioid analgesic or the sedative-hypnotic infusion to maintain hemodynamic stability during the intraoperative period.

Acute hemodynamic changes during nitrous oxide/opioid/relaxant ("balanced") anesthetic techniques are associated with increases in stress hormones (10,11). Marked elevations in heart rate (HR), mean arterial blood pressure (MAP), and catecholamine levels are stressful to patients with cardiac disease and have been associated with an increased incidence of postoperative renal and cardiac complications (12,13). Both alfentanil and isoflurane are equally effective in treating these acute autonomic responses (11). However, the optimal technique for treating acute hemodynamic and stress hormone responses during TIVA is unknown. Therefore, we designed a randomized, single-blind protocol to eval-

uate the intraoperative hemodynamic and stress hormone responses during a standardized TIVA technique involving alfentanil, propofol, and vecuronium infusions. In addition, we compared the effectiveness of administering either supplemental analgesic (alfentanil) or hypnotic (propofol) medication to control acute autonomic responses during TIVA. Finally, we compared the effects of variable-rate alfentanil and propofol infusions on recovery profiles.

Methods

After approval of this study by the Washington University Human Studies Committee, 25 consenting adult men, ASA physical status I–III, scheduled to undergo elective radical prostatectomy procedures under general anesthesia were assigned to one of two anesthetic treatment groups according to a randomized, single-blind protocol in which the patient was unaware of the treatment group. Exclusionary criteria included history of allergic reaction to the study medications, long-term opioid or sedative use, obesity (>130% of ideal body weight), clinically significant hepatic or renal dysfunction, endocrine disease, and inadequately controlled chronic hypertension.

On arrival in the preoperative holding area, a peripheral venous catheter was inserted, and all patients received midazolam (2–4 mg IV). After placement of a radial artery catheter, patients were transported to the operating room, and preinduction (baseline) hemodynamic values were obtained. Anesthesia was induced with alfentanil (20 $\mu g/kg$), propofol (1.5 mg/kg IV), and vecuronium (0.1 mg/kg IV). After tracheal intubation, anesthesia was maintained with constant-rate infusions of alfentanil (0.5 $\mu g \cdot kg^{-1} \cdot min^{-1}$) and propofol (50 $\mu g \cdot kg^{-1} \cdot min^{-1}$). Neuromuscular blockade was maintained with a vecuronium infusion at 0.8 $\mu g \cdot kg^{-1} \cdot min^{-1}$. Ventilation was controlled with 30% oxygen in air to maintain an end-tidal carbon dioxide tension (P_{ETCO_2}) of 34 ± 3 mm Hg (mean ± SD). Arterial blood samples were obtained 1–2 min before skin incision to determine Pa_{CO_2} (37 ± 5 mm Hg). The MAP and HR were continuously monitored using an integrated monitor (Cardiocap II, Datex Medical Instrumentation, Tewksbury, Mass.). Central venous pressure was monitored via a catheter placed in an internal jugular vein after tracheal intubation. The central venous pressure was maintained between 3 and 8 mm Hg throughout the study period by administering crystalloid and hetastarch (Hespan) or blood products.

Blood samples were obtained from the arterial catheter for determination of plasma catecholamines, vasopressin (antidiuretic hormone [ADH]), β-endorphin, cortisol, insulin, pancreatic polypeptide, and C-peptide concentrations at 1–2 min before skin incision (preincision) and 3–5 min after the onset of the hypertensive response during retropubic dissection (pretherapy). Plasma alfentanil and propofol concentrations were measured using arterial blood samples obtained at the same time intervals. Blood for catecholamine analysis was collected into tubes containing reduced glutathione and ethyleneglycol bis(aminoethylether)tetraacetate, and the blood samples for the remainder of the hormone assays were collected into ethylenediaminetetraacetate-containing tubes. These samples were immediately placed on ice and the plasma separated with a refrigerated centrifuge. All samples were stored at −70°C until the assays were performed.

Epinephrine and norepinephrine concentrations were determined using radioenzymatic assay techniques, with minimal assay sensitivities of 20 pg/mL and coefficients of variation of ±10%; all other hormone concentrations were determined using radioimmune assay techniques (14–17). The lower limits of sensitivity for the radioimmune assay were ADH (1 pg/mL), β-endorphin (8 pg/mL), cortisol (1 $\mu g/dL$), insulin (4 $\mu U/mL$), pancreatic polypeptide (20 pg/mL), and C-peptide (0.05 ng/mL). Plasma alfentanil concentrations were measured using a standardized radioimmunoassay with a lower limit of sensitivity of 5 ng/mL (18), and plasma propofol concentrations were measured using high-performance liquid chromatography by ICI Americas Inc. (Wilmington, Del.), with a lower limit of sensitivity of 50 ng/mL.

Patients exhibiting an increase in MAP of 25% or more above their preincision MAP for a minimum of 3 min were randomly treated using supplemental alfentanil or propofol to return the MAP to within 10% of the preincision value. In the alfentanil group, patients initially received a 10-$\mu g/kg$ bolus dose, and the infusion rate was increased by 0.5 $\mu g \cdot kg^{-1} \cdot min^{-1}$ (with an additional bolus dose and increases in the infusion rate repeated every 2–3 min until the MAP decreased). In the propofol group, patients initially received a 0.3-mg/kg bolus dose, and the infusion rate was increased by 50 $\mu g \cdot kg^{-1} \cdot min^{-1}$ (these supplemental dosages were repeated every 2–3 min until the MAP decreased). After maintaining a stable MAP for 10 min, repeat blood samples were obtained for determination of posttherapy hormone as well as analgesic and hypnotic drug concentrations. This sampling point was chosen because plasma catecholamines have a plasma half-life of <2 min, and this time interval allowed us to evaluate the effect of the treatment on the catecholamine stress response (10). In addition, secretion of stress hormones by the anterior pituitary occurs 5–10 min after the occurrence of an acute hypertensive event (19).

During the remainder of the operative period, the adjunctive therapy was adjusted to maintain hemodynamic stability in the two treatment groups. If the MAP remained within 10% of the preincision MAP for a period of 20–30 min, the alfentanil or propofol variable rate infusion was decreased by 50%. If the MAP remained stable, the adjunctive therapy was further decreased by 25% every 20–30 min until the minimal effective supplemental dose of the variable-rate alfentanil or propofol infusion was determined during the maintenance period. Adjunctive therapy was returned to the pretherapy baseline infusion rate if MAP decreased below the preincision value for >5 min.

On initiating skin closure, the vecuronium and alfentanil infusions were discontinued. At the end of surgery, residual neuromuscular blockade was reversed with neostigmine (0.07 mg/kg) and glycopyrrolate (0.01 mg/kg), and the propofol infusion was discontinued. The times from termination of the propofol infusion to spontaneous eye opening, purposeful response to verbal commands, adequate spontaneous ventilation, tracheal extubation, and orientation (to person, place, and time) were recorded. The recovery endpoints were evaluated at 5–10-s intervals after spontaneous eye opening. If adequate spontaneous ventilation did not occur within 10 min (with $P_{ET}CO_2$ ≥45 mm Hg), naloxone (0.04 mg IV) was administered every 60 s until spontaneous ventilation was adequate ($P_{ET}CO_2$ <50 mm Hg).

On arrival in the postanesthesia care unit (PACU), the patients were given 40% oxygen via face mask and observed by a nurse who was unaware of the treatment groups. If a patient complained of pain, morphine sulfate (1–2 mg IV) was administered at 2–5-min intervals until the patient was comfortable. Postoperative nausea or vomiting, or both, was treated with metoclopramide (10–20 mg IV). If the patients' postoperative MAP exceeded 25% of their preoperative baseline value for >5 min after achieving adequate pain control, labetalol (5–10 mg IV) or hydralazine (2.5–5 mg IV) was administered as needed to return the MAP value to within 10% of the preoperative baseline value. The dosage requirements for analgesic, antiemetic, and antihypertensive drugs in the PACU were recorded. Standardized PACU discharge criteria required that the patient be alert and oriented, have a stable MAP, HR, and respiratory rate, hemoglobin oxygen saturation >95%, and that residual side effects (e.g., nausea, pain) be minimal.

At the time of discharge from the PACU, patients were given a patient-controlled analgesia device (Baxter Infusor, Chicago, Ill.) that allowed them to self-administer morphine sulfate (2 mg [0.5 mL] IV) at minimal intervals of 6 min. All patients were visited daily to evaluate their overall recovery status and analgesia usage. On the fifth postoperative day, the patients completed a questionnaire with regard to their satisfaction with the anesthetic technique.

Table 1. Demographic Characteristics, Baseline Hemodynamic Values, and Plasma Drug Concentrations in the Two Treatment Groups

	Alfentanil (n = 11)	Propofol (n = 11)
Age (yr)	66 ± 6	67 ± 6
Weight (kg)	83 ± 11	83 ± 9
Height (cm)	177 ± 9	175 ± 5
Preexisting conditions		
Chronic hypertension	3	4
Coronary artery disease	2	3
β-Blocker therapy	2	3
Ca^+-channel blocker therapy	2	2
Mean arterial blood pressure (mm Hg)	105 ± 10	100 ± 11
Heart rate (beats/min)	70 ± 9	67 ± 11
Alfentanil concentration (ng/mL)		
Preincision	64 ± 15	79 ± 16
Pretherapy	67 ± 19	80 ± 14
Propofol concentration (μg/mL)		
Preincision	1.7 ± 1.0	1.9 ± 0.6
Pretherapy	1.5 ± 0.6	2.2 ± 1.9
Surgical time (min)	245 ± 22	225 ± 64

Values are mean ± SD, or numbers.

Data were analyzed using the STATA statistical analysis program, with one-way analysis of variance for continuous variables and the χ^2 test for discrete variables. Changes over time were evaluated using repeated measures of analysis of variance and Student's t-test, with a Bonferroni correction for multiple comparisons. Intergroup differences were evaluated using Tukey's post hoc test. Differences were considered to be statistically significant if the P value was <0.05. Values are expressed as mean ± SD (unless otherwise specified).

Results

Of the 25 study patients, 22 (88%) exhibited acute hypertensive responses on surgical entry into the retropubic space and were randomized to one of the two drug treatment groups. There were no differences in age, weight, height, and baseline hemodynamic values between the two study groups (Table 1). In addition, both groups had similar incidences of preexisting hypertension, coronary artery disease, and long-term usage of calcium-channel and β-adrenergic blocking drugs (Table 1).

Similar dosages of midazolam (2.6 ± 0.5 vs 2.6 ± 0.8 mg), alfentanil (1.6 ± 0.2 vs 1.7 ± 0.2 mg), propofol (122.7 ± 12.7 vs 125.1 ± 13.2 mg), and vecuronium (9.2 ± 1.0 vs 9.3 ± 1.0 mg) were administered during the induction period in the alfentanil and propofol treatment groups, respectively. Plasma

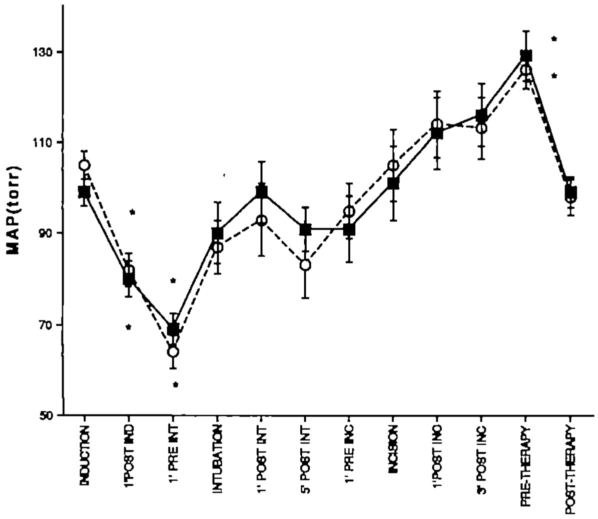

Figure 1. Intraoperative changes in mean arterial pressure (MAP) in patients receiving adjunctive therapy with either alfentanil (n = 11 [○]) or propofol (n = 11 [■]). Values are mean ± SEM. $^{*}P < 0.05$ was considered statistically significant when compared with induction (IND) (baseline) values. No differences were noted between the two treatment groups. INT, intubation; INC, incision.

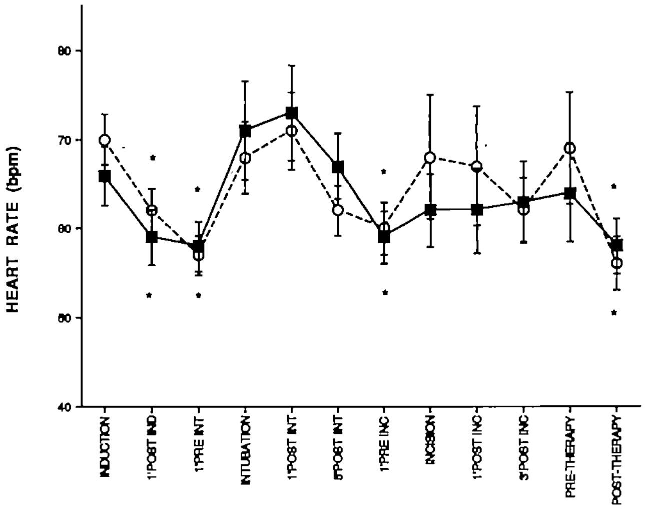

Figure 2. Intraoperative changes in heart rate (HR) in patients receiving adjunctive therapy with either alfentanil (n = 11 [○]) or propofol (n = 11 [■]). Values are mean ± SEM. $^{*}P < 0.05$ was considered statistically significant when compared with induction (IND) (baseline) values. No differences were noted between the two treatment groups. bpm, beats per minute; INT, intubation; INC, incision.

alfentanil and propofol concentrations were comparable in both groups at the preincision and pretherapy time intervals (Table 1). As expected, the posttherapy alfentanil concentration was significantly higher in the alfentanil-treated patients (162 ± 59 ng/mL) compared with the propofol group (93 ± 17 ng/mL). Conversely, the posttherapy propofol concentration was significantly higher in the propofol-treated patients (5.5 ± 2.7 μg/mL) than in the alfentanil group (1.4 ± 0.4 μg/mL). In the alfentanil group, the total alfentanil and propofol dosages were 25.6 ± 9.1 mg (range 15.0–46.8) and 1185 ± 161 mg (range 958–1424 mg), respectively. In the propofol group, the total alfentanil and propofol dosages were 10.5 ± 2.5 mg (range 6.0–13.7) and 1980 ± 774 mg (range 877–3049), respectively. The total vecuronium dosages in the alfentanil and propofol groups were similar (27.0 ± 5.0 mg [range 19–34] vs 24.5 ± 6.2 mg [range 11–30], respectively).

Perioperative changes in hemodynamic variables are summarized in Figures 1 and 2. Both groups had similar preinduction baseline MAP and HR values. After induction of anesthesia, there was a significant decrease in MAP and HR that persisted until the time of laryngoscopy in both groups. With tracheal intubation, MAP and HR returned to baseline values and remained stable until the surgeon entered the retropubic space (8.2 ± 7.8 and 8.6 ± 4.2 min after skin incision in the alfentanil and propofol groups, respectively). At that time, MAP values increased 30% ± 8% and 36% ± 12% in the two groups, respectively. However, HR values remained unchanged in both groups at the time of the acute hypertensive response. The time required for MAP values to return to within 10% of the preincision values was significantly shorter for alfentanil-treated patients (6.3 ± 2.6 min) compared with those receiving supplemental propofol (10.1 ± 2.5 min). Both groups experienced a significant decrease in HR after treatment of the acute hypertensive response. The MAP values were subsequently maintained within 10% of preincision values in both groups. Posttherapy stress hormone blood samples were obtained after maintaining a stable MAP for 10 min. There were no significant differences in MAP or HR values between the two treatment groups during the remainder of the surgical procedure.

All patients experienced significant increases in plasma epinephrine, norepinephrine, and ADH concentrations with the acute hypertensive response to retropubic dissection (Table 2). The plasma catecholamine concentrations returned to baseline values within 10 min after supplemental alfentanil or propofol treatment. Although the ADH levels decreased with both treatment modalities, the concentrations remained above baseline values. Although cortisol concentrations were unchanged immediately after the acute hypertensive response, they were significantly increased 10 min after "control" of the hypertensive response in both groups. Similarly, β-endorphin levels were significantly increased in both groups after treatment with either additional alfentanil or propofol. There were no changes in the plasma insulin, pancreatic polypeptide, or C-peptide

Table 2. Intraoperative Changes in Plasma Hormone Concentrations in the Two Treatment Groups

concentrations from their preincision values during he evaluation period (data not reported). No intergroup differences were found in any of the plasma hormone concentrations.

Similarly, there were no differences in the duration of surgery or times to resume spontaneous ventilaion or tracheal extubation after discontinuation of he propofol infusion between the two groups (Tables and 3). However, the time to awakening was ignificantly shorter in the alfentanil-treated patients. Although there was no difference in the requirement or opioid antagonism at the termination of the proedure, only 9% of the propofol-treated patients compared with 36% in the alfentanil group) required ntihypertensive therapy during their PACU stay. None of the patients in either group required antimetic therapy in the PACU. There was also no ifference in the duration of PACU stay or length of ospitalization between the two groups (Table 3). Postoperative opioid analgesic (morphine) requirements were similar in both TIVA treatment groups data not reported). The postoperative follow-up uestionnaire revealed that none of the patients exerienced recall of intraoperative events, and most of the patients were highly satisfied with their anesthetic technique (94%–97%).

Discussion

The alfentanil/propofol/vecuronium TIVA technique used in this study prevented clinical signs of inadequate anesthesia during skin incision in all patients; however, 88% of these patients experienced acute hypertensive responses and increases in stress hormone concentrations during retropubic dissection. The magnitude of the changes described during this operation were similar to the responses previously reported with a standardized nitrous oxide/opioid/muscle relaxant anesthetic technique (11). These observations are also in agreement with previous studies, indicating that skin incision was not the most intense stimulus during the intraoperative period (11,20).

In this patient population, a mean plasma alfentanil concentration of 70 (±17) ng/mL, in combination with a plasma propofol concentration of 1.8 (±1.0) μg/mL, was adequate to prevent clinical signs of inadequate anesthesia in response to skin incision. In previous studies utilizing balanced anesthesia with alfentanil, nitrous oxide, and a muscle relaxant, plasma alfentanil concentrations of 159–279 ng/mL were needed to prevent acute hemodynamic responses to skin incision (11,20). Analogous to the findings of Vuyk et al. (9), our data support the suggestion that the alfentanil requirement is decreased when administered with propofol during TIVA, compared with 67% nitrous oxide (as part of a "balanced" anesthetic technique) (11,20).

Other investigators have reported significant increases in plasma catecholamines, ADH, cortisol, and β-endorphin concentrations after acute hypertensive responses during general anesthesia with various combinations of intravenous and inhaled anesthetics (10,11,13,21–25). With the TIVA technique utilized in this study, we found significant increases in epinephrine, norepinephrine, and ADH concentrations within 5 min after the acute hypertensive response to retropubic dissection. Plasma cortisol and β-endorphin levels increased more slowly in both groups. The delayed elevation in plasma cortisol concentrations was not surprising, because changes in plasma cortisol concentration are mediated via adrenocorticotropic hormone and typically occur 5–15 min after the occurrence of a stressful event. Thus, the pretherapy sampling interval (3–5 min after the hypertensive response) was too short to reflect changes in this stress hormone. As reported previously during general anesthesia with volatile anesthetics (26,27), we found that gastrointestinal hormones (insulin, pancreatic polypeptide, C-peptide) were unchanged during retropubic dissection under TIVA.

Control of the acute hypertensive response to retropubic surgical dissection was achieved by administering additional alfentanil or propofol during TIVA. Although arterial blood pressure values returned to baseline more rapidly with alfentanil administration (6.3 ± 2.6 vs 10.1 ± 2.5 min for the propofol group), it is of limited (if any) clinical significance. Given the differing pharmacologic properties of alfentanil and propofol (i.e., opioid analgesic vs sedative-hypnotic), it is difficult to determine equipotent dosages for the two drugs. However, by increasing the size of the supplemental bolus dose of propofol, arterial blood pressure control could have been more rapidly achieved.

A recent study by Glass et al. (28) also evaluated the capacity of either supplemental opioid or hypnotic to control inadequate anesthesia during TIVA with fentanyl and propofol. They found more treatment "failures" in the fentanyl (vs propofol) treatment group. This apparent difference from our findings is probably related to the use of different opioids (alfentanil vs fentanyl) and dosage regimens (bolus dose plus an increase in the infusion rate vs an increase in the infusion rate alone) to control the acute autonomic signs of inadequate anesthesia.

During periods of surgical stress, stimulation of the sympathetic nervous system results in increased circulating levels of epinephrine and norepinephrine. If untreated, these levels may remain elevated throughout the procedure (29,30). In our study, treatment of the acute hypertensive response with either additional alfentanil or propofol resulted in a return of epinephrine and norepinephrine concentrations to their preincision values. These findings are in agreement with other studies, suggesting that supplemental opioid analgesic or anesthetic administration can block the sympathetic response to surgical stimulation (11,28,31–33). Increases in plasma cortisol and β-endorphin concentrations at the posttherapy sampling interval reflect the fact that β-endorphin and adrenocorticotropic hormone are secreted simultaneously from the anterior pituitary and that increases in plasma levels can peak as late as 15 min after a stressful event (19,34). However, there were no significant differences in neuroendocrine responses between the two treatment groups at any time during the study period.

Analogous to previous findings during balanced anesthesia (11), these findings suggest that the type of pharmacologic agent chosen to control acute hemodynamic responses during TIVA does not significantly affect the outcome after this major surgical procedure. Of note, the requirement for antihypertensive therapy in the PACU was significantly higher in the variable-rate alfentanil (vs propofol) infusion group. Because there were no differences in the postoperative analgesic requirements, a possible explanation relates to the residual cardiovascular depressant effects of propofol.

In achieving hemodynamic stability during TIVA, alfentanil and propofol were chosen because their relatively short durations of pharmacologic effects would minimize the possibility of prolonging the recovery period. These data support the suggestion that general anesthesia can be produced by using an hypnotic as the sole anesthetic agent. However, Glass et al. (28) found that the use of a fentanyl/propofol combination was associated with significantly shorter recovery times than propofol alone during TIVA. In using an opioid to treat signs of inadequate anesthesia during TIVA, it is important to ensure that the patient has an adequate level of hypnosis to prevent intraoperative recall. Adjunctive use of an amnestic premedicant (e.g., midazolam) will provide an additional "margin of safety" during TIVA.

In conclusion, hemodynamic and plasma hormone responses to noxious surgical stimuli during radical prostatectomy procedures under TIVA were similar to those reported during balanced anesthesia with nitrous oxide/alfentanil/muscle relaxant (11). Supplemental doses of alfentanil or propofol provided rapid control of both the acute hemodynamic and plasma hormone responses during TIVA with alfentanil, propofol, and vecuronium. Although emergence from TIVA was more rapid in alfentanil-supplemented patients, there were no significant differences in surgical outcome after this operation. During a TIVA technique with alfentanil and propofol, careful titration of either the opioid analgesic or the sedative-hypnotic will result in comparable intraoperative conditions and postoperative outcome. Further studies are needed to determine the optimal dosage regimens to maintain hemodynamic stability during TIVA.

The authors thank Dr. Ian Smith for his assistance in the early stages of this study, Drs. Phil Cryer and Ronald Gingerich for their assistance with the plasma hormone assays, Dr. Ahmed Ghouri for his assistance with our data analysis, and Sandy Hawes for secretarial assistance in preparing the manuscript.

---

We evaluated the clinical effectiveness of esmolol, an ultra-short-acting, β-adrenergic receptor blocking drug, to control the sinus tachycardia and increase in arterial blood pressure induced by electroconvulsive therapy (ECT). Each of 20 patients, ASA physical status I–III, participated in a double-blind, randomized Latin-Square study involving two matched-pair trials (placebo versus esmolol given as a 500-μg/kg bolus followed by either 300 $\mu g \cdot kg^{-1} \cdot min^{-1}$ [high dose], 200 $\mu g \cdot kg^{-1} \cdot min^{-1}$ [medium dose], or 100 $\mu g \cdot kg^{-1} \cdot min^{-1}$ [low dose] infusion of esmolol) during ECT. Each patient acted as his or her own control (total number of ECT procedures were 160). We administered a 1-min bolus of placebo (normal saline) or esmolol at the rate of 500 $\mu g \cdot kg^{-1} \cdot min^{-1}$ followed by either high-, medium-, or low-dose esmolol or placebo for an additional 3 min. We then induced anesthesia with methohexital (1 mg/kg) and succinylcholine (0.5 mg/kg) IV. Ninety seconds after the administration of succinylcholine, the electrical stimulus was applied to induce seizure. The infusion of placebo or esmolol was discontinued 3 min after the electrical stimulus. Significant decreases were found in mean heart rate from minute 3 until minute 7 and in the maximum heart rate. The mean of each patient's maximum heart rate after seizure changed from 147 ± 18 bpm in placebo patients to 112 ± 20 bpm in high-dose esmolol patients; to 121 ± 23 bpm in medium-dose esmolol patients; and to 124 ± 20 bpm in low-dose esmolol patients. Mean arterial blood pressure was significantly lower in the high-dose esmolol patients (100 ± 18 mm Hg) compared with the same patients given placebo (122 ± 25 mm Hg). Finally, the side effect of clinically determined length of seizures decreased in the high- (36 ± 14 s) and medium-dose (34 ± 14 s) esmolol patients as compared with placebo (42 ± 11 s) patients. Low-dose esmolol did not significantly reduce the clinically determined length of seizure (38 ± 11 s). We conclude that the 100-$\mu g \cdot kg^{-1} \cdot min^{-1}$ infusion following a 500-μg/kg bolus of esmolol effectively controls the hyperdynamic response to ECT.

(Anesth Analg 1992;75:805–10)

Electroconvulsive therapy (ECT) is used in the treatment of psychiatric illness, primarily major affective disorders, and certain cases of schizophrenia (1). This therapy works by electrically inducing grand mal seizures. Electroconvulsive therapy is known for its well-described, brief parasympathetic sequence followed by adrenergic outflow during the seizure, which markedly increases heart rate (HR) (2–6), arterial blood pressure (6,7), and plasma levels of catecholamines (8–10). These changes can produce cardiovascular stress in patients with heart disease.

This adrenergic response can be blunted effectively by premedication with clonidine or β-adrenergic blocking drugs (11,12). Of the β-blockers studied, esmolol seems uniquely suited to blocking the effects of adrenergic outflow during ECT based on its quick onset and short duration of action (13). A number of investigators have documented esmolol's ability to blunt the increases in HR and arterial blood pressure associated with ECT, using either a single bolus or an infusion at a variety of doses (6,11,14–17).

In a previous study (14), we noted that a large premedication dose of esmolol (2.9 mg/kg) for ECT decreased the duration of seizure by 27% as measured by electroencephalogram (EEG). Whether this effect is clinically relevant is not known (5,18), but it would be ideal to give the smallest dose of esmolol that would be clinically effective in blunting the adrenergic consequences of ECT to minimize any other potentially unwanted effects of the drug. A very low dose of esmolol (1-mg/kg bolus [6,16], 1.4-mg/kg bolus [17], or 1.5-mg/kg bolus [11]) does not influence duration of seizure. However, no es-

molol dose-response study of hemodynamic response and seizure duration has been undertaken. This dose-response study investigates the effect of three different doses of esmolol premedication for ECT based on the hemodynamics and seizure duration in patients undergoing repetitive ECT treatments.

Methods

After approval by the Human Subjects Review Committee had been obtained, 20 consenting adult inpatients under the care of the Department of Psychiatry and scheduled for ECT were enrolled in the study. All patients were ASA class II–III. Exclusion criteria included pregnancy, age <21 yr, greater than first-degree atrioventricular block, allergy to β-adrenergic blockers, use of a β-blocker or calcium-channel blocker within four drug half-lives, atrial fibrillation or flutter, congestive heart failure, systolic blood pressure (SBP) consistently <100 mm Hg or diastolic blood pressure (DBP) <50 mm Hg, myocardial infarction within 6 mo, renal or hepatic failure, bronchospasm, or bronchial asthma.

Patients were entered into a randomized Latin-Square study so that every patient was placed twice into each of the four test groups: placebo control, high-dose esmolol, medium-dose esmolol, and low-dose esmolol. They were given no premedication before their arrival in the ECT suite. Patients were placed in a supine position, and a peripheral intravenous cannula infusing placebo (normal saline solution) or esmolol (high, medium, or low dose) was started. One author, not involved in the management of the patient, controlled the rate of infusion, which was hidden by a paper shroud from the view of others in the room. Patients were monitored with electrocardiography lead II, automated noninvasive blood pressure cuff, pulse oximetry, and EEG.

Anticholinergic premedication was not administered. After breathing oxygen, the patient received an infusion of either normal saline or esmolol. Those receiving esmolol were given 500 μg/kg over 1 min followed by 300 $\mu g \cdot kg^{-1} \cdot min^{-1}$ (high dose), 200 $\mu g \cdot kg^{-1} \cdot min^{-1}$ (medium dose), or 100 $\mu g \cdot kg^{-1} \cdot min^{-1}$ (low dose). Four minutes after initiating the esmolol or placebo infusion, induction of anesthesia proceeded with 1 mg/kg methohexital. After loss of the eyelash reflex, 0.5 mg/kg succinylcholine was administered, followed 90 s later by the electrical stimulus to induce seizure. The esmolol or placebo infusion was discontinued 3 min after the electrical stimulus.

Heart rate, SBP, DBP, and mean blood pressure (MBP) were recorded at the following times: morning ward value, pretreatment baseline, every minute for 15 min after the initiation of esmolol or placebo infusion, and then every 5 min for an additional 20 min.

Statistical comparisons of the hemodynamic variables for the 160 trials from the 20 patients were performed using the one-way repeated measures analysis of variance tests with Duncan's multiple-range test to assess the significance of the results. The duration of the induced seizure as measured by the EEG and by clinical observation was recorded and compared between the study groups by the Kruskal-Wallis rank sum statistic.

Results

Each patient received an average of 12 ± 2 ECT treatments. Because all patients were entered twice in each of the four study groups, the mean demographics of the groups were identical: age 44 ± 18 yr, height 163 ± 18 cm, weight 64 ± 17 kg, and body surface area 1.68 ± 0.30 m^2. Hemodynamic variables (i.e., HR, SBP, DBP, and MBP) were equivalent during morning ward measurements and at baseline measurement in all four groups. There were no significant differences among shock stimulus variables used to induce seizure activity in any of the study groups (Table 1).

Patients given placebo manifested the expected significant increase in HR with seizure (Figure 1, minutes 6 and 7). In all three esmolol groups, HR was significantly decreased compared with placebo means (Figure 1, minute 3 until minute 7). This decrease was equivalent in all three esmolol groups. Maximal HR (the mean of each patient's maximal HR after seizure) changed from 147 ± 18 bpm in placebo patients to 112 ± 20 bpm in high-dose patients, to 121 ± 23 bpm in medium-dose patients, and to 124 ± 20 bpm in low-dose patients and was significantly ($P < 0.03$) more rapid in the placebo group when compared with baseline and with each esmolol group. There were no significant differences among the three esmolol study groups with respect to maximal HR.

Systolic blood pressure never changed from baseline after seizure in the three esmolol study groups; however, SBP increased significantly ($P < 0.05$) above baseline in the patients given placebo (Figure 2, minutes 7 and 8). Systolic blood pressure means from patients given placebo were significantly greater than SBP means from the three esmolol study groups at minutes 6, 7, and 8. There were no significant differences among the three esmolol study groups with respect to SBP. Diastolic blood pressure never changed from baseline after seizure in the patients given high-dose esmolol; however, DBP increased significantly from baseline at minute 7 in patients given placebo, medium-dose esmolol, and low-dose esmolol (Figure 3). In addition, the patients given placebo had significantly greater DBP at minute 7 than those patients given high-dose esmolol. There were no significant differences among the three es-

EEG, electroencephalogram.
Values are mean ± SD.
[a] Electroconvulsive stimulus was given to all patients using the same electroconvulsive therapy device, model SR, Mecta Corp., Portland, Ore.
[b] Statistically significant ($P < 0.05$) difference compared with placebo measurements.

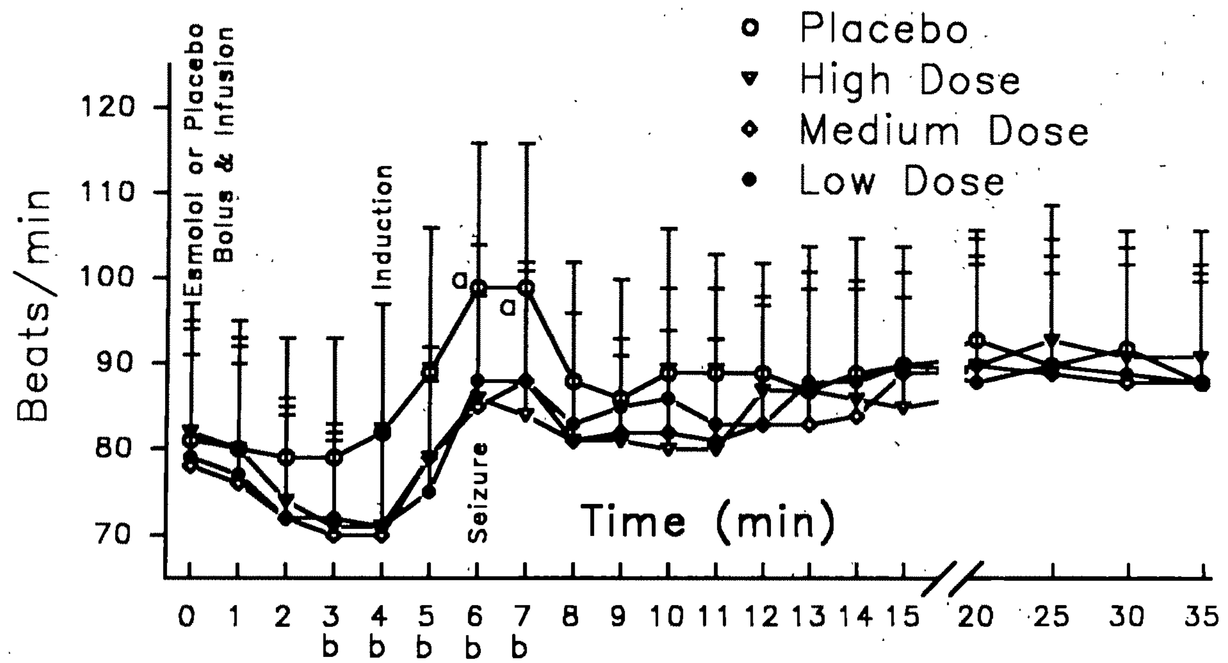

Figure 1. Mean values ± SD for heart rate (beats/min) for all 20 patients given either placebo or esmolol at high dose (300 $\mu g \cdot kg^{-1} \cdot min^{-1}$), medium dose (200 $\mu g \cdot kg^{-1} \cdot min^{-1}$), and low dose (100 $\mu g \cdot kg^{-1} \cdot min^{-1}$) during electroconvulsive therapy. [a] $P < 0.05$, significantly greater than placebo baseline. [b] $P < 0.05$, significantly less than placebo heart rate.

molol study groups with respect to DBP. Mean blood pressure never significantly changed from baseline after seizure in the three esmolol study groups; however, MBP increased significantly ($P < 0.05$) above baseline in the patients given placebo (Figure 4, minutes 7 and 8). There were no significant differences among the three esmolol study groups with respect to MBP.

No adverse events, such as bradycardia, hypotension, congestive heart failure, or bronchospasm, occurred in any of our study patients. Only the duration of seizure, as determined clinically, was statistically different between the placebo and medium- and high-dose esmolol groups, with seizure duration diminished in the latter two; however, there was no significant difference between the placebo and low-dose esmolol groups for the clinically determined duration of seizure (Table 1).

Discussion

These data demonstrate that an intravenous esmolol bolus of 500 μg/kg followed by an infusion of 100 $\mu g \cdot kg^{-1} \cdot min^{-1}$ is as efficacious as larger doses in

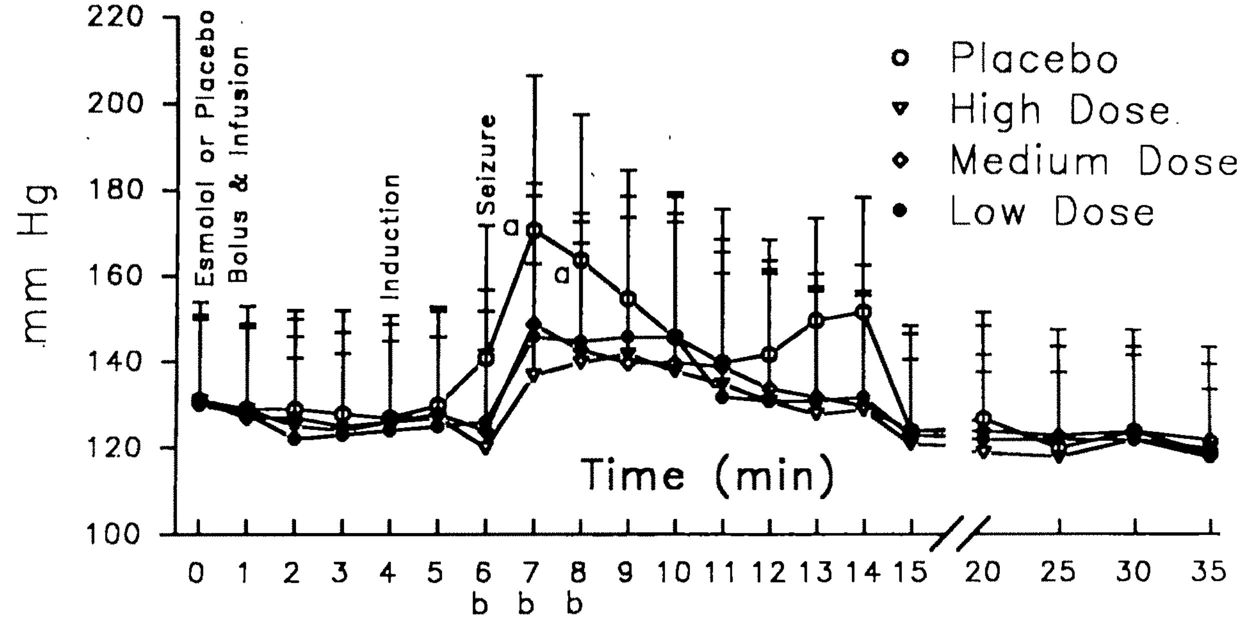

Figure 2. Mean values ± SD for systolic arterial blood pressure (mm Hg) for all 20 patients given either placebo or esmolol at high dose (300 μg·kg^{-1}·min^{-1}), medium dose (200 μg·kg^{-1}·min^{-1}), and low dose (100 μg·kg^{-1}·min^{-1}) during electroconvulsive therapy. $^{a}P < 0.05$, significantly greater than placebo baseline. $^{b}P < 0.05$, significantly less than placebo systolic blood pressure.

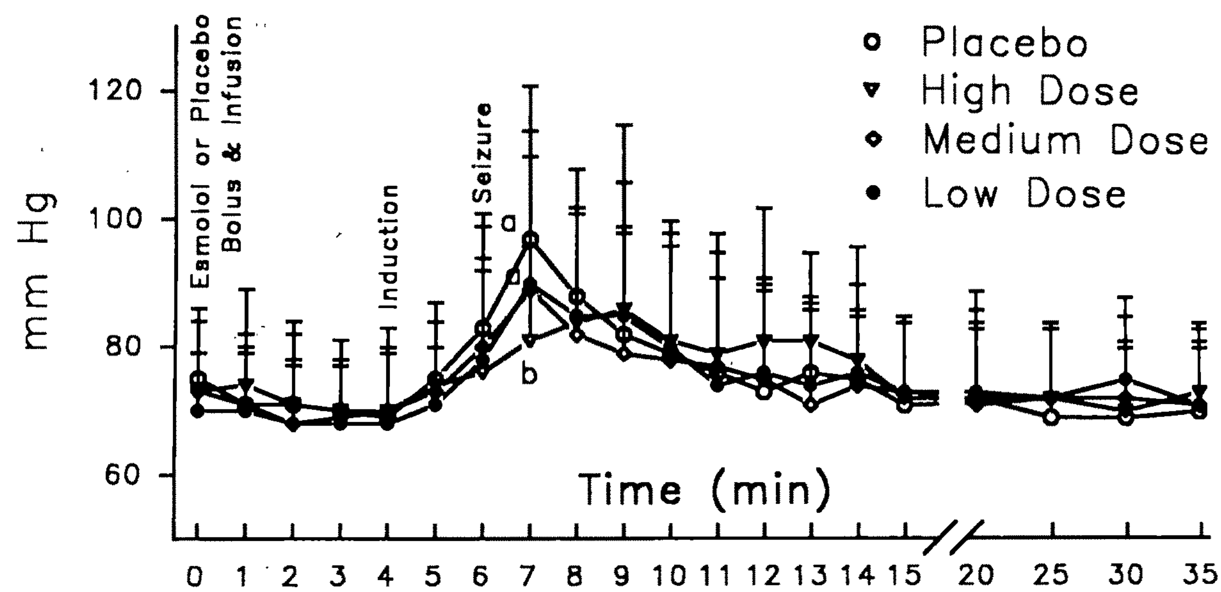

Figure 3. Mean values ± SD for diastolic arterial blood pressure (mm Hg) for all 20 patients given either placebo or esmolol at high dose (300 μg·kg^{-1}·min^{-1}), medium dose (200 μg·kg^{-1}·min^{-1}), and low dose (100 μg·kg^{-1}·min^{-1}) during electroconvulsive therapy. $^{a}P < 0.05$, significantly greater than their baseline. $^{b}P < 0.05$, significantly less than placebo diastolic blood pressure.

attenuating the hemodynamic changes of ECT when considering its effect on maximal HR and its ability to maintain arterial blood pressure at baseline levels. This dose does not appear to reduce the clinical or EEG-determined duration of seizure during ECT.

The effectiveness of premedication with β-adrenergic receptor blockers, especially esmolol, to attenuate the hemodynamic changes associated with ECT has been well documented. The application of any therapeutic technique in medicine requires careful evaluation of the benefits versus risks. As with any medical therapy, some effects are necessary for efficacy whereas others are superfluous.

Our placebo group yielded the characteristic pattern of ECT-associated hemodynamic changes: a marked tachycardia and increase in arterial blood

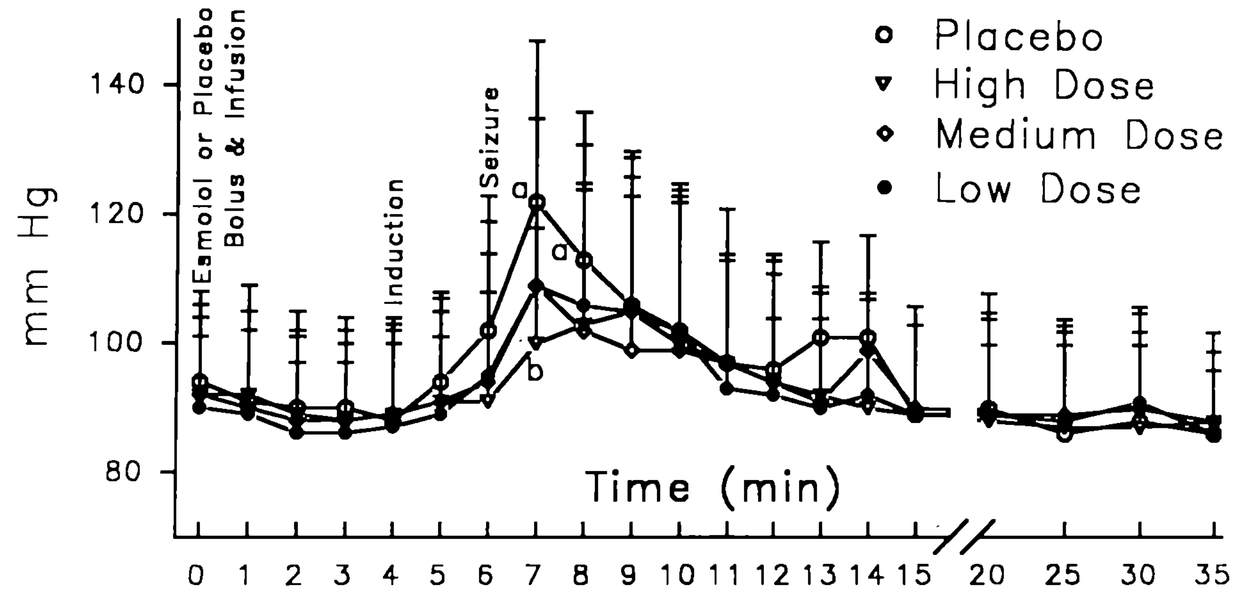

Figure 4. Mean values ± SD for mean arterial blood pressure (mm Hg) for all 20 patients given either placebo or esmolol at high dose (300 $\mu g \cdot kg^{-1} \cdot min^{-1}$), medium dose (200 $\mu g \cdot kg^{-1} \cdot min^{-1}$), and low dose (100 $\mu g \cdot kg^{-1} \cdot min^{-1}$) during electroconvulsive therapy. $^{a}P < 0.05$, significantly greater than placebo baseline. $^{b}P < 0.05$, significantly less than placebo mean blood pressure.

pressure beginning at seizure induction and persisting for several minutes. As was expected, in all three esmolol groups the HR decreased after the initiation of esmolol infusion until seizure initiation. After seizure initiation, however, the HR returned to baseline values and then remained there. There was no significant difference in HR among the low-dose, medium-dose, and high-dose esmolol groups.

Low-dose esmolol (i.e., a 500-μg/kg bolus dose followed by an infusion of 100 $\mu g \cdot kg^{-1} \cdot min^{-1}$) was just as effective in attenuating the tachycardia and hypertension of ECT as a medium-range or high-range dose of esmolol (i.e., a 500-μg/kg bolus dose followed by an infusion of 200 $\mu g \cdot kg^{-1} \cdot min^{-1}$ or 300 $\mu g \cdot kg^{-1} \cdot min^{-1}$). In addition, there was a significant decrease in clinically observed seizure duration (8 s) between the placebo group and the medium-dose esmolol and high-dose esmolol groups, but no significant difference between the seizure duration in the placebo and low-dose esmolol groups. This is supported by others giving bolus doses of esmolol at 1 mg/kg (6,16), 1.4 mg/kg (17), or 1.5 mg/kg (11) without shortening duration of seizure, whereas a bolus of 2.86 mg/kg (17) and a bolus and infusion to a total of 2.9 mg/kg (14) did significantly shorten the duration of seizure. The only conflicting report was by Kovac et al. (15), where a bolus and infusion to a total of 3.88 mg/kg did not significantly shorten duration of seizure. However, Kovac premedicated placebo and esmolol patients with 0.3 mg of glycopyrrolate, which reduced the placebo patients' duration of EEG-measured seizure to only 45 s, making any shortening of seizure duration by esmolol difficult to detect. Whether duration of seizure is a significant determinant of the effectiveness of ECT remains unresolved. It is prudent, therefore, to use the lowest dose of esmolol that reliably attenuates the undesired hemodynamic effects of ECT. This study demonstrates that infusion of esmolol at 100 $\mu g \cdot kg^{-1} \cdot min^{-1}$ after a bolus dose of 500 μg/kg is efficacious in blunting the hemodynamic response to ECT while not significantly changing the duration of the electrically induced seizure.

We thank Critikon, Inc. for the loan of a Dinamap model 1846 SX/P. We also thank medical students Peter Y. Kim, Robert Lee Cheng, Gregory Benson, Ami J. Wittenberg, Lisa K. Wise, Karen E. von Haam, and Lisa M. Egbert for their assistance in data collection. The medical students were recipients of Samuel J. Roessler Memorial Medical Research Scholarships.

"The duration of action of mivacurium defines a new class of non-depolarizing neuromuscular blocking drugs."p.397

Caldwell JE, Heier T, Kitts JB, Lynam DP, Fahey MR, Miller RD. Comparison of the neuromuscular block induced by mivacurium, suxamethonium or atracurium during nitrous oxide-fentanyl anaesthesia. *Br J Anaesth*. 1989;63:393-399.

Please see brief summaries for MIVACRON® (mivacurium chloride) and Tracrium® (atracurium besylate) following this ad.

MIVACRON®

The first and only shor

Duration of action and spontaneous recovery profile approximately one-third to one-half that of intermediate agents such as atracurium or vecuronium

Initial dose 0.15 mg/kg

Profound neuromuscular block

Recommended initial adult dose

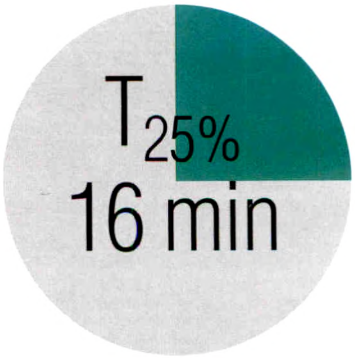
The recommended initial adult bolus dose of 0.15 mg/kg (administered over 5 to 15 seconds) provides profound neuromuscular block.

Intubation 2.5 min

Generally good to excellent intubating conditions

Useful for routine intubation

MIVACRON provides generally good to excellent intubating conditions in 2.5 minutes at a dose of 0.15 mg/kg. Succinylcholine remains the drug of choice for rapid sequence intubation.



Short duration of action

Well-suited for short procedures

Duration of clinically effective block (time to 25% recovery of T_1) following injection of 0.15 mg/kg is 16 minutes, making **M**IVACRON excellent for short procedures.[1]

from Burroughs Wellcome Co.

acting nondepolarizer

Reduce spontaneous recovery time by up to 50% *vs* vecuronium

	Duration of continuous infusion (min)	Recovery times (min)		
		Off-25%*	25-75%	5-95%
MIVACRON (n=25)	**86.2±5.6**	**5.7±0.3**	**6.4±0.2**	**13.6±0.6**
vecuronium (n=18)	96.8±6.6	12.7±1.3†	13.8±0.9‡	32.0±1.2‡§
atracurium (n=22)	91.3±2.9	12.5±0.6†	10.9±0.3†	26.6±0.4†

Adapted from Ali et al, p. 544.[2] *Time from discontinuation of infusion to 25% recovery. †P<0.01 atracurium or vecuronium vs **M**IVACRON; ‡P<0.001 vecuronium vs **M**IVACRON; §P<0.05 vecuronium vs atracurium.

Noncumulative

Continuous infusion of **M**IVACRON for up to 2.5 hours is not associated with the development of tachyphylaxis or cumulative neuromuscular blocking effects in ASA Physical Status I-II patients. Steady-state levels of block are rapidly achieved with minimal adjustment to the infusion rate. Limited data are available on **M**IVACRON (a mixture of three isomers) for infusions longer than 2.5 hours.

Savarese et al found...

Fast recovery following bolus or infusion

MIVACRON®

Up to half the duration;

Excellent cardiovascular profile at recommended doses

MIVACRON Initial Dose* (mg/kg)	% of patients with ≥30% change			
	MAP		HR	
	↓	↑	↓	↑
0.07 to 0.10	0%	2%	0%	0%
0.15	4%	4%	4%	2%
0.20†	30%	0%	0%	8%
0.25†	39%	2%	0%	14%

*During opioid/N_2O/O_2 anesthesia.

†Experimental dose, in excess of the maximum recommended dose of 0.15 mg/kg.

Minimal CV effects

At the recommended initial dose of 0.15 mg/kg, cardiovascular response to **M**IVACRON is minimal. Higher doses may produce effects associated with histamine release and may result in a decrease in blood pressure in some individuals. The incidence and magnitude of these hemodynamic changes are related to size of the dose and speed of the injection. In patients with clinically significant CV disease, the initial dose of **M**IVACRON should be administered over 60 seconds.

Metabolized by plasma cholinesterase

Like succinylcholine, **M**IVACRON should be used with caution in patients with reduced plasma cholinesterase activity. In patients heterozygous for the atypical plasma cholinesterase gene, clinically effective duration may be prolonged by approximately 10 minutes. Homozygous patients (1 in 2500) are *extremely sensitive* to **M**IVACRON. **M**IVACRON should be used with great caution, if at all, in homozygous patients.

However, unlike succinylcholine, once recovery has begun, **M**IVACRON can be reversed with conventional doses of neostigmine.

Individualization of dosages

- Significant CV disease
- Obesity
- Renal or hepatic disease
- History suggesting greater sensitivity to release of histamine or related mediators

from Burroughs Wellcome Co.

MIVACRON® INJECTION
MIVACRON® PREMIXED INFUSION
(MIVACURIUM CHLORIDE)

Brief Summary

This drug should be administered only by adequately trained individuals familiar with its actions, characteristics, and hazards.

INDICATIONS AND USAGE: MIVACRON is a short-acting neuromuscular blocking agent indicated for inpatients and outpatients, as an adjunct to general anesthesia, to facilitate tracheal intubation and to provide skeletal muscle relaxation during surgery or mechanical ventilation.

CONTRAINDICATIONS: MIVACRON is contraindicated in patients known to have an allergic hypersensitivity to mivacurium chloride or other benzylisoquinolinium agents, as manifested by reactions such as urticaria or severe respiratory distress or hypotension. Use of MIVACRON from multi-dose vials is contraindicated in patients with a known allergy to benzyl alcohol.

WARNINGS: MIVACRON SHOULD BE ADMINISTERED IN CAREFULLY ADJUSTED DOSAGE BY OR UNDER THE SUPERVISION OF EXPERIENCED CLINICIANS WHO ARE FAMILIAR WITH THE DRUG'S ACTIONS AND THE POSSIBLE COMPLICATIONS OF ITS USE. THE DRUG SHOULD NOT BE ADMINISTERED UNLESS PERSONNEL AND FACILITIES FOR RESUSCITATION AND LIFE SUPPORT (TRACHEAL INTUBATION, ARTIFICIAL VENTILATION, OXYGEN THERAPY), AND AN ANTAGONIST OF MIVACRON ARE IMMEDIATELY AVAILABLE. IT IS RECOMMENDED THAT A PERIPHERAL NERVE STIMULATOR BE USED TO MEASURE NEUROMUSCULAR FUNCTION DURING THE ADMINISTRATION OF MIVACRON IN ORDER TO MONITOR DRUG EFFECT, DETERMINE THE NEED FOR ADDITIONAL DRUG, AND CONFIRM RECOVERY FROM NEUROMUSCULAR BLOCK.

MIVACRON HAS NO KNOWN EFFECT ON CONSCIOUSNESS, PAIN THRESHOLD, OR CEREBRATION. TO AVOID DISTRESS TO THE PATIENT, NEUROMUSCULAR BLOCK SHOULD NOT BE INDUCED BEFORE UNCONSCIOUSNESS.

MIVACRON IS METABOLIZED BY PLASMA CHOLINESTERASE AND SHOULD BE USED WITH GREAT CAUTION, IF AT ALL, IN PATIENTS KNOWN TO BE OR SUSPECTED OF BEING HOMOZYGOUS FOR THE ATYPICAL PLASMA CHOLINESTERASE GENE.

MIVACRON Injection and MIVACRON Premixed Infusion are acidic (pH 3.5 to 5.0) and may not be compatible with alkaline solutions having a pH greater than 8.5 (*e.g.*, barbiturate solutions).

PRECAUTIONS:

General: Although MIVACRON (a mixture of three stereoisomers) is not a potent histamine releaser, the possibility of substantial histamine release must be considered. Release of histamine is related to the dose and speed of injection.

Caution should be exercised in administering MIVACRON to patients with clinically significant cardiovascular disease and patients with any history suggesting a greater sensitivity to the release of histamine or related mediators (*e.g.*, asthma). In such patients, the initial dose of MIVACRON should be 0.15 mg/kg or less, administered over 60 seconds; assurance of adequate hydration and careful monitoring of hemodynamic status are important (see **Hemodynamics** and **Individualization of Dosages** subsections of CLINICAL PHARMACOLOGY).

Obese patients may be more likely to experience clinically significant transient decreases in MAP than non-obese patients when the dose of MIVACRON is based on actual rather than ideal body weight. Therefore, in obese patients, the initial dose should be determined using the patient's ideal body weight (see **Hemodynamics** and **Individualization of Dosages** subsections of CLINICAL PHARMACOLOGY).

Recommended doses of MIVACRON have no clinically significant effects on heart rate; therefore, MIVACRON will not counteract the bradycardia produced by many anesthetic agents or by vagal stimulation.

Neuromuscular blocking agents may have a profound effect in patients with neuromuscular diseases (*e.g.*, myasthenia gravis and the myasthenic syndrome). In these and other conditions in which prolonged neuromuscular block is a possibility (*e.g.*, carcinomatosis), the use of a peripheral nerve stimulator and a dose of not more than 0.015–0.020 mg/kg MIVACRON is recommended to assess the level of neuromuscular block and to monitor dosage requirements (see **Individualization of Dosages** subsection of CLINICAL PHARMACOLOGY).

MIVACRON has not been studied in patients with burns. Resistance to nondepolarizing neuromuscular blocking agents may develop in patients with burns, depending upon the time elapsed since the injury and the size of the burn. Patients with burns may have reduced plasma cholinesterase activity which may offset this resistance (see **Individualization of Dosages** subsection of CLINICAL PHARMACOLOGY).

Acid-base and/or serum electrolyte abnormalities may potentiate or antagonize the action of neuromuscular blocking agents. The action of neuromuscular blocking agents may be enhanced by magnesium salts administered for the management of toxemia of pregnancy (see **Individualization of Dosages** subsection of CLINICAL PHARMACOLOGY).

No data are available to support the use of MIVACRON by intramuscular injection.

Renal and Hepatic Disease: The possibility of prolonged neuromuscular block must be considered when MIVACRON is used in patients with renal or hepatic disease (see **Pharmacokinetics** subsection of CLINICAL PHARMACOLOGY). Most patients with chronic hepatic disease such as hepatitis, liver abscess, and cirrhosis of the liver exhibit a marked reduction in plasma cholinesterase activity. Patients with acute or chronic renal disease may also show a reduction in plasma cholinesterase activity (see **Individualization of Dosages** subsection of CLINICAL PHARMACOLOGY).

Reduced Plasma Cholinesterase Activity: The possibility of prolonged neuromuscular block following administration of MIVACRON must be considered in patients with reduced plasma cholinesterase (pseudocholinesterase) activity.

Plasma cholinesterase activity may be diminished in the presence of genetic abnormalities of plasma cholinesterase (*e.g.*, patients heterozygous or homozygous for the atypical plasma cholinesterase gene), pregnancy, liver or kidney disease, malignant tumors, infections, burns, anemia, decompensated heart disease, peptic ulcer, or myxedema. Plasma cholinesterase activity may also be diminished by chronic administration of oral contraceptives, glucocorticoids, or certain monoamine oxidase inhibitors and by irreversible inhibitors of plasma cholinesterase (*e.g.*, organophosphate insecticides, echothiophate, and certain antineoplastic drugs).

MIVACRON has been used safely in patients heterozygous for the atypical plasma cholinesterase gene. At doses of 0.10 to 0.20 mg/kg MIVACRON, the clinically effective duration of action was 8 to 11 minutes longer in patients heterozygous for the atypical gene than in genotypically normal patients.

As with succinylcholine, patients homozygous for the atypical plasma cholinesterase gene (1 in 2500 patients) are extremely sensitive to the neuromuscular blocking effect of MIVACRON. In three such adult patients, a small dose of 0.03 mg/kg (approximately the ED_{10-20} in genotypically normal patients) produced complete neuromuscular block for 26 to 128 minutes. Once spontaneous recovery had begun, neuromuscular block in these patients was antagonized with conventional doses of neostigmine. One adult patient, who was homozygous for the atypical plasma cholinesterase gene, received a dose of 0.18 mg/kg MIVACRON and exhibited complete neuromuscular block for about 4 hours. Response to post-tetanic stimulation was present after 4 hours, all four responses to train-of-four stimulation were present after 6 hours, and the patient was extubated after 8 hours. Reversal was not attempted in this patient.

Malignant Hyperthermia (MH): In a study of MH-susceptible pigs, MIVACRON did not trigger MH. MIVACRON has not been studied in MH-susceptible patients. Because MH can develop in the absence of established triggering agents, the clinician should be prepared to recognize and treat MH in any patient undergoing general anesthesia.

Long-Term Use in the Intensive Care Unit (ICU): No data are available on the long-term use of MIVACRON in patients undergoing mechanical ventilation in the ICU.

Drug Interactions: Although MIVACRON (a mixture of three stereoisomers) has been administered safely following succinylcholine-facilitated tracheal intubation, the interaction between the stereoisomers in MIVACRON and succinylcholine has not been systematically studied. Prior administration of succinylcholine can potentiate the neuromuscular blocking effects of nondepolarizing agents. Evidence of spontaneous recovery from succinylcholine should be observed before the administration of MIVACRON.

The use of MIVACRON before succinylcholine to attenuate some of the side effects of succinylcholine has not been studied.

There are no clinical data on the use of MIVACRON with other nondepolarizing neuromuscular blocking agents.

Isoflurane and enflurane (administered with nitrous oxide/oxygen to achieve 1.25 MAC) decrease the ED_{50} of MIVACRON by as much as 25% (see **Pharmacodynamics** and **Individualization of Dosages** subsections of CLINICAL PHARMACOLOGY). These agents may also prolong the clinically effective duration of action and decrease the average infusion requirement of MIVACRON by as much as 35% to 40%. A greater potentiation of the neuromuscular blocking effects of the stereoisomers in MIVACRON may be expected with higher concentrations of enflurane or isoflurane. Halothane has little or no effect on the ED_{50}, but may prolong the duration of action and decrease the average infusion requirement by as much as 20%.

Other drugs which may enhance the neuromuscular blocking action of nondepolarizing agents such as the stereoisomers in MIVACRON include certain antibiotics (*e.g.*, aminoglycosides, tetracyclines, bacitracin, polymyxins, lincomycin, clindamycin, colistin, and sodium colistimethate), magnesium salts, lithium, local anesthetics, procainamide, and quinidine. Drugs that may enhance the neuromuscular blocking effects of mivacurium by a reduction in plasma cholinesterase activity include chronic administration of oral contraceptives, glucocorticoids, or certain monoamine oxidase inhibitors and by irreversible inhibitors of plasma cholinesterase (see **Reduced Plasma Cholinesterase Activity** subsection of PRECAUTIONS).

Resistance to the neuromuscular blocking action of nondepolarizing neuromuscular blocking agents has been demonstrated in patients chronically administered phenytoin or carbamazepine. While the effects of chronic phenytoin or carbamazepine therapy on the action of the stereoisomers in MIVACRON are unknown, slightly shorter durations of neuromuscular block may be anticipated and infusion rate requirements may be higher.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Carcinogenesis and fertility studies have not been performed. MIVACRON was evaluated in a battery of four short-term mutagenicity tests. It was non-mutagenic in the Ames Salmonella assay, the mouse lymphoma assay, the human lymphocyte assay, and the *in vivo* rat bone marrow cytogenetic assay.

Pregnancy: *Teratogenic Effects*: Pregnancy Category C. Teratology testing in nonventilated pregnant rats and mice treated subcutaneously with maximum subparalyzing doses of MIVACRON revealed no maternal or fetal toxicity or teratogenic effects. There are no adequate and well-controlled studies of MIVACRON in pregnant women. Because animal studies are not always predictive of human response, and the doses used were subparalyzing, MIVACRON should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Labor and Delivery: The use of MIVACRON during labor, vaginal delivery, or cesarean section has not been studied in humans and it is not known whether MIVACRON administered to the mother has effects on the fetus. Doses of 0.08 and 0.20 mg/kg MIVACRON given to female beagles undergoing cesarean section resulted in negligible levels of the stereoisomers in MIVACRON in umbilical vessel blood of neonates and no deleterious effects on the puppies.

Nursing Mothers: It is not known whether any of the stereoisomers of mivacurium are excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised following administration of MIVACRON to a nursing woman.

Pediatric Use: MIVACRON has not been studied in children below the age of 2 years (see CLINICAL PHARMACOLOGY and DOSAGE AND ADMINISTRATION for clinical experience and recommendations for use in children 2 to 12 years of age).

Geriatric Use: MIVACRON was safely administered during clinical trials to 64 elderly (≥65 years) patients, including 31 patients with significant cardiovascular disease (see **General** subsection of PRECAUTIONS). The duration of neuromuscular block may be slightly longer in elderly patients than in young adult patients (see CLINICAL PHARMACOLOGY).

ADVERSE REACTIONS:

Observed in Clinical Trials: MIVACRON (a mixture of three stereoisomers) was well tolerated during extensive clinical trials in inpatients and outpatients. Prolonged neuromuscular block, which is an important adverse experience associated with neuromuscular blocking agents as a class, was reported as an adverse experience in 3 of 2074 patients administered MIVACRON. The most commonly reported adverse experience following the administration of MIVACRON was transient, dose-dependent cutaneous flushing about the face, neck, and/or chest. Flushing was most frequently noted after the initial dose of MIVACRON and was reported in about 20% of adult patients who received the recommended dose of 0.15 mg/kg MIVACRON over 5 to 15 seconds. When present, flushing typically began within 1 to 2 minutes after the dose of MIVACRON and lasted for 3 to 5 minutes. Of 60 patients who experienced flushing after 0.15 mg/kg MIVACRON, one patient also experienced mild hypotension that was not treated, and one patient experienced moderate wheezing that was successfully treated.

Overall, hypotension was infrequently reported as an adverse experience in the clinical trials of MIVACRON. None of the 397 adults or 63 children who received recommended doses was treated for a decrease in blood pressure associated with the administration of MIVACRON. Above the recommended dosage range, 1% to 2% of healthy adults given ≥0.20 mg/kg over 5 to 15 seconds and 2% to 4% of cardiac surgery patients given ≥0.20 mg/kg over 60 seconds were treated for decreases in blood pressure associated with the administration of MIVACRON.

The following adverse experiences were reported in patients administered MIVACRON (all events judged by investigators during the clinical trials to have a possible causal relationship):

Incidence Greater Than 1% -

Cardiovascular:	Flushing (15%)

Incidence Less Than 1% -

Cardiovascular:	Hypotension, Tachycardia, Bradycardia, Cardiac Arrhythmia, Phlebitis
Respiratory:	Bronchospasm, Wheezing, Hypoxemia
Dermatological:	Rash, Urticaria, Erythema, Injection Site Reaction
Nonspecific:	Prolonged Drug Effect
Neurologic:	Dizziness
Musculoskeletal:	Muscle Spasms

OVERDOSAGE: Overdosage with neuromuscular blocking agents may result in neuromuscular block beyond the time needed for surgery and anesthesia. The primary treatment is maintenance of a patent airway and controlled ventilation until recovery of normal neuromuscular function is assured. Once evidence of recovery from neuromuscular block is observed, further recovery may be facilitated by administration of an anticholinesterase agent (*e.g.*, neostigmine, edrophonium) in conjunction with an appropriate anticholinergic agent. (see **Antagonism of Neuromuscular Block**). Overdosage may increase the risk of hemodynamic side effects, especially decreases in blood pressure. If needed, cardiovascular support may be provided by proper positioning of the patient, fluid administration, and/or vasopressor agent administration.

Antagonism of Neuromuscular Block:

ANTAGONISTS (SUCH AS NEOSTIGMINE) SHOULD NOT BE ADMINISTERED WHEN COMPLETE NEUROMUSCULAR BLOCK IS EVIDENT OR SUSPECTED. THE USE OF A PERIPHERAL NERVE STIMULATOR TO EVALUATE RECOVERY AND ANTAGONISM OF NEUROMUSCULAR BLOCK IS RECOMMENDED.

Administration of 0.030 to 0.064 mg/kg neostigmine or 0.5 mg/kg edrophonium at approximately 10% recovery from neuromuscular block (range: 1 to 15) produced 95% recovery of the muscle twitch response and a T_4/T_1 ratio ≥75% in about 10 minutes. The times from 25% recovery of the muscle twitch response to T_4/T_1 ratio ≥75% following these doses of antagonists averaged about 7 to 9 minutes. In comparison, average times for spontaneous recovery from 25% to T_4/T_1 ≥75% were 12 to 13 minutes.

Patients administered antagonists should be evaluated for adequate clinical evidence of antagonism, *e.g.*, 5-second head lift and grip strength. Ventilation must be supported until no longer required.

Antagonism may be delayed in the presence of debilitation, carcinomatosis, and the concomitant use of certain broad spectrum antibiotics, or anesthetic agents and other drugs which enhance neuromuscular block or separately cause respiratory depression (see **Drug Interactions** subsection of PRECAUTIONS). Under such circumstances the management is the same as that of prolonged neuromuscular block (see OVERDOSAGE).

DOSAGE AND ADMINISTRATION: MIVACRON SHOULD ONLY BE ADMINISTERED INTRAVENOUSLY.

The dosage information provided below is intended as a guide only. Doses of MIVACRON should be individualized (see **Individualization of Dosages** subsection of CLINICAL PHARMACOLOGY). Factors that may warrant dosage adjustment include but may not be limited to: the presence of significant kidney, liver, or cardiovascular disease, obesity (patients weighing ≥30% more than ideal body weight for height), asthma, reduction in plasma cholinesterase activity, and the presence of inhalational anesthetic agents. The use of a peripheral nerve stimulator will permit the most advantageous use of MIVACRON, minimize the possibility of overdosage or underdosage, and assist in the evaluation of recovery.

Adults:

Initial Doses:

A dose of 0.15 mg/kg MIVACRON administered over 5 to 15 seconds is recommended for facilitation of tracheal intubation for most patients. When administered as a component of a thiopental/opioid/nitrous oxide/oxygen induction-intubation technique, 0.15 mg/kg (2 x ED_{95}) MIVACRON produces generally good-to-excellent conditions for tracheal intubation in 2.5 minutes. Lower doses of MIVACRON may result in a longer time for development of satisfactory intubation conditions. Administration of MIVACRON doses above the recommended range (≥0.20 mg/kg) is associated with the development of transient decreases in blood pressure in some patients (see CLINICAL PHARMACOLOGY and ADVERSE REACTIONS).

STORAGE: Store MIVACRON Injection at room temperature of 15° to 25°C (59° to 77°F). Avoid exposure to direct ultraviolet light. DO NOT FREEZE.

Recommended storage for MIVACRON Premixed Infusion is room temperature (15° to 25°C/59° to 77°F). Avoid excessive heat. Avoid exposure to direct ultraviolet light. Protect from freezing.

TRACRIUM® INJECTION

(atracurium besylate)

Brief Summary

This drug should be used only by adequately trained individuals familiar with its actions, characteristics, and hazards.

INDICATIONS AND USAGE: Tracrium is indicated, as an adjunct to general anesthesia, to facilitate endotracheal intubation and to provide skeletal muscle relaxation during surgery or mechanical ventilation.

CONTRAINDICATIONS: Tracrium is contraindicated in patients known to have a hypersensitivity to it.

WARNINGS: TRACRIUM SHOULD BE USED ONLY BY THOSE SKILLED IN AIRWAY MANAGEMENT AND RESPIRATORY SUPPORT. EQUIPMENT AND PERSONNEL MUST BE IMMEDIATELY AVAILABLE FOR ENDOTRACHEAL INTUBATION AND SUPPORT OF VENTILATION, INCLUDING ADMINISTRATION OF POSITIVE PRESSURE OXYGEN. ADEQUACY OF RESPIRATION MUST BE ASSURED THROUGH ASSISTED OR CONTROLLED VENTILATION. ANTICHOLINESTERASE REVERSAL AGENTS SHOULD BE IMMEDIATELY AVAILABLE. DO NOT GIVE TRACRIUM BY INTRAMUSCULAR ADMINISTRATION. Tracrium has no known effect on consciousness, pain threshold, or cerebration. It should be used only with adequate anesthesia. Tracrium Injection, which has an acid pH, should not be mixed with alkaline solutions (e.g., barbiturate solutions) in the same syringe or administered simultaneously during intravenous infusion through the same needle. Depending on the resultant pH of such mixtures, Tracrium may be inactivated and a free acid may be precipitated. Tracrium Injection 10 mL multiple dose vials contain benzyl alcohol. Benzyl alcohol has been associated with an increased incidence of neurological and other complications in newborn infants which are sometimes fatal. Tracrium Injection 5 mL single use vials do not contain benzyl alcohol.

PRECAUTIONS: General: Although Tracrium is a less potent histamine releaser than d-tubocurarine or metocurine, the possibility of substantial histamine release in sensitive individuals must be considered. Special caution should be exercised in administering Tracrium to patients in whom substantial histamine release would be especially hazardous (e.g., patients with clinically significant cardiovascular disease) and in patients with any history (e.g., severe anaphylactoid reactions or asthma) suggesting a greater risk of histamine release. In these patients, the recommended initial Tracrium dose is lower (0.3 to 0.4 mg/kg) than for other patients and should be administered slowly or in divided doses over one minute. Since Tracrium has no clinically significant effects on heart rate in the recommended dosage range, it will not counteract the bradycardia produced by many anesthetic agents or vagal stimulation. As a result, bradycardia during anesthesia may be more common with Tracrium than with other muscle relaxants. Tracrium may have profound effects in patients with myasthenia gravis, Eaton-Lambert syndrome, or other neuromuscular diseases in which potentiation of nondepolarizing agents has been noted. The use of a peripheral nerve stimulator is especially important for assessing neuromuscular blockade in these patients. Similar precautions should be taken in patients with severe electrolyte disorders or carcinomatosis. Multiple factors in anesthesia practice are suspected of triggering malignant hyperthermia (MH), a potentially fatal hypermetabolic state of skeletal muscle. Halogenated anesthetic agents and succinylcholine are recognized as the principal pharmacologic triggering agents in MH-susceptible patients; however, since MH can develop in the absence of established triggering agents, the clinician should be prepared to recognize and treat MH in any patient scheduled for general anesthesia. Reports of MH have been rare in cases in which Tracrium has been used. In studies of MH-susceptible animals (swine) and in a clinical study of MH-susceptible patients, Tracrium did not trigger this syndrome. Resistance to nondepolarizing neuromuscular blocking agents may develop in burn patients. Increased doses of nondepolarizing muscle relaxants may be required in burn patients and are dependent on the time elapsed since the burn injury and the size of the burn. The safety of Tracrium has not been established in patients with bronchial asthma. **Long-Term Use in Intensive Care Unit (ICU):** Tracrium has been used to facilitate mechanical ventilation in ICU patients. When there is a need for long-term mechanical ventilation, the benefits to risk ratio of neuromuscular blockade must be considered. There is only limited information on the efficacy and safety of Tracrium administered by long-term (days to weeks) intravenous infusion to facilitate mechanical ventilation in intensive care facilities. For Tracrium, as with other neuromuscular blocking agents used in intensive care facilities, available evidence suggests that there is wide interpatient variability in dosage requirements and that these requirements may change with time. Limited data suggest that Tracrium infusion requirements may increase with prolonged administration in the ICU. As with other neuromuscular blocking agents, little information is available on the plasma levels or clinical consequences of atracurium metabolites following long-term (days to weeks) infusion of Tracrium in the intensive care unit setting. One metabolite of atracurium, laudanosine, when administered alone to laboratory animals, has been associated with cerebral excitatory effects. Physiological effects of laudanosine in humans have not been demonstrated. The effects of hemodialysis, hemoperfusion and hemofiltration on plasma levels of atracurium and its metabolites are unknown. **Drug Interactions:** Drugs which may enhance neuromuscular blocking action of Tracrium include: enflurane; isoflurane; halothane; certain antibiotics, especially the aminoglycosides and polymyxins; lithium; magnesium salts; procainamide; and quinidine. If other muscle relaxants are used during the same procedure, the possibility of a synergistic or antagonist effect should be considered. The prior administration of succinylcholine does not enhance the duration, but quickens the onset and may increase the depth, of neuromuscular blockade induced by Tracrium. Tracrium should not be administered until a patient has recovered from succinylcholine-induced neuromuscular blockade. **Carcinogenesis, Mutagenesis, Impairment of Fertility:** A positive response was observed in the mouse lymphoma assay under conditions which killed over 80% of the treated cells. A far weaker response was observed in the presence of metabolic activation at concentrations which also killed over 80% of the treated cells. **Pregnancy: *Teratogenic Effects:*** Pregnancy Category C. Tracrium has been shown to be potentially teratogenic in rabbits, when given in doses up to approximately one-half the human dose. There are no adequate and well-controlled studies in pregnant women. Tracrium should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus. **Labor and Delivery:** It is not known whether muscle relaxants administered during vaginal delivery have immediate or delayed adverse effects on the fetus or increase the likelihood that resuscitation of the newborn will be necessary. The possibility that forceps delivery will be necessary may increase. Tracrium (0.3 mg/kg) has been administered to 26 pregnant women during delivery by cesarean section. No harmful effects were attributable to Tracrium in any of the newborn infants, although small amounts of Tracrium were shown to cross the placental barrier. The possibility of respiratory depression in the newborn infant should always be considered following cesarean section during which a neuromuscular blocking agent has been administered. In patients receiving magnesium sulfate, the reversal of neuromuscular blockade may be unsatisfactory and Tracrium dose should be lowered as indicated. **Nursing Mothers:** It is not known whether this drug is excreted in human milk. Caution should be exercised when Tracrium is administered to a nursing woman. **Pediatric Use:** Safety and effectiveness in children below the age of 1 month have not been established.

ADVERSE REACTIONS: Observed in Controlled Clinical Studies: Tracrium produced few adverse reactions during extensive clinical trials. Most were suggestive of histamine release (see Precautions Section). The overall incidence rate for clinically important adverse reactions was 7/875 or 0.8%. Most adverse reactions were of little clinical significance unless they were associated with significant hemodynamic changes. Substantial vital sign changes greater than or equal to 30% observed in 530 patients, without cardiovascular disease, were as follows: In those patients given the recommended initial dosage range of 0.31 to 0.50 mg/kg of Tracrium, mean arterial pressure increased in 2.8% and decreased in 2.1% of patients while the heart rate increased in 2.8% of these patients. At doses of ≥ 0.60 mg/kg, 14.3% of the studied patients had a decrease in mean arterial pressure while 4.8% had an increase in heart rate. At doses ≤ 0.30 mg/kg, mean arterial pressure increased in 1.9% and decreased in 1.1% of patients, while heart rate increased in 1.6% and decreased in 0.8% of these patients. **Observed in Clinical Practice:** Based on clinical experience in the U.S. and the United Kingdom of approximately 3 million patients given Tracrium the following adverse reactions are among the most frequently reported: *General:* allergic reactions (anaphylactic or anaphylactoid) which, in rare instances, were severe (e.g., cardiac arrest); *Musculoskeletal:* inadequate, prolonged block; *Cardiovascular:* hypotension, vasodilatation (flushing), tachycardia, bradycardia; *Respiratory:* dyspnea, bronchospasm, laryngospasm; *Integumentary:* rash, urticaria, injection site reaction.

STORAGE: Tracrium Injection should be refrigerated at 2° to 8° C (36° to 46° F) to preserve potency. DO NOT FREEZE. Upon removal from refrigeration to room temperature storage conditions (25°C/77°F), use Tracrium Injection within 14 days even if rerefrigerated.

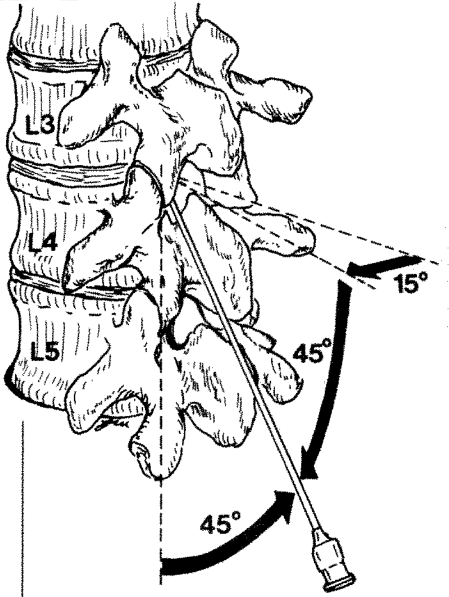
Wouldn't it be helpful to have a book that mirrors the way obstetricians speak?

...and the way you practice?

OBSTETRIC ANESTHESIA

By Mark C. Norris, MD
of Thomas Jefferson University Hospital,
Philadelphia, PA.
With 54 Contributors.

NEW!



Pre, Peri, and Post

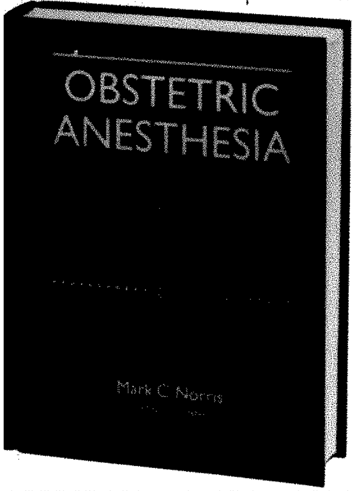
OBSTETRIC ANESTHESIA approaches this specialty the same way you approach a patient...

☑ FIRST,

Preoperative Evaluation

provides you with the background information you need to...

- evaluate and prepare the healthy *and* the high-risk parturient for anesthesia.
- conduct a routine fetal evaluation and surveillance.
- diagnose and manage in utero anomalies and complications.



...and, most importantly, you'll find explanations for why a given course of action is appropriate, *and* why another is not.

☑ SECOND,

Perioperative Management

focuses on anesthetic planning and management of the parturient throughout gestation and into the postpartum period.

☑ THIRD,

Postoperative Care

reviews postoperative analgesia and the complications that can arise after anesthesia.

You'll also find significant coverage of obstetrics and the concerns and language common to the anesthesiologist and the obstetrician.

About 928 Pages. 276 Illustrations. 169 Tables. 1992. (ISBN-0-397-51115-9) $95.00.

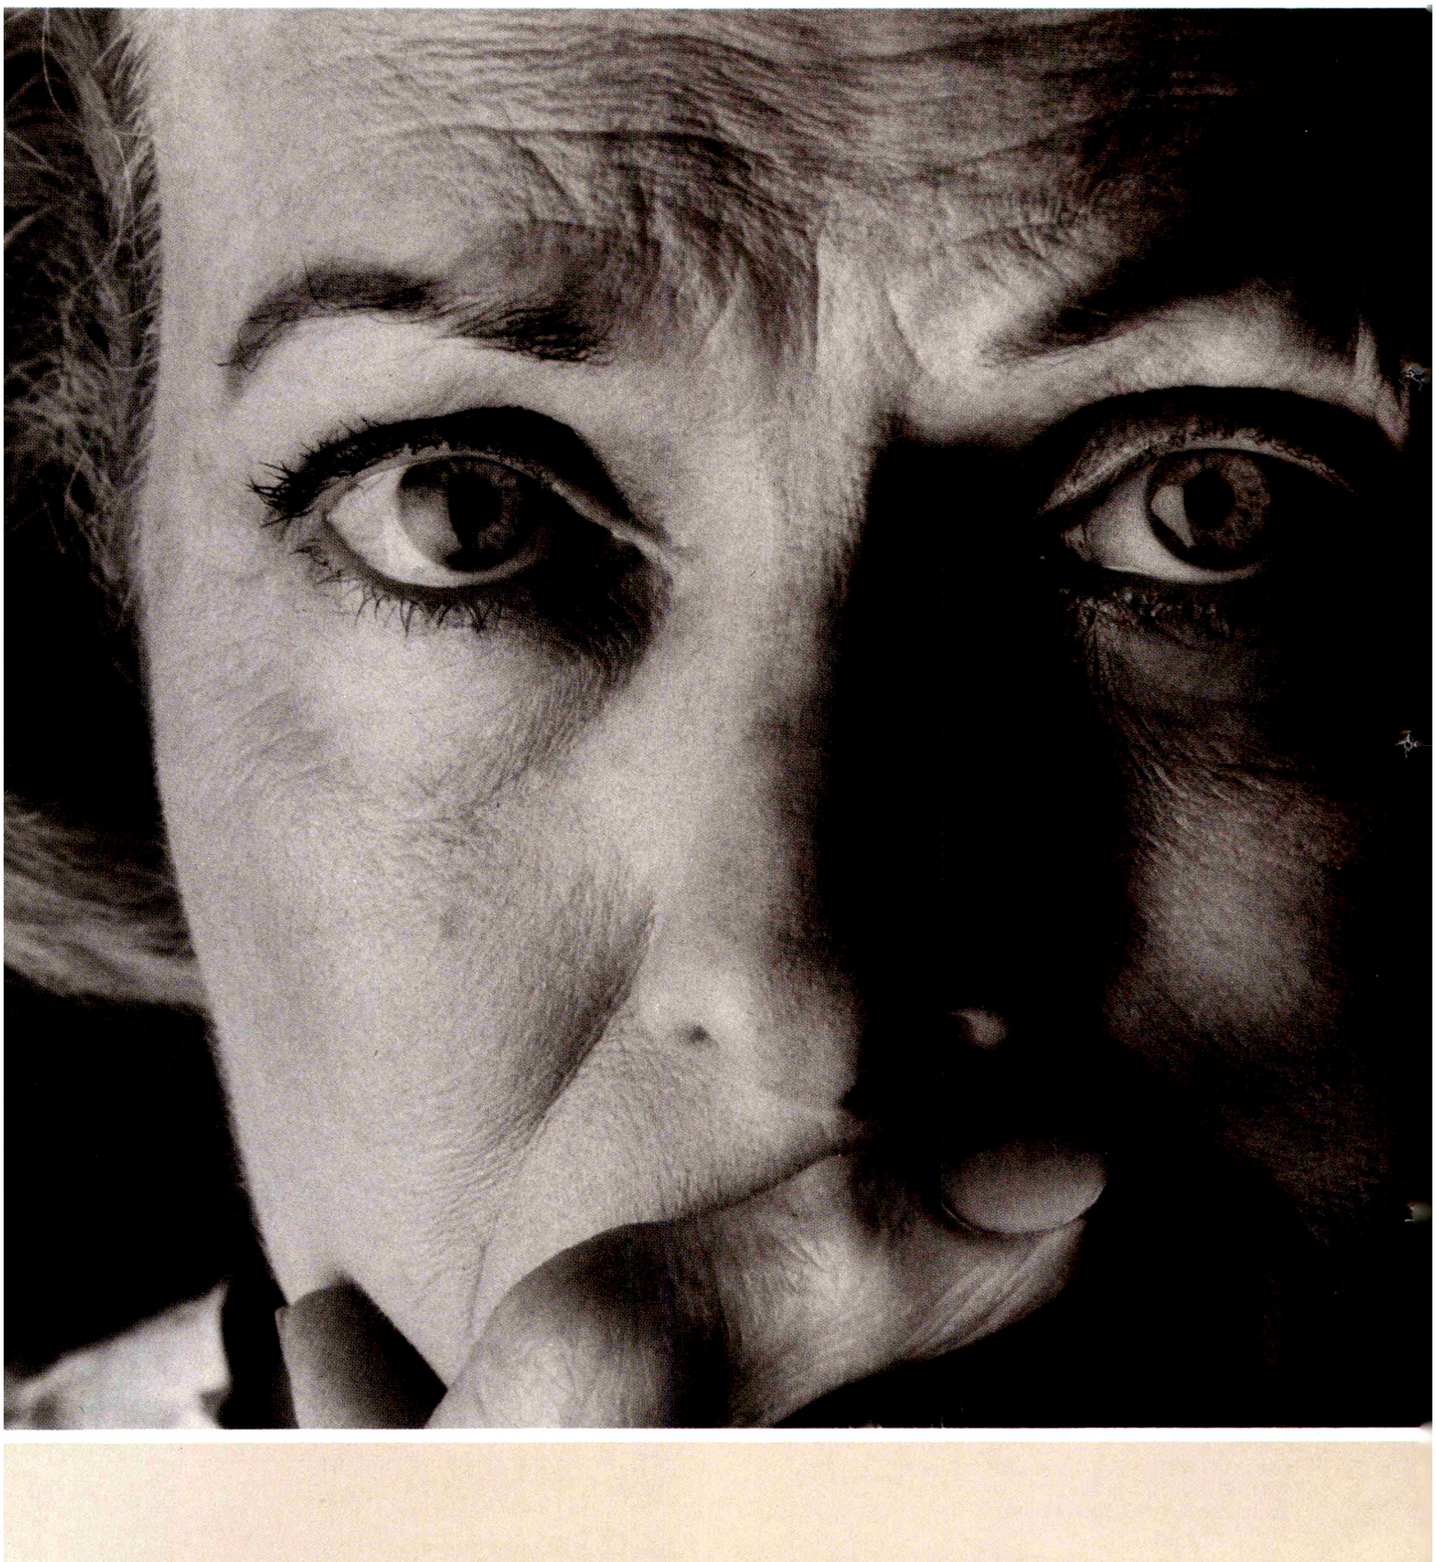
Doctor, I'm concerned about blood products. Is there something else you can use?"



In plasma volume expansion

YES!

Hespan®

(6% hetastarch in 0.9% sodium chloride injection)

Derived from corn, not blood...no risk of serum-transmitted diseases with HESPAN®

HESPAN® is derived from a waxy starch consisting almost entirely of amylopectin.[1] Consequently, there is no risk of serum-transmitted diseases, such as HIV or hepatitis, with HESPAN®.[2] Furthermore, HESPAN® is as effective as albumin for plasma volume expansion.[2,3]

Flexible bag, conveniently packaged for easy access and storage...won't shatter like glass

HESPAN® is packaged in a lightweight plastic bag. The compact, sturdy bag can be stored easily, retrieved quickly, and is designed for convenient setup and infusion.

For more information about HESPAN®, please call **1-800-543-8693.**

Hespan®

(6% Hetastarch in 0.9% Sodium Chloride Injection)
BRIEF SUMMARY

CONTRAINDICATIONS

HESPAN is contraindicated in patients with known hypersensitivity to hydroxyethyl starch, or with bleeding disorders, or with congestive heart failure where volume overload is a potential problem. HESPAN should not be used in renal disease with oliguria or anuria not related to hypovolemia.

WARNINGS

Usage in Plasma Volume Expansion: Large volumes may alter the coagulation mechanism. Thus, administration of HESPAN may result in transient prolongation of prothrombin, partial thromboplastin and clotting times. With administration of large doses, the physician should also be alert to the possibility of transient prolongation of bleeding time.

Hematocrit may be decreased and plasma proteins diluted excessively by administration of large volumes of HESPAN. Administration of packed red cells, platelets, and fresh frozen plasma should be considered if excessive dilution occurs.

Use over extended periods: HESPAN has not been adequately evaluated to establish its safety in situations other than leukapheresis that require frequent use of colloidal solutions over extended periods. Certain conditions may affect the safe use of HESPAN on a chronic basis. For example, in patients with subarachnoid hemorrhage where HESPAN is used repeatedly over a period of days for the prevention of cerebral vasospasm, significant clinical bleeding may occur.

Usage in Leukapheresis: Slight declines in platelet counts and hemoglobin levels have been observed in donors undergoing repeated leukapheresis procedures using HESPAN due to the volume expanding effects of HESPAN and to the collection of platelets and erythrocytes. Hemoglobin levels usually return to normal within 24 hours. Hemodilution by HESPAN and saline may also result in 24 hour declines of total protein, albumin, calcium and fibrinogen values. None of these decreases are to a degree recognized to be clinically significant risks to healthy donors.

PRECAUTIONS

General: Regular and frequent clinical evaluation and complete blood counts (CBC) are necessary for proper monitoring of HESPAN® (6% hetastarch in 0.9% sodium chloride injection) use during leukapheresis. If the frequency of leukapheresis is to exceed the guidelines for whole blood donation, you may wish to consider the following additional studies: total leukocyte and platelet counts, leukocyte differential count, hemoglobin and hematocrit, prothrombin time (PT), and partial thromboplastin time (PTT) tests.

The possibility of circulatory overload should be kept in mind. Caution should be used when the risk of pulmonary edema and/or congestive heart failure is increased. Special care should be exercised in patients who have impaired renal clearance since this is the principal way in which hetastarch is eliminated.

Indirect bilirubin levels of 8.3 mg/L (normal 0.0 –7.0 mg/L) have been reported in 2 out of 20 normal subjects who received multiple HESPAN infusions. Total bilirubin was within normal limits at all times; indirect bilirubin returned to normal by 96 hours following the final infusion. The significance, if any, of these elevations is not known; however, caution should be observed before administering HESPAN to patients with a history of liver disease.

HESPAN has been reported to produce hypersensitivity reactions such as wheezing and urticaria. However, hetastarch has not been observed to stimulate antibody formation. If hypersensitivity effects occur, they are readily controlled by discontinuation of the drug and, if necessary, administration of an antihistaminic agent.

Elevated serum amylase levels may be observed temporarily following administration of HESPAN, although no association with pancreatitis has been demonstrated.

If administration is by pressure infusion, all air should be withdrawn or expelled from the bag through the medication port prior to infusion.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term studies of animals have not been performed to evaluate the carcinogenic potential of hetastarch.

Teratogenic Effects: Pregnancy Category C. Animal reproduction studies have not been conducted with HESPAN. It is also not known whether HESPAN can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. HESPAN should be given to a pregnant woman only if clearly needed.

Nursing Mothers: It is not known whether hetastarch is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when HESPAN is administered to a nursing woman.

Pediatrics: The safety and effectiveness of HESPAN in children have not been established.

ADVERSE REACTIONS

The following have been reported: vomiting, fever, chills, pruritus, submaxillary and parotid glandular enlargement, mild influenza-like symptoms, headaches, muscle pains, peripheral edema of the lower extremities, anaphylactoid reactions (periorbital edema, urticaria, wheezing), bleeding due to hemodilution (see *Warnings*), and circulatory overload and pulmonary edema (see *Precautions*).

DOSAGE AND ADMINISTRATION

Dosage for Acute Use in Plasma Volume Expansion: HESPAN® (6% hetastarch in 0.9% sodium chloride injection) is administered by intravenous infusion only. Total dosage and rate of infusion depend upon the amount of blood or plasma lost and the resultant hemoconcentration. In adults, the amount usually administered is 500 to 1000 mL. Doses of more than 1500 mL per day for the typical 70 kg patient (approximately 20 mL per kg of body weight) are usually not required, although higher doses have been reported in postoperative and trauma patients where severe blood loss has occurred.

Dosage in Leukapheresis: 250 to 700 mL of HESPAN to which citrate anticoagulant has been added is typically administered by aseptic addition to the input line of the centrifugation apparatus at a ratio of 1:8 to 1:13 to venous whole blood. The HESPAN and citrate should be thoroughly mixed to assure effective anticoagulation of blood as it flows through the leukapheresis machine.

Do not use plastic container in series connection.

If administration is controlled by a pumping device, care must be taken to discontinue pumping action before the container runs dry or air embolism may result.

This solution is intended for intravenous administration using sterile equipment. It is recommended that intravenous administration apparatus be replaced at least once every 24 hours.

Use only if solution is clear and container and seals are intact.

The safety and compatibility of other additives have not been established.

Parenteral drug products should be inspected for particulate matter and discoloration prior to administration whenever solution and container permit.

If administration is by pressure infusion, all air should be withdrawn or expelled from the bag through the medication port prior to infusion.

HOW SUPPLIED

HESPAN® (6% hetastarch in 0.9% sodium chloride injection) is supplied sterile and nonpyrogenic in 500 mL EXCEL® Containers packaged 12 per case (NDC 0056-0037-46).

Exposure of pharmaceutical products to heat should be minimized. Avoid excessive heat. Protect from freezing. It is recommended that the product be stored at room temperature (25°C); however, brief exposure up to 40°C does not adversely affect the product.

CAUTION

Federal (USA) law prohibits dispensing without prescription.

To Open

Tear overwrap down at notch and remove solution container. Check for minute leaks by squeezing solution container firmly. If leaks are found, discard solution as sterility may be impaired.

Invert container and carefully inspect the solution in good light for cloudiness, haze, or particulate matter. Any container which is suspect should not be used.

ACADEMIC TRAUMA ANESTHESIOLOGIST

The Department of Anesthesiology of the University of Miami School of Medicine/Jackson Memorial Hospital is seeking a sixth member to join the Division of Trauma Anesthesia which provides clinical anesthesia care in the Ryder Trauma Center. This state-of-the-art, recently opened, free standing, level 1 trauma facility is one of the largest, most comprehensive trauma centers in the world.
The successful candidate will be involved in all aspects of Trauma Anesthesia including teaching and supervision of residents and fellows, clinical research, and acute perioperative care from resuscitation to postoperative pain management.
Very competitive academic salary and an excellent benefit package are offered. Faculty rank will be commensurate with training and experience.
Interested individuals should send C.V. to:

Albert J. Varon, MD
Director, Division of Trauma Anesthesia
Department of Anesthesiology
University of Miami School of Medicine
P.O. Box 016370
Miami, FL 33101

Requests for single issues beginning with Vol. 62, for the Ten-Year Cumulative Index (1975–1984), and for the Ten-Year Cumulative Index (1980–1989) should be sent to Elsevier Science Publishing Co., Inc., Journal Customer Service Department, 655 Avenue of the Americas, New York, New York 10010.

Tracrium®

For many procedures

For many reasons

	Cholecystectomy	**Biliary tract repair**
Common patient type Obese	**Common patient type** Both adults and children
Advantage of Tracrium No difference in recovery from neuromuscular blockade between normal and obese patients.[1]	**Advantage of Tracrium** Clinical response unaffected by hepatic function[2] or patient age.[3]

			Total hip replacement	**Renal surgery**	**Neurosurgery for trauma**	**Everyday procedures**
Common patient type Elderly women and men	**Common patient type** Both adults and children	**Common patient type** Both adults and children	**Common patient type** Average
Advantage of Tracrium Recovery time unaffected by age.[3]	**Advantage of Tracrium** Recovery time unaffected by renal dysfunction.[2]	**Advantage of Tracrium** Effect unchanged by concomitant anticonvulsant medications (phenytoin, carbamazepine).[4,5]	**Advantage of Tracrium** The same reasons Tracrium is ideal for special patient types make it the choice for everyday procedures.

TRACRIUM® INJECTION

(atracurium besylate) 10 mg/mL

For predictable recovery

TR-Y03368

See brief summary of prescribing information on adjacent page.

TRACRIUM® INJECTION

(atracurium besylate)

Brief Summary
This drug should be used only by adequately trained individuals familiar with its actions, characteristics, and hazards.

INDICATIONS AND USAGE: Tracrium is indicated, as an adjunct to general anesthesia, to facilitate endotracheal intubation and to provide skeletal muscle relaxation during surgery or mechanical ventilation.

CONTRAINDICATIONS: Tracrium is contraindicated in patients known to have a hypersensitivity to it.

WARNINGS: TRACRIUM SHOULD BE USED ONLY BY THOSE SKILLED IN AIRWAY MANAGEMENT AND RESPIRATORY SUPPORT. EQUIPMENT AND PERSONNEL MUST BE IMMEDIATELY AVAILABLE FOR ENDOTRACHEAL INTUBATION AND SUPPORT OF VENTILATION, INCLUDING ADMINISTRATION OF POSITIVE PRESSURE OXYGEN. ADEQUACY OF RESPIRATION MUST BE ASSURED THROUGH ASSISTED OR CONTROLLED VENTILATION. ANTICHOLINESTERASE REVERSAL AGENTS SHOULD BE IMMEDIATELY AVAILABLE. DO NOT GIVE TRACRIUM BY INTRAMUSCULAR ADMINISTRATION. Tracrium has no known effect on consciousness, pain threshold, or cerebration. It should be used only with adequate anesthesia. Tracrium Injection, which has an acid pH, should not be mixed with alkaline solutions (e.g., barbiturate solutions) in the same syringe or administered simultaneously during intravenous infusion through the same needle. Depending on the resultant pH of such mixtures, Tracrium may be inactivated and a free acid may be precipitated. Tracrium Injection 10 mL multiple dose vials contain benzyl alcohol. Benzyl alcohol has been associated with an increased incidence of neurological and other complications in newborn infants which are sometimes fatal. Tracrium Injection 5 mL ampule and 5 mL single use vials do not contain benzyl alcohol.

PRECAUTIONS: General: Although Tracrium is a less potent histamine releaser than d-tubocurarine or metocurine, the possibility of substantial histamine release in sensitive individuals must be considered. Special caution should be exercised in administering Tracrium to patients in whom substantial histamine release would be especially hazardous (e.g., patients with clinically significant cardiovascular disease) and in patients with any history (e.g., severe anaphylactoid reactions or asthma) suggesting a greater risk of histamine release. In these patients, the recommended initial Tracrium dose is lower (0.3 to 0.4 mg/kg) than for other patients and should be administered slowly or in divided doses over one minute. Since Tracrium has no clinically significant effects on heart rate in the recommended dosage range, it will not counteract the bradycardia produced by many anesthetic agents or vagal stimulation. As a result, bradycardia during anesthesia may be more common with Tracrium than with other muscle relaxants. Tracrium may have profound effects in patients with myasthenia gravis, Eaton-Lambert syndrome, or other neuromuscular diseases in which potentiation of nondepolarizing agents has been noted. The use of a peripheral nerve stimulator is especially important for assessing neuromuscular blockade in these patients. Similar precautions should be taken in patients with severe electrolyte disorders or carcinomatosis. Multiple factors in anesthesia practice are suspected of triggering malignant hyperthermia (MH), a potentially fatal hypermetabolic state of skeletal muscle. Halogenated anesthetic agents and succinylcholine are recognized as the principal pharmacologic triggering agents in MH-susceptible patients; however, since MH can develop in the absence of established triggering agents, the clinician should be prepared to recognize and treat MH in any patient scheduled for general anesthesia. Reports of MH have been rare in cases in which Tracrium has been used. In studies of MH-susceptible animals (swine) and in a clinical study of MH-susceptible patients, Tracrium did not trigger this syndrome. Resistance to nondepolarizing neuromuscular blocking agents may develop in burn patients. Increased doses of nondepolarizing muscle relaxants may be required in burn patients and are dependent on the time elapsed since the burn injury and the size of the burn. The safety of Tracrium has not been established in patients with bronchial asthma. **Long-Term Use in Intensive Care Unit (ICU):** Tracrium has been used to facilitate mechanical ventilation in ICU patients. When there is a need for long-term mechanical ventilation, the benefits to risk ratio of neuromuscular blockade must be considered. There is only limited information on the efficacy and safety of Tracrium administered by long-term (days to weeks) intravenous infusion to facilitate mechanical ventilation in intensive care facilities. For Tracrium, as with other neuromuscular blocking agents used in intensive care facilities, available evidence suggests that there is wide interpatient variability in dosage requirements and that these requirements may change with time. Limited data suggest that Tracrium infusion requirements may increase with prolonged administration in the ICU. As with other neuromuscular blocking agents, little information is available on the plasma levels or clinical consequences of atracurium metabolites following long-term (days to weeks) infusion of Tracrium in the intensive care unit setting. One metabolite of atracurium, laudanosine, when administered alone to laboratory animals, has been associated with cerebral excitatory effects. Physiological effects of laudanosine in humans have not been demonstrated. The effects of hemodialysis, hemoperfusion and hemofiltration on plasma levels of atracurium and its metabolites are unknown. **Drug Interactions:** Drugs which may enhance neuromuscular blocking action of Tracrium include: enflurane; isoflurane; halothane; certain antibiotics, especially the aminoglycosides and polymyxins; lithium; magnesium salts; procainamide; and quinidine. If other muscle relaxants are used during the same procedure, the possibility of a synergistic or antagonist effect should be considered. The prior administration of succinylcholine does not enhance the duration, but quickens the onset and may increase the depth, of neuromuscular blockade induced by Tracrium. Tracrium should not be administered until a patient has recovered from succinylcholine-induced neuromuscular blockade. **Carcinogenesis, Mutagenesis, Impairment of Fertility:** A positive response was observed in the mouse lymphoma assay under conditions which killed over 80% of the treated cells. A far weaker response was observed in the presence of metabolic activation at concentrations which also killed over 80% of the treated cells. **Pregnancy:** ***Teratogenic Effects:*** Pregnancy Category C. Tracrium has been shown to be potentially teratogenic in rabbits, when given in doses up to approximately one-half the human dose. There are no adequate and well-controlled studies in pregnant women. Tracrium should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus. **Labor and Delivery:** It is not known whether muscle relaxants administered during vaginal delivery have immediate or delayed adverse effects on the fetus or increase the likelihood that resuscitation of the newborn will be necessary. The possibility that forceps delivery will be necessary may increase. Tracrium (0.3 mg/kg) has been administered to 26 pregnant women during delivery by cesarean section. No harmful effects were attributable to Tracrium in any of the newborn infants, although small amounts of Tracrium were shown to cross the placental barrier. The possibility of respiratory depression in the newborn infant should always be considered following cesarean section during which a neuromuscular blocking agent has been administered. In patients receiving magnesium sulfate, the reversal of neuromuscular blockade may be unsatisfactory and Tracrium dose should be lowered as indicated. **Nursing Mothers:** It is not known whether this drug is excreted in human milk. Caution should be exercised when Tracrium is administered to a nursing woman. **Pediatric Use:** Safety and effectiveness in children below the age of 1 month have not been established.

ADVERSE REACTIONS: Observed in Controlled Clinical Studies: Tracrium produced few adverse reactions during extensive clinical trials. Most were suggestive of histamine release (see Precautions Section). The overall incidence rate for clinically important adverse reactions was 7/875 or 0.8%. Most adverse reactions were of little clinical significance unless they were associated with significant hemodynamic changes. Substantial vital sign changes greater than or equal to 30% observed in 530 patients, without cardiovascular disease, were as follows: in those patients given the recommended initial dosage range of 0.31 to 0.50 mg/kg of Tracrium, mean arterial pressure increased in 2.8% and decreased in 2.1% of patients while the heart rate increased in 2.8% of these patients. At doses of ≥ 0.60 mg/kg, 14.3% of the studied patients had a decrease in mean arterial pressure while 4.8% had an increase in heart rate. At doses ≤ 0.30 mg/kg, mean arterial pressure increased in 1.9% and decreased in 1.1% of patients, while heart rate increased in 1.6% and decreased in 0.8% of these patients. **Observed in Clinical Practice:** Based on clinical experience in the U.S. and the United Kingdom of approximately 3 million patients given Tracrium the following adverse reactions are among the most frequently reported: *General:* allergic reactions (anaphylactic or anaphylactoid) which, in rare instances, were severe (e.g., cardiac arrest); *Musculoskeletal:* inadequate, prolonged block; *Cardiovascular:* hypotension, vasodilatation (flushing), tachycardia, bradycardia; *Respiratory:* dyspnea, bronchospasm, laryngospasm; *Integumentary:* rash, urticaria, injection site reaction.

STORAGE: Tracrium Injection should be refrigerated at 2° to 8° C (36° to 46° F) to preserve potency. DO NOT FREEZE. Upon removal from refrigeration to room temperature storage conditions (25° C/77° F), use Tracrium Injection within 14 days even if rerefrigerated.

Chairperson,

Department of Anesthesiology

The University of Massachusetts Medical Center, Worcester, MA is seeking candidates with the demonstrated leadership ability to foster excellence in an academic Department of Anesthesiology with major responsibilities in patient care, teaching and research. The Medical Center is Massachusetts' only public academic health center and consists of a School of Medicine, Graduate Schools of Biomedical Sciences and Nursing, and a 361-bed University Hospital. The University Hospital does approximately 11,000 operations a year with an emphasis on tertiary care. In addition to patient care and research activities, the Department of Anesthesiology has an established and successful Residency Program, a Critical Care Fellowship, a Pain Control Program, and teaching responsibilities for medical students. The University of Massachusetts Medical Center has experienced remarkable growth and academic distinction since its inception in the early 1970's. It recognizes the essential contribution of the Department of Anesthesiology to the overall Medical Center and is firmly committed to its continued growth and excellence.

Nominations and applications, including curriculum vitae, should be forwarded to: H. Brownell Wheeler, M.D., Chairman, Anesthesiology Search Committee, Department of Surgery, University of Massachusetts Medical Center, Worcester, MA 01655.

U•MASS
MEDICAL
CENTER

Women and minorities are encouraged to apply. The University of Massachusetts is an Equal Opportunity/Affirmative Action employer

VIRGINIA PEDIATRIC ANESTHESIOLOGIST

Immediate opening for a pediatric anesthesiologist to join prestigious university affiliated children's hospital in Norfolk, VA. Opportunity for teaching and research, with excellent starting salary and benefits package. Enjoy coastal living with a mild, southern climate in a popular metro area. For more information contact Mr. Jim Davis, 800-683-0259 or fax CV to 804-626-0651.

— THE BEN COVINO RESEARCH AWARD —

Applications for up to $10,000 are invited for the 1993 Ben Covino Award, subject to the following basic conditions:

- The proposal should primarily relate to the use of local anesthetics/regional anesthesia, specifically within the preclinical and explorative clinical research fields.
- Applications to the Covino Award Committee must be received in the IARS Cleveland office no later than November 20, 1992. Where relevant, applications must include institutional approval of human studies and/or animal research.
- The official application for the Award must be used. This form, as well as the guidelines for applicants, is available on request to:

International Anesthesia Research Society
2 Summit Park Drive, Suite 140
Cleveland, OH 44131
USA
Telephone: (216) 642-1124

The establishment of the Ben Covino Award was announced at the 1992 Annual Scientific Meeting of the International Anesthesia Research Society held at the San Francisco Hilton. The Ben Covino Award has been instituted by Astra Pain Control, Sweden.

Journal of Clinical Anesthesia

An International Journal of Anesthesia Practice

Editor-in-Chief
Richard J. Kitz, M.D.
Professor of Anaesthesia, Harvard Medical School;
Anesthetist-in-Chief, Massachusetts General Hospital

Featuring peer-reviewed original contributions—

The core of the journal is original contributions, rigorously peer-reviewed, on subjects relevant to anesthesia practice. The journal also publishes review articles, "grand rounds," clinical cases, editorials, letters to the editor, and news and notices.

Headed by an outstanding international Editorial Board—

Highly respected international experts have joined together to form the Editorial Board. Recognized clinicians and scholars share their years of experience and clinical expertise.

Keeping your practical clinical skills current—

In a time of rapid advances in all aspects of anesthesiology, practitioners often find it difficult to keep abreast of important changes that could influence their approach to patient care. The journal bridges the gap between the laboratory and the clinical practice of anesthesiology and critical care to clarify how new insights can improve daily practice.

Covering every aspect of anesthesia practice—

The journal addresses all aspects of anesthesia practice, including anesthetic administration, pharmacokinetics, preoperative and postoperative considerations, coexisting disease and other complicating factors, and similar concerns anesthesiologists must contend with every day.

Be Prepared for Malignant Hyperthermia

Fatalities resulting from malignant hyperthermia are **unexpected, unfair** and almost always, **unnecessary.**

Unexpected because the patient - child or adult - shows no outward signs of this genetic disorder. And there is no simple diagnostic test. Most people have never heard of malignant hyperthermia **until** it strikes.

Unfair because it is triggered by the patient's reaction to certain common anesthetics used during surgery. The life-threatening episode that results has nothing whatsoever to do with the condition requiring the surgery.

Unnecessary, in most cases, because preparedneess and prompt treatment can arrest the episode before it reaches dangerous levels. Persons who know of their susceptibility can have surgery safely using non-triggering anesthetics. When MH strikes unexpectedly during an operation, it can be brought under control by early diagnosis and immediate treatment.

As a medical professional, you can combat this silent killer. For the latest information on diagnosing and treating malignant hyperthermia, contact the Malignant Hyperthermia Association of the United States (MHAUS) at (203) 655-3007. It may mean the difference between life or death.

WHY REVERSE BENZODIAZEPINE SEDATION?

A specific antagonist for a prompt return to consciousness

MAZICON® (flumazenil/Roche) is a specific benzodiazepine antagonist, which is indicated to reverse the sedative effects of benzodiazepines following general anesthesia, conscious sedation or in cases of benzodiazepine overdose.

In the clinical practice of anesthesia, there are excellent reasons to reverse benzodiazepine sedation with MAZICON. Intravenous administration of 0.2 mg/min (up to a total of 1 mg) of MAZICON:

- Provides a prompt, controlled awakening from benzodiazepine sedation
- Enhances your control over the depth and duration of sedation
- Facilitates postanesthesia patient assessment
- Returns patients to consciousness sooner—which is reassuring to the patient and the family
- Reverses benzodiazepine sedation only—not narcotics or other CNS agents

When to reverse

There are specific cases where MAZICON reversal of benzodiazepine sedation may be particularly appropriate:

- When postprocedural sedation is not desirable, especially after short surgical or diagnostic procedures
- In elderly patients, who may be at greater risk of adverse effects
- In patients with underlying cardiovascular disease, to minimize the risk of adverse events
- After ambulatory procedures, such as biopsy, dilatation and curettage, hernia repair, arthroscopic surgery, plastic surgery or ophthalmic surgery—in these situations, reversal of sedation with MAZICON allows the patient to cooperate, so that patient management can be facilitated

Adverse effects

The most common side effects in clinical trials were nausea and vomiting (11%), dizziness (10%), agitation (3% to 9%) and injection-site pain (3% to 9%).

MAZICON has been associated with seizures, most often in patients on benzodiazepines for long-term sedation or patients showing signs of serious cyclic antidepressant overdose. Practitioners should individualize the dosage and be prepared to manage seizures.

Important safety information

Patients should be monitored for possible resedation, respiratory depression or other residual effects of benzodiazepines.

The availability of MAZICON does not diminish the need for prompt detection of hypoventilation and the need to be prepared to effectively intervene by establishing an airway and assisting ventilation. MAZICON has not been established as an effective treatment for benzodiazepine-induced hypoventilation.

Contraindicated in hypersensitivity to benzodiazepines or MAZICON; in patients taking benzodiazepines for control of potentially life-threatening conditions; and in patients showing signs of serious cyclic antidepressant overdose. In patients who are dependent on benzodiazepines, MAZICON may precipitate withdrawal syndromes.

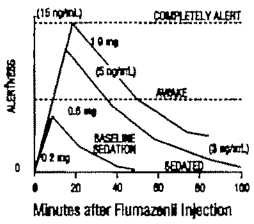
Please see following pages for complete product information.

MAZICON™
(flumazenil/Roche)
INJECTION

DESCRIPTION: MAZICON™ (flumazenil/Roche) is a benzodiazepine receptor antagonist. Chemically, flumazenil is ethyl 8-fluoro-5,6-dihydro-5-methyl-6-oxo-4H-imidazo[1,5-a](1,4) benzodiazepine-3-carboxylate. Flumazenil has an imidazobenzodiazepine structure, a calculated molecular weight of 303.3.
Flumazenil is a white to off-white crystalline compound with an octanol:buffer partition coefficient of 14 to 1 at pH 7.4. It is insoluble in water but slightly soluble in acidic aqueous solutions. MAZICON is available as a sterile parenteral dosage form for intravenous administration. Each mL contains 0.1 mg of flumazenil compounded with 1.8 mg of methylparaben, 0.2 mg of propylparaben, 0.9% sodium chloride, 0.01% edetate disodium, and 0.01% acetic acid; the pH is adjusted to approximately 4 with hydrochloric acid and/or, if necessary, sodium hydroxide.

CLINICAL PHARMACOLOGY: Flumazenil, an imidazobenzodiazepine derivative, antagonizes the actions of benzodiazepines on the central nervous system. Flumazenil competitively inhibits the activity at the benzodiazepine recognition site on the GABA/benzodiazepine receptor complex. Flumazenil is a weak partial agonist in some animal models of activity, but has little or no agonist activity in man.
Flumazenil does not antagonize the central nervous system effects of drugs affecting GABA-ergic neurons by means other than the benzodiazepine receptor (including ethanol, barbiturates, or general anesthetics) and does not reverse the effects of opioids.
PHARMACODYNAMICS: Intravenous MAZICON has been shown to antagonize sedation, impairment of recall and psychomotor impairment produced by benzodiazepines in healthy human volunteers.
The duration and degree of reversal of benzodiazepine effects are related to the dose and plasma concentrations of flumazenil as shown in the following data from a study in normal volunteers.

Magnitude and Duration of Reversal of Sedation as a Function of Flumazenil Dose*
Flumazenil doses of 0.2, 0.6 & 1.0 mg
(blood level in ng/mL)



*Sedation produced by midazolam infusion at a rate of 0.06 - 0.20 mg/kg/hr in healthy volunteers

Generally, doses of approximately 0.1 to 0.2 mg (corresponding to peak plasma levels of 3 to 6 ng/mL) produce partial antagonism, whereas higher doses of 0.4 to 1.0 mg (peak plasma levels of 12 to 28 ng/mL) usually produce complete antagonism in patients who have received the usual sedating doses of benzodiazepines. The onset of reversal is usually evident within 1 to 2 minutes after the injection is completed. Eighty percent response will be reached within 3 minutes, with the peak effect occurring at 6 to 10 minutes. The duration and degree of reversal are related to the plasma concentration of the sedating benzodiazepine as well as the dose of MAZICON given.
In healthy volunteers, MAZICON did not alter intraocular pressure when given alone and reversed the decrease in intraocular pressure seen after administration of midazolam.
PHARMACOKINETICS: After IV administration, plasma concentrations of flumazenil follow a two compartment open pharmacokinetic model with an initial distribution half-life of 7 to 15 minutes and a terminal half-life of 41 to 79 minutes. Peak concentrations of flumazenil are proportional to dose, with an apparent initial volume of distribution of 0.5 L/kg. After redistribution the apparent volume of distribution (V_{ss}) ranges from 0.77 to 1.60 L/kg. Protein binding is approximately 50% and the drug shows no preferential partitioning into red blood cells. Flumazenil is a highly extracted drug. Clearance of flumazenil occurs primarily by hepatic metabolism and is dependent on hepatic blood flow. In pharmacokinetic studies of normal volunteers, total clearance ranges from 0.7 to 1.3 L/hr/kg, with less than 1% of the administered dose eliminated unchanged in the urine. The major metabolites of flumazenil identified in urine are the de-ethylated free acid and its glucuronide conjugate. In preclinical studies there was no evidence of pharmacologic activity exhibited by the de-ethylated free acid. Elimination of radiolabelled drug is essentially complete within 72 hours, with 90% to 95% of the radioactivity appearing in urine and 5% to 10% in the feces.

Pharmacokinetic Parameters Following a 5-minute Infusion of a total of 1.0 mg of MAZICON Mean (Coefficient of variation, Range)

C_{max} (ng/mL)	24 (38%, 11-43)
AUC (ng•hr/mL)	15 (22%, 10-22)
V_{ss} (L/kg)	1 (24%, 0.8-1.6)
Cl (L/hr/kg)	1 (20%, 0.7-1.4)
Half-life (min)	54 (21%, 41-79)

The pharmacokinetics of flumazenil are not significantly affected by gender, age, renal failure (creatinine clearance <10 mL/min), or hemodialysis beginning 1 hour after drug administration. Mean total clearance is decreased to 40% to 60% of normal in patients with moderate liver dysfunction and to 25% of normal in patients with severe liver dysfunction compared with age-matched healthy subjects. This results in a prolongation of the half-life from 0.8 hours in healthy subjects to 1.3 hours in patients with moderate hepatic impairment and 2.4 hours in severely impaired patients. Ingestion of food during an intravenous infusion of the drug results in a 50% increase in clearance, most likely due to the increased hepatic blood flow that accompanies a meal. The pharmacokinetic profile of flumazenil is unaltered in the presence of benzodiazepine agonists and the kinetic profiles of those benzodiazepines are unaltered by flumazenil.

CLINICAL TRIALS: MAZICON has been administered to reverse the effects of benzodiazepines in conscious sedation, general anesthesia, and the management of suspected benzodiazepine overdose.
CONSCIOUS SEDATION: MAZICON was studied in four trials in 970 patients who received an average of 30 mg diazepam or 10 mg midazolam for sedation (with or without a narcotic) in conjunction with both inpatient and outpatient diagnostic or surgical procedures. MAZICON was effective in reversing the sedating and psychomotor effects of the benzodiazepine, however, amnesia was less completely and less consistently reversed. In these studies, MAZICON was administered as an initial dose of 0.4 mg I.V. (two doses of 0.2 mg) with additional 0.2 mg doses as needed to achieve complete awakening, up to a maximum total dose of 1.0 mg. Seventy-eight percent of patients receiving flumazenil responded by becoming completely alert. Of those patients, approximately half responded to doses of 0.4 to 0.6 mg, while the other half responded to doses of 0.8 to 1.0 mg. Adverse effects were infrequent in patients who received 1 mg of MAZICON or less, although injection site pain, agitation and anxiety did occur. Reversal of sedation was not associated with any increase in the frequency of inadequate analgesia or increase in narcotic demand in these studies. While most patients remained alert throughout the 3 hour post-procedure observation period, resedation was observed to occur in 3% to 9% of the patients, and was most common in patients who had received high doses of benzodiazepine. (See PRECAUTIONS.)
GENERAL ANESTHESIA: MAZICON was studied in four trials in 644 patients who received midazolam as an induction and/or maintenance agent in both balanced and inhalational anesthesia. Midazolam was generally administered in doses ranging from 5 to 80 mg, alone and/or in conjunction with muscle relaxants, nitrous oxide, regional or local anesthetics, narcotics and/or inhalational anesthetics. Flumazenil was given as an initial dose of 0.2 mg IV, with additional 0.2 mg doses as needed to reach a complete response, up to a maximum total dose of 1.0 mg. These doses were effective in reversing sedation and restoring psychomotor function, but did not completely restore memory as tested by picture recall. MAZICON was not as effective in the reversal of sedation in patients who had received multiple anesthetic agents in addition to benzodiazepines.
Eighty-one percent of patients sedated with midazolam responded to flumazenil by becoming completely alert or just slightly drowsy. Of those patients, 36% responded to doses of 0.4 to 0.6 mg, while 64% responded to doses of 0.8 to 1.0 mg.
Resedation in patients who responded to MAZICON occurred in 10% to 15% of patients studied and was more common with larger doses of midazolam (>20 mg), long procedures (>60 minutes) and use of neuromuscular blocking agents. (See PRECAUTIONS.)
MANAGEMENT OF SUSPECTED BENZODIAZEPINE OVERDOSE: MAZICON was studied in two trials in 497 patients who were presumed to have taken an overdose of a benzodiazepine, either alone or in combination with a variety of other agents. In these trials, 299 patients were proven to have taken a benzodiazepine as part of the overdose, and 80% of the 148 who received MAZICON responded by an improvement in level of consciousness. Of the patients who responded to flumazenil, 75% responded to a total dose of 1.0 to 3.0 mg. Reversal of sedation was associated with an increased frequency of symptoms of CNS excitation. Of the

patients treated with flumazenil, 1% to 3% were treated for agitation or anxiety. Serious side effects were uncommon, but six seizures were observed in 446 patients treated with flumazenil in these studies. Four of these 6 patients had ingested a large dose of cyclic antidepressants, which increased the risk of seizures. (See WARNINGS.)

INDIVIDUALIZATION OF DOSAGE: GENERAL PRINCIPLES: The serious adverse effects of MAZICON are related to the reversal of benzodiazepine effects. Using more than the minimally effective dose of MAZICON is tolerated by most patients but may complicate the management of patients who are physically dependent on benzodiazepines or patients who are depending on benzodiazepines for therapeutic effect (such as suppression of seizures in cyclic antidepressant overdose).
In high-risk patients, it is important to administer the smallest amount of MAZICON that is effective. The 1-minute wait between individual doses in the dose-titration recommended for general clinical populations may be too short for high risk patients. This is because it takes 6 to 10 minutes for any single dose of flumazenil to reach full effects. Practitioners should slow the rate of administration of MAZICON administered to high risk patients as recommended below.
ANESTHESIA AND CONSCIOUS SEDATION: MAZICON is well tolerated at the recommended doses in individuals who have no tolerance to (or dependence on) benzodiazepines. The recommended dosages and titration rates in anesthesia and conscious sedation (0.2 to 1.0 mg given at 0.2 mg/min) are well tolerated in patients receiving the drug for reversal of a single benzodiazepine exposure in most clinical settings (see Adverse Events). The major risk will be resedation because the duration of effect of a long-acting (or large dose of a short-acting) benzodiazepine may exceed that of MAZICON. Resedation may be treated by giving a repeat dose at no less than 20-minute intervals. For repeat treatment, no more than 1.0 mg (at 0.2 mg/min doses) should be given at any one time and no more than 3.0 mg should be given in any one hour.
OVERDOSE PATIENTS: The risk of confusion, agitation, emotional lability and perceptual distortion with the doses recommended in patients with benzodiazepine overdose (3 to 5 mg administered as 0.5 mg/min) may be greater than that expected with lower doses and slower administration. The recommended doses represent a compromise between a desirable slow awakening and the need for prompt response and a persistent effect in the overdose situation. If circumstances permit, the physician may elect to use the 0.2 mg/minute titration rate to slowly awaken the patient over 5 to 10 minutes, which may help to reduce signs and symptoms on emergence.
MAZICON has no effect in cases where benzodiazepines are not responsible for sedation. Once doses of 3 to 5 mg have been reached without clinical response, additional MAZICON is likely to have no effect.
PATIENTS TOLERANT TO BENZODIAZEPINES: MAZICON may cause benzodiazepine withdrawal symptoms in individuals who have been taking benzodiazepines long enough to have some degree of tolerance. Patients who had been taking benzodiazepines prior to entry into the MAZICON trials who were given flumazenil in doses over 1 mg experienced withdrawal-like events 2 to 5 times more frequently than patients who received less than 1 mg.
In patients who may have tolerance to benzodiazepines, as indicated by clinical history or by the need for larger than usual doses of benzodiazepine, slower titration rates of 0.1 mg/min and lower total doses may help reduce the frequency of emergent confusion and agitation. In such cases special care must be taken to monitor the patients for resedation because of the lower doses of MAZICON used.
PATIENTS PHYSICALLY DEPENDENT ON BENZODIAZEPINES: MAZICON is known to precipitate withdrawal seizures in patients who are physically dependent on benzodiazepines, even if such dependence was established in a relatively few days of high dose sedation in Intensive Care Unit environments. The risk of either seizures or resedation in such cases is high and patients have experienced seizures before regaining consciousness. MAZICON should be used in such settings with extreme caution, since the use of flumazenil in this situation has not been studied and no information as to dose and rate of titration is available. MAZICON should be used in such patients only if the potential benefits of using the drug outweigh the risks of precipitated seizures. Physicians are directed to the scientific literature for the most current information in this area.

INDICATIONS AND USAGE: MAZICON is indicated for the complete or partial reversal of the sedative effects of benzodiazepines in cases where general anesthesia has been induced and/or maintained with benzodiazepines, where sedation has been produced with benzodiazepines for diagnostic and therapeutic procedures, and for the management of benzodiazepine overdose.

CONTRAINDICATIONS: MAZICON is contraindicated:
- in patients with a known hypersensitivity to flumazenil or to benzodiazepines.
- in patients who have been given a benzodiazepine for control of a potentially life-threatening condition (*e.g.* control of intracranial pressure or status epilepticus).
- in patients who are showing signs of serious cyclic antidepressant overdose. (See WARNINGS.)

WARNINGS:

**THE USE OF MAZICON HAS BEEN ASSOCIATED WITH THE OCCURRENCE OF SEIZURES.
THESE ARE MOST FREQUENT IN PATIENTS WHO HAVE BEEN ON BENZODIAZEPINES FOR LONG-TERM SEDATION OR IN OVERDOSE CASES WHERE PATIENTS ARE SHOWING SIGNS OF SERIOUS CYCLIC ANTIDEPRESSANT OVERDOSE.
PRACTITIONERS SHOULD INDIVIDUALIZE THE DOSAGE OF MAZICON AND BE PREPARED TO MANAGE SEIZURES.**

**Risk of Seizures: The reversal of benzodiazepine effects may be associated with the onset of seizures in certain high-risk populations. Possible risk factors for seizures include: concurrent major sedative-hypnotic drug withdrawal, recent therapy with repeated doses of parenteral benzodiazepines, myoclonic jerking or seizure activity prior to flumazenil administration in overdose cases, or concurrent cyclic antidepressant poisoning.
MAZICON is not recommended in cases of serious cyclic antidepressant poisoning, as manifested by motor abnormalities (twitching, rigidity, focal seizure), dysrhythmia (wide QRS, ventricular dysrhythmia, heart block), anticholinergic signs (mydriasis, dry mucosa, hypo-peristalsis), and cardiovascular collapse at presentation. In such cases MAZICON should be withheld and the patient should be allowed to remain sedated (with ventilatory and circulatory support as needed) until the signs of antidepressant toxicity have subsided. Treatment with MAZICON has no known benefit to the seriously ill mixed-overdose patient other than reversing sedation and should not be used in cases where seizures (from any cause) are likely.
Most convulsions associated with flumazenil administration require treatment and have been successfully managed with benzodiazepines, phenytoin or barbiturates. Because of the presence of flumazenil, higher than usual doses of benzodiazepines may be required.**

**HYPOVENTILATION: Patients who have received MAZICON for the reversal of benzodiazepine effects (after conscious sedation or general anesthesia) should be monitored for resedation, respiratory depression, or other residual benzodiazepine effects for an appropriate period (up to 120 minutes) based on the dose and duration of effect of the benzodiazepine employed.
This is because MAZICON has not been established as an effective treatment for hypoventilation due to benzodiazepine administration. The availability of flumazenil does not diminish the need for prompt detection of hypoventilation and the ability to effectively intervene by establishing an airway and assisting ventilation.
MAZICON may not fully reverse postoperative airway problems or ventilatory insufficiency induced by benzodiazepines. In addition, even if MAZICON is initially effective, such problems may recur because the effects of MAZICON wear off before the effects of many benzodiazepines.
Overdose cases should always be monitored for resedation until the patients are stable and resedation is unlikely.**

PRECAUTIONS: RETURN OF SEDATION: MAZICON may be expected to improve the alertness of patients recovering from a procedure involving sedation or anesthesia with benzodiazepines, but should not be substituted for an adequate period of post-procedure monitoring. The availability of MAZICON does not reduce the risks associated with the use of large doses of benzodiazepines for sedation.
Patients should be monitored for resedation, respiratory depression (see WARNINGS), or other persistent or recurrent agonist effects for an adequate period of time after administration of MAZICON.
Resedation is least likely in cases where MAZICON is administered to reverse a low dose of a short-acting benzodiazepine (<10 mg midazolam). It is most likely in cases where a large single or cumulative dose of a benzodiazepine has been given in the course of a long procedure along with neuromuscular blocking agents and multiple anesthetic agents.
Profound resedation was observed in 1% to 3% of patients in the clinical studies. In clinical situations where resedation must be prevented, physicians may wish to repeat the initial dose (up to 1 mg of MAZICON given at 0.2 mg/min) at 30 minutes and possibly again at 60 minutes. This dosage schedule, although not studied in clinical trials, was effective in preventing resedation in a pharmacologic study in normal volunteers.
USE IN THE ICU: MAZICON should be used with caution in the Intensive Care Unit because of the increased risk of unrecognized benzodiazepine dependence in such settings. MAZICON may produce convulsions in patients physically dependent on benzodiazepines. (See INDIVIDUALIZATION OF DOSAGE AND WARNINGS.)
Administration of MAZICON to diagnose benzodiazepine-induced sedation in the Intensive Care Unit is not recommended due to the risk of adverse events as described above. In addition, the prognostic significance of a patient's failure to respond to flumazenil in cases confounded by metabolic disorder, traumatic injury, drugs other than benzodiazepines, or any other reasons not associated with benzodiazepine receptor occupancy is not known.

USE IN OVERDOSE: **MAZICON** is intended as an adjunct to, not as a substitute for, proper management of airway, assisted breathing, circulatory access and support, internal decontamination by lavage and charcoal, and adequate clinical evaluation.

Necessary measures should be instituted to secure airway, ventilation and intravenous access prior to administering flumazenil. Upon arousal patients may attempt to withdraw endotracheal tubes and/or intravenous lines as the result of confusion and agitation following awakening.

HEAD INJURY: **MAZICON** should be used with caution in patients with head injury as it may be capable of precipitating convulsions or altering cerebral blood flow in patients receiving benzodiazepines. It should be used only by practitioners prepared to manage such complications should they occur.

USE WITH NEUROMUSCULAR BLOCKING AGENTS: **MAZICON** should not be used until the effects of neuromuscular blockade have been fully reversed.

USE IN PSYCHIATRIC PATIENTS: **MAZICON** has been reported to provoke panic attacks in patients with a history of panic disorder.

PAIN ON INJECTION: To minimize the likelihood of pain or inflammation at the injection site, MAZICON should be administered through a freely flowing intravenous infusion into a large vein. Local irritation may occur following extravasation into perivascular tissues.

USE IN RESPIRATORY DISEASE: The primary treatment of patients with serious lung disease who experience serious respiratory depression due to benzodiazepines should be appropriate ventilatory support (See PRECAUTIONS) rather than the administration of MAZICON. Flumazenil is capable of partially reversing benzodiazepine-induced alterations in ventilatory drive in healthy volunteers, but has not been shown to be clinically effective.

USE IN CARDIOVASCULAR DISEASE: **MAZICON** did not increase the work of the heart when used to reverse benzodiazepines in cardiac patients when given at a rate of 0.1 mg/min in total doses of less than 0.5 mg in studies reported in the clinical literature. Flumazenil alone had no significant effects on cardiovascular parameters when administered to patients with stable ischemic heart disease.

USE IN LIVER DISEASE: The clearance of **MAZICON** is reduced to 40% to 60% of normal in patients with mild to moderate hepatic disease and to 25% of normal in patients with severe hepatic dysfunction. (See PHARMACOKINETICS.) While the dose of flumazenil used for initial reversal of benzodiazepine effects is not affected, repeat doses of the drug in liver disease should be reduced in size or frequency.

USE IN DRUG AND ALCOHOL DEPENDENT PATIENTS: **MAZICON** should be used with caution in patients with alcoholism and other drug dependencies due to the increased frequency of benzodiazepine tolerance and dependence observed in these patient populations.

MAZICON is not recommended either as a treatment for benzodiazepine dependence or for the management of protracted benzodiazepine abstinence syndromes, as such use has not been studied.

The administration of flumazenil can precipitate benzodiazepine withdrawal in animals and man. This has been seen in healthy volunteers treated with therapeutic doses of oral lorazepam for up to 2 weeks who exhibited effects such as hot flushes, agitation and tremor when treated with cumulative doses of up to 3 mg doses of flumazenil.

Similar adverse experiences suggestive of flumazenil precipitation of benzodiazepine withdrawal have occurred in some patients in clinical trials. Such patients had a short-lived syndrome characterized by dizziness, mild confusion, emotional lability, agitation (with signs and symptoms of anxiety), and mild sensory distortions. This response was dose-related, most common at doses above 1 mg, rarely required treatment other than reassurance and was usually short lived. When required (5 to 10 cases), these patients were successfully treated with usual doses of a barbiturate, a benzodiazepine, or other sedative drug.

Practitioners should assume that flumazenil administration may trigger dose-dependent withdrawal syndromes in patients with established physical dependence on benzodiazepines and may complicate the management of withdrawal syndromes for alcohol, barbiturates and cross-tolerant sedatives.

DRUG INTERACTIONS: Interaction with central nervous system depressants other than benzodiazepines has not been specifically studied; however, no deleterious interactions were seen when **MAZICON** was administered after narcotics, inhalational anesthetics, muscle relaxants and muscle relaxant antagonists administered in conjunction with sedation or anesthesia.

Particular caution is necessary when using MAZICON in cases of mixed drug overdosage since the toxic effects (such as convulsions and cardiac dysrhythmias) of other drugs taken in overdose (especially cyclic antidepressants) may emerge with the reversal of the benzodiazepine effect by flumazenil. (See WARNINGS.)

The pharmacokinetics of benzodiazepines are unaltered in the presence of flumazenil.

USE IN AMBULATORY PATIENTS: The effects of MAZICON may wear off before a long-acting benzodiazepine is completely cleared from the body. In general, if a patient shows no signs of sedation within 2 hours after a 1.0 mg dose of flumazenil, serious resedation at a later time is unlikely. An adequate period of observation must be provided for any patient in whom either long-acting benzodiazepines (such as diazepam) or large doses of short-acting benzodiazepines (such as >10 mg of midazolam) have been used. (See INDIVIDUALIZATION OF DOSAGE.)

Because of the increased risk of adverse reactions in patients who have been taking benzodiazepines on a regular basis, it is particularly important that physicians query carefully about benzodiazepine, alcohol and sedative use as part of the history prior to any procedure in which the use of **MAZICON** is planned. (See DRUG AND ALCOHOL DEPENDENT PATIENTS.)

INFORMATION FOR PATIENTS: **MAZICON** does not consistently reverse amnesia. Patients cannot be expected to remember information told to them in the post-procedure period and instructions given to patients should be reinforced in writing or given to a responsible family member. Physicians are advised to discuss with their patients, both before surgery and at discharge, that although the patient may feel alert at the time of discharge, the effects of the benzodiazepine may recur. As a result, the patient should be instructed, preferably in writing, that their memory and judgment may be impaired and specifically advised:

1. Not to engage in any activities requiring complete alertness, and not to operate hazardous machinery or a motor vehicle until at least 18 to 24 hours after discharge, and it is certain no residual sedative effects of the benzodiazepine remain.
2. Not to take any alcohol or non-prescription drugs for 18 to 24 hours after flumazenil administration or if the effects of the benzodiazepine persist.

LABORATORY TESTS: No specific laboratory tests are recommended to follow the patient's response or to identify possible adverse reactions.

DRUG/LABORATORY TEST INTERACTIONS: The possible interaction of flumazenil with commonly used laboratory tests has not been evaluated.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Carcinogenesis: No studies in animals to evaluate the carcinogenic potential of flumazenil have been conducted.

Mutagenesis: No evidence for mutagenicity was noted in the Ames test using five different tester strains. Assays for mutagenic potential in *S. cerevisiae* D7 and in Chinese hamster cells were considered to be negative as were blastogenesis assays *in vitro* in peripheral human lymphocytes and *in vivo* in a mouse micronucleus assay. Flumazenil caused a slight increase in unscheduled DNA synthesis in rat hepatocyte culture at concentrations which were also cytotoxic; no increase in DNA repair was observed in male mouse germ cells in an *in vivo* DNA repair assay.

Impairment of fertility: A reproduction study in male and female rats did not show any impairment of fertility at oral dosages of 125 mg/kg/day. From the available data on the area under the curve (AUC) in animals and man the dose represented 120 x the human exposure from a maximum recommended intravenous dose of 5 mg.

PREGNANCY: CATEGORY C. There are no adequate and well-controlled studies of the use of flumazenil in pregnant women. Flumazenil should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Teratogenic Effects: Flumazenil has been studied for teratogenicity in rats and rabbits following oral treatments of up to 150 mg/kg/day. The treatments during the major organogenesis were on days 6 to 15 of gestation in the rat and days 6 to 18 of gestation in the rabbit. No teratogenic effects were observed in rats or rabbits at 150 mg/kg; the dose, based on the available data on the area under the plasma concentration-time curve (AUC) represented 120 x to 600 x the human exposure from a maximum recommended intravenous dose of 5 mg in humans. In rabbits, embryocidal effects (as evidenced by increased pre-implantation and post-implantation losses) were observed at 50 mg/kg or 200 x the human exposure from a maximum recommended intravenous dose of 5 mg. The no-effect dose of 15 mg/kg in rabbits represents 60 x the human exposure.

Nonteratogenic Effects: An animal reproduction study was conducted in rats at oral dosages of 5, 25 and 125 mg/kg/day of flumazenil. Pup survival was decreased during the lactating period, pup liver weight at weaning was increased for the high-dose group (125 mg/kg/day) and incisor eruption and ear opening in the offspring were delayed; the delay in ear opening was associated with a delay in the appearance of the auditory startle response. No treatment-related adverse effects were noted for the other dose groups. Based on the available data from AUC, the effect level (125 mg/kg), represents 120 x the human exposure from 5 mg, the maximum recommended intravenous dose in humans. The no-effect level represents 24 x the human exposure from an intravenous dose of 5 mg.

LABOR AND DELIVERY: The use of **MAZICON** to reverse the effects of benzodiazepines used during labor and delivery is not recommended because the effects of the drug in the newborn are unknown.

NURSING MOTHERS: Caution should be exercised when deciding to administer **MAZICON** to a nursing woman because it is not known whether flumazenil is excreted in human milk.

PEDIATRIC USE: **MAZICON** is not recommended for use in children (either for the reversal of sedation, the management of overdose or the resuscitation of the newborn), as no clinical studies have been performed to determine the risks, benefits and dosages to be used.

GERIATRIC USE: The pharmacokinetics of flumazenil have been studied in the elderly and are not significantly different from younger patients. Several studies of **MAZICON** in patients over the age of 65 and one study in patients over the age of 80 suggest that while the doses of benzodiazepine used to induce sedation should be reduced, ordinary doses of **MAZICON** may be used for reversal.

ADVERSE REACTIONS: SERIOUS ADVERSE REACTIONS: Deaths have occurred in patients who received MAZICON in a variety of clinical settings. The majority of deaths occurred in patients with serious underlying disease or in patients who had ingested large amounts of non-benzodiazepine drugs, (usually cyclic antidepressants) as part of an overdose.

Serious adverse events have occurred in all clinical settings, and convulsions are the most common serious adverse event reported. **MAZICON** administration has been associated with the onset of convulsions in patients who are relying on benzodiazepine effects to control seizures, are physically dependent on benzodiazepines, or who have ingested large doses of other drugs. (See WARNINGS.)

Two of the 446 patients who received **MAZICON** in controlled clinical trials for the management of a benzodiazepine overdosage had cardiac dysrhythmias (1 ventricular tachycardia, 1 junctional tachycardia).

ADVERSE EVENTS IN CLINICAL STUDIES: The following adverse reactions were considered to be related to **MAZICON** administration (both alone and for the reversal of benzodiazepine effects) and were reported in studies involving 1875 individuals who received flumazenil in controlled trials. Adverse events most frequently associated with flumazenil alone were limited to dizziness, injection site pain, increased sweating, headache and abnormal or blurred vision (3% to 9%).

BODY AS A WHOLE: Fatigue (asthenia, malaise), Headache, Injection Site Pain*, Injection Site Reaction (thrombophlebitis, skin abnormality, rash)

CARDIOVASCULAR SYSTEM: Cutaneous vasodilation (sweating, flushing, hot flushes)

DIGESTIVE SYSTEM: Nausea and Vomiting (11%)

NERVOUS SYSTEM: Agitation (anxiety, nervousness, dry mouth, tremor, palpitations, insomnia, dyspnea, hyperventilation)*, Dizziness (vertigo, ataxia) (10%), Emotional lability (crying abnormal, depersonalization, euphoria, increased tears, depression, dysphoria, paranoia).

SPECIAL SENSES: Abnormal Vision (visual field defect, diplopia), Paresthesia (sensation abnormal, hypoesthesia)

All adverse reactions occurred in 1% to 3% of cases unless otherwise marked.

*Indicates reaction in 3% to 9% of cases.

Observed percentage reported if greater than 9%.

The following adverse events were observed infrequently (less than 1%) in the clinical studies, but were judged as probably related to **MAZICON** administration and/or reversal of benzodiazepine effects:

NERVOUS SYSTEM: Confusion (difficulty concentrating, delirium), Convulsions (see WARNINGS), Somnolence (stupor).

SPECIAL SENSES: Abnormal Hearing (transient hearing impairment, hyperacusis, tinnitus).

The following adverse events occurred with frequencies less than 1% in the clinical trials. Their relationship to **MAZICON** administration is unknown, but they are included as alerting information for the physician.

BODY AS A WHOLE: Rigors, shivering.

CARDIOVASCULAR: Arrhythmia (atrial, nodal, ventricular extrasystoles), bradycardia, tachycardia, hypertension, chest pain.

DIGESTIVE SYSTEM: Hiccup.

NERVOUS SYSTEM: Speech disorder (dysphonia, thick tongue).

Not included in this list is operative site pain that occurred with the same frequency in patients receiving placebo as in patients receiving flumazenil for reversal of sedation following a surgical procedure.

DRUG ABUSE AND DEPENDENCE: MAZICON acts as a benzodiazepine antagonist, blocks the effects of benzodiazepines in animals and man, antagonizes benzodiazepine reinforcement in animal models, produces dysphoria in normal subjects, and has had no reported abuse in foreign marketing.

Although **MAZICON** has a benzodiazepine-like structure it does not act as a benzodiazepine agonist in man and is not a controlled substance.

OVERDOSAGE: Large intravenous doses of **MAZICON**, when administered to healthy normal volunteers in the absence of a benzodiazepine agonist, produced no serious adverse reactions, severe signs or symptoms, or clinically significant laboratory test abnormalities. In clinical studies, most adverse reactions to flumazenil were an extension of the pharmacologic effects of the drug in reversing benzodiazepine effects.

Reversal with an excessively high dose of **MAZICON** may produce anxiety, agitation, increased muscle tone, hyperesthesia and possibly convulsions. Convulsions have been treated with barbiturates, benzodiazepines and phenytoin, generally with prompt resolution of the seizures. (See WARNINGS.)

DOSE AND ADMINISTRATION: **MAZICON** is recommended for intravenous use only. It is compatible with 5% dextrose in water, lactated Ringer's and normal saline solutions. If **MAZICON** is drawn into a syringe or mixed with any of these solutions, it should be discarded after 24 hours. For optimum sterility, **MAZICON** should remain in the vial until just before use. As with all parenteral drug products, MAZICON should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

To minimize the likelihood of pain at the injection site, MAZICON should be administered through a freely running intravenous infusion into a large vein.

REVERSAL OF CONSCIOUS SEDATION OR IN GENERAL ANESTHESIA: For the reversal of the sedative effects of benzodiazepines administered for conscious sedation or general anesthesia, the recommended initial dose of **MAZICON** is 0.2 mg (2 mL) administered intravenously over 15 seconds. If the desired level of consciousness is not obtained after waiting an additional 45 seconds, a further dose of 0.2 mg (2 mL) can be injected and repeated at 60-second intervals where necessary (up to a maximum of 4 additional times) to a maximum total dose of 1 mg (10 mL). The dose should be individualized based on the patient's response, with most patients responding to doses of 0.6 to 1 mg. (See INDIVIDUALIZATION OF DOSAGE.)

In the event of resedation, repeated doses may be administered at 20 minute intervals as needed. For repeat treatment, no more than 1 mg (given as 0.2 mg/min) should be administered at any one time, and no more than 3 mg should be given in any one hour.

It is recommended that MAZICON be administered as the series of small injections described (not as a single bolus injection) to allow the practitioner to control the reversal of sedation to the approximate endpoint desired and to minimize the possibility of adverse effects. (See INDIVIDUALIZATION OF DOSAGE.)

MANAGEMENT OF SUSPECTED BENZODIAZEPINE OVERDOSE: For initial management of a known or suspected benzodiazepine overdose, the recommended initial dose of **MAZICON** is 0.2 mg (2 mL) administered intravenously over 30 seconds. If the desired level of consciousness is not obtained after waiting 30 seconds, a further dose of 0.3 mg (3 mL) can be administered over another 30 seconds. Further doses of 0.5 mg (5 mL) can be administered over 30 seconds at 1-minute intervals up to a cumulative dose of 3 mg.

Do not rush the administration of **MAZICON**. Patients should have a secure airway and intravenous access before administration of the drug and be awakened gradually. (See PRECAUTIONS.)

Most patients with benzodiazepine overdose will respond to a cumulative dose of 1-3 mg of **MAZICON**, and doses beyond 3 mg do not reliably produce additional effects. On rare occasions, patients with a partial response at 3 mg may require additional titration up to a total dose of 5 mg (administered slowly in the same manner).

If a patient has not responded 5 minutes after receiving a cumulative dose of 5 mg **MAZICON**, the major cause of sedation is likely not to be due to benzodiazepines, and additional **MAZICON** is likely to have no effect.

In the event of resedation, repeated doses may be given at 20-minute intervals if needed. For repeat treatment, no more than 1 mg (given as 0.5 mg/min) should be given at any one time and no more than 3 mg should be given in any one hour.

SAFETY AND HANDLING: **MAZICON** is supplied in sealed dosage forms and poses no known risk to the health care provider. Routine care should be taken to avoid aerosol generation when preparing syringes for injection, and spilled medication should be rinsed from the skin with cool water.

HOW SUPPLIED: 5 mL multiple-use vials containing 0.1 mg/mL flumazenil:
Boxes of 10 (NDC 0004-6904-14).
10 mL multiple-use vials containing 0.1 mg/mL flumazenil:
Boxes of 10 (NDC 0004-6905-14).
Store at 59° to 86° F (15° to 30° C).

Free Polymerized Hemoglobin Versus Hydroxyethyl Starch in Resuscitation of Hypovolemic Dogs

Rob J. Bosman, MD, Jaak Minten, PhD, Hua R. Lu, MD, Hugo Van Aken, MD, and Willem Flameng, MD

Department of Anesthesiology, Center of Experimental Surgery and Anesthesiology, Katholieke Universiteit, Leuven, Belgium

---

Polymerized bovine hemoglobin (PBH) was compared with hydroxyethyl starch (HES) in a hypovolemic shock model. Eighteen dogs were subjected to hemorrhage; systolic arterial blood pressure was maintained at 40 mm Hg for 30 min (mean blood pressure 37.8 ± 4.7 [SD] mm Hg). Resuscitation was conducted by infusing their own shed blood (control group) or 6% HES (mol wt 200,000) in 0.9% NaCl (HES group) or PBH (PBH group), both in an equal amount to the shed blood. Directly after infusion, oxygen delivery and consumption returned to prehemorrhage levels in all three groups. In the HES group, the lowered arterial oxygen content was compensated by a 158% increase in cardiac output, in contrast to an increase of 31% and 9%, respectively, in the control and PBH groups. Early recovery from hypovolemic shock with regard to oxygen transport and delivery in the PBH group seemed to be comparable to the control group, without the increase in cardiac output seen with HES infusion.

(Anesth Analg 1992;75:811–7)

Instantaneous restoration of (micro)circulation and (tissue)oxygenation is essential for the outcome of hypovolemic shock (1–3). The ideal fluid would be directly available in large amounts, would preferably exert colloid osmotic pressure, would possess oxygen transport capacity, and would have no serious side effects. Human hemoglobin solutions (whole blood or packed cells, or both) are limited in quantity (shortage of donors), are not immediately available (time-consuming blood group determinations or cross-matching procedures, or both), and still present some serious side effects (e.g., infections). The most frequently advocated colloid solutions, such as dextran and hydroxyethyl starch (HES), whether or not in combination with hyperosmotic solutions, fulfill many of these demands, except for oxygen transport capacity. Although there is rapid improvement in hemodynamic status after administration of these solutions, oxygen utilization during anemia is predominantly limited by oxygen supply—total volume available to the tissues per unit time (4). In 1934, the first attempts were made to use a solution containing free hemoglobin (5). Hypercoagulability and renal failure were caused by red cell stroma (6). Rabiner and coworkers (7) described a purifying method that resulted in almost complete clearance of the erythrocyte debris ("stroma-free hemoglobin"). Polymerization of the hemoglobin tetramer prolonged its intravascular persistence, increased its half-life, and reduced its colloid osmotic pressure (8,9). However, none of the previously described solutions have been clinically accepted (10–12).

Because there are limitations with the use of human blood, as mentioned earlier, other mammalian sources of hemoglobin have been sought. Polymerized bovine hemoglobin (PBH) consists of an ultrapurified polymerized hemoglobin solution of bovine origin. An important difference between human and bovine hemoglobin is found in the regulation of oxygen affinity: bovine hemoglobin is controlled by chloride ions rather than by 2,3-diphosphoglycerate (2,3-DPG) (13,14). The P_{50} (Po_2 required for 50% saturation with O_2) of the oxygen dissociation curve of PBH under standard conditions (pH 7.4, Pco_2 40 mm Hg, 37°C) is 17–23 mm Hg (B. Braun Melsungen AG: Wissenstand Hemopure I, Stand: März 1990). Bovine hemoglobin also shows a more pronounced Bohr effect (15), resulting in an enhanced oxygen delivery in regions characterized by low pH or elevated Pco_2, or both. Endotoxin and phospholipid levels are lower than those in earlier preparations (16). Vlahakes et al. (16) previously demonstrated in a

blood exchange model that this PBH solution is capable of oxygen and carbon dioxide transport.

The objectives in these experiments were twofold: first, to observe the immediate effects of PBH as an oxygen-carrying resuscitation fluid under conditions of severe hypovolemia and subsequent normovolemia; second, to study the medium-term effects (7 days) of a large-volume infusion of stroma-free hemoglobin after hypovolemic shock.

Methods

The study protocol was approved by our institutional animal investigation committee; the experiments were performed according to the institutional standards for laboratory animal care. A total of 18 male and female mongrel dogs (mean body wt 17.33 ± 3.86 [SD] kg) were randomly assigned to one of three groups. After premedication with fluanison (0.1 mg/kg IM) and fentanyl (0.02 mg/kg IM), they were anesthetized by sodium pentobarbital (20–25 mg/kg IV). The trachea was intubated, and ventilation with an air/oxygen mixture (inspired O_2 concentration 0.4) was controlled to maintain CO_2 tension between 38 and 42 mm Hg, as assessed by the continuous measurement of end-tidal CO_2 concentration. A catheter was inserted into the femoral artery for direct measurement of arterial pressure and for withdrawal of blood. A balloon-tipped, flow-directed, pulmonary artery thermodilution catheter was introduced through the jugular vein to the pulmonary artery for measurement of pulmonary artery pressure, pulmonary capillary wedge pressure, and cardiac output, using a thermodilution technique. An additional catheter was introduced in a peripheral vein for administration of fluids (3 $mL \cdot kg^{-1} \cdot h^{-1}$, lactated Ringer's solution). After catheterization, the animals were heparinized by an intravenous single bolus injection of 250 IU/kg.

The arterial and venous blood samples were simultaneously and anaerobically collected. Blood gas analysis was performed immediately. The blood samples were further analyzed for hemoglobin, hematocrit, sodium, potassium, protein, calcium, urea, creatinine, magnesium, glutamate oxaloacetate transaminase (GOT), glutamate pyruvate transaminase (GPT), creatine kinase (CK), lactate dehydrogenase, and osmolality. The red color of plasma containing free hemoglobin could cause a disturbance of clinicochemical test procedures based on optical density measurement. An additional set of plasma samples was screened for free hemoglobin content. If free hemoglobin was present in the plasma, a precipitation step (using zinc) was performed, and subsequent centrifugation left the supernatant with a rest concentration of hemoglobin ≤0.5 g/dL (B. Braun Melsungen AG). This supernatant was again analyzed for the above-mentioned variables. Urine was collected for quantity, creatinine, and urea measurement.

Table 1. Characteristics of Ultrapurified Polymerized Bovine Hemoglobin as Stated by the Manufacturer[a]

Hemoglobin concentration	11 ± 2 g/100 mL
Methemoglobin content	<10%
Polymerized fraction	50%–60%
Molecular size	68,000–500,000 daltons
Colloid oncotic pressure	±20 mm Hg
Sodium content	120 ± 20 mmol/L
Potassium content	4.0 ± 1 mmol/L
Chloride content	115 ± 25 mmol/L
pH	7.8 ± 0.4
Osmolarity	250 ± 40 mOsm/kg
P_{50}	17–23 mm Hg
Endotoxin content[b]	<0.5 EU/mL
Phospholipid content[b]	1 nmol/mL

P_{50}, Po_2 required for 50% saturation with O_2; EU, endotoxin units.
Mean ± SD.

[b] Vlahakes et al. (16).

Cardiac output was calculated by a cardiac output computer (model 78231D, Hewlett Packard). Using 10 mL of an iced 5% dextrose in water solution, the mean of at least three sequential cardiac output measurements with a coefficient of variation <10% was taken as a representative value. For the calculation of arterial and venous oxygen content, the dissolved oxygen is added to the hemoglobin-bound oxygen by using the measured Po_2 and the solubility coefficient of 0.0031 mL of oxygen/dL/mm Hg Po_2. In the PBH group, oxygen content was calculated using the total hemoglobin (native and bovine) amount. Pressures were recorded on a four-channel writer.

After stabilization, blood samples and baseline values of hemodynamic variables were obtained. Within 15–20 min, the dogs were bled sufficiently to maintain a systolic arterial pressure of 40 mm Hg. This pressure was sustained for a 30-min period by further withdrawal or reinfusion of blood. At the end of this 30-min period, blood samples were taken and hemodynamics measured. The first group was resuscitated with their own shed blood (control group); the second group received 6% HES (mol wt 200,000) in 0.9% NaCl (B. Braun Melsungen AG) (HES group); the third group received bovine stroma-free hemoglobin (PBH, units of approximately 120 mL; composition is listed in Table 1 [B. Braun Melsungen AG]) (PBH group); the HES and PBH groups each received an amount equal to the shed blood. All solutions were administered over a 15–20-min period and infused at ±37°C. On completion of the infusion, a 30-min stabilization period followed, after which another series of measurements and blood collection was performed. At the end of the experiment, the

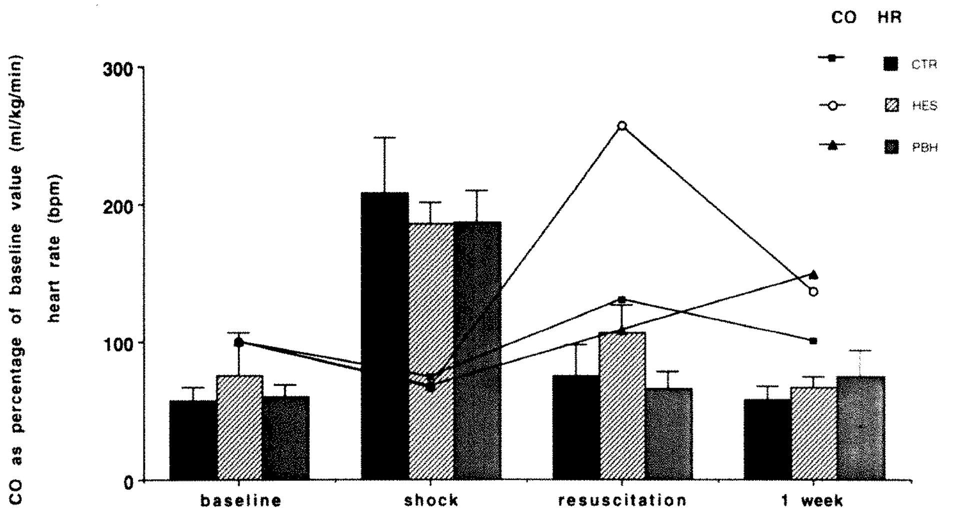

Figure 1. Changes in cardiac output (as % of baseline value) and heart rate throughout the hypovolemic shock experiment. bpm, beats/min.

tracheas were extubated and the animals transported to the animal care facility.

At approximately 24, 48, and 72 h after the end of the shock phase, 24-h urine and blood samples were obtained. At day 7, the animals were again anesthetized and ventilated, hemodynamic variables were measured, and blood samples were taken (same procedures and blood analysis as day 1). Finally, the animals were killed, and biopsy specimens of the left ventricle, lungs, liver, spleen, and kidney were sent for histologic examination.

Results are expressed as mean ± SD. Statistical analyses were performed using analysis of variance for a two-factor repeated measures or the paired Student's *t*-test where appropriate. A *P* value <0.05 was considered significant.

Results

All animals survived the 7-day period. The mean weight loss over this period was 1.12 (±0.93) kg in the control and PBH groups and 1.63 (±1.02) kg in the HES group (difference not significant). The mean volume of shed blood amounted to 30.85 (±6.11) mL/kg. None of the dogs showed adverse reactions on infusion of the fluids.

The hemodynamic variables changed to a similar extent in the three groups during the shock period; heart rate increased and cardiac output and central filling pressures decreased (Table 2). After resuscitation, heart rate in the HES group remained significantly elevated ($P < 0.05$) compared with the control and PBH groups (Figure 1). Cardiac output in the control and the PBH groups increased to values slightly above prehemorrhage levels (respectively, 131% and 109% of baseline values), whereas in the HES group, it peaked to 258% of baseline value ($P < 0.05$; Figure 1). Arterial and venous oxygen content were both depressed in the HES group after resuscitation ($P < 0.05$), whereas in the PBH group, values comparable to the control group were found. Oxygen delivery, consumption, and extraction ratio showed no significant difference among the three groups.

Hemoglobin content decreased to 62% of baseline value in the HES group after infusion (Table 3); hematocrit decreased to 56% and 62% in PBH and HES groups, respectively (Figure 2). Both hemoglobin and hematocrit returned to near-normal values at day 1. The plasma creatinine values were equally increased in the three groups on the first day. Diuresis during the first 24 h was significantly increased in the PBH group, whereas the other two groups showed a decrease. Creatinine clearance during this period was less in the HES group compared with the control and PBH groups. No significant differences were found in serum sodium, potassium, chloride, urea, magnesium, and osmolality over the course of the experiment. Total blood protein and calcium content was less in the HES group after infusion (for protein even up to the third day). The CK, GOT, GPT, and lactate dehydrogenase values all increased after the shock period; CK, GOT, and GPT were more pronounced in the PBH group. Even after precipitation of the free hemoglobin, GOT and CK remained significantly increased compared with the HES group.

One dog (in the control group) had a subendocardial infarction. Further histologic examination produced no abnormalities in heart, lungs, or kidneys. Some aspecific vascular congestion was observed in

the liver biopsies in all three groups. The same was true for iron deposits in the spleen: limited in quantity and no evident preference for one of the groups.

Discussion

The goal of resuscitation should be the restoration of normal tissue oxygenation (3), as defined by oxygen

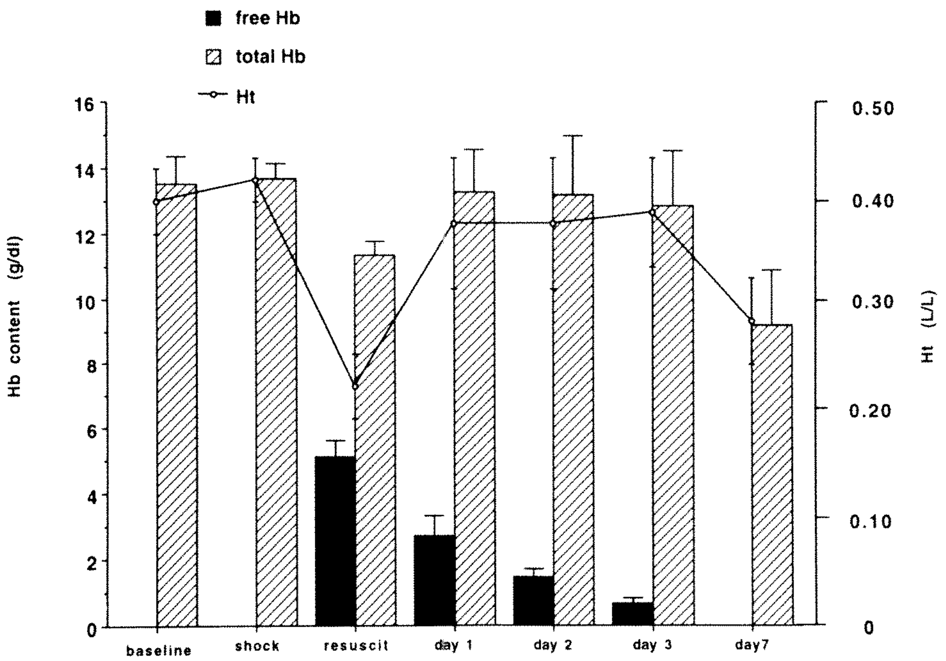

Figure 2. Free and erythrocytic hemoglobin (Hb) content and hematocrit (Ht) in the PBH group (mean ± SD). resuscit, resuscitation.

delivery and consumption. Sufficient oxygen supply can only be achieved by increasing heart rate and cardiac output when non-oxygen-carrying solutions (e.g., dextran, HES) are infused. Oxygen content in the PBH group was calculated using the total hemoglobin (native and bovine) amount. Vlahakes et al. (16) demonstrated in sheep that the oxygen transport capability of PBH is nearly identical to that of native hemoglobin, supported by an almost linear correlation between PBH contribution to oxygen content and declining hematocrit. Oxygen supply in our HES and PBH groups was equal to the control group. In the HES group, the lower arterial oxygen content was compensated by a 158% increase in cardiac output. However, when healthy animals are exposed to a hematocrit of <6%–10%, oxygen delivery and mixed venous P_{O_2} decrease precipitously, resulting in death (3,17,18). Despite a significant decrease in mixed venous oxygen content in the HES-group animals, the oxygen extraction ratio showed no difference among the three groups.

Gould et al. (19) showed that an adequate hemoglobin content is far more important to tissue oxygenation than a high P_{50}. Oxygen delivery is further dependent on diffusion distance (4). The effect of dextran on microcirculation has been well described (20–22); the reduced red cell sludging and platelet and leukocyte adhesiveness are probably due to hemodilution or coating of these cells, or both, resulting in enhanced tissue perfusion (23,24). A free hemoglobin solution should theoretically present a similar "hemodiluting" effect. Hauser and Shoemaker (3) demonstrated a lowered viscosity after crystalline hemoglobin infusion. However, systemic vascular resistance did not decrease. Further investigation into this presumed "dextran effect" of stroma-free hemoglobin seems appropriate.

Hemoglobin is removed from the circulation in two principal ways: (a) complex formation with haptoglobin and consequent absorption of this complex by the reticuloendothelial system; and (b) dissociation of the free hemoglobin in monomers and dimers, followed by glomerular filtration (12). Although we measured high levels of GOT, GPT, and CK in the PBH group, there was no histologic evidence of any damage to the liver. The reversible increase of these enzymes during the first 3 days was possibly due to an interference between the photometric assay and the hemoglobin rest concentration after the precipitation process. Although some increase in enzyme levels might be attributed to this interference, the rest concentration of free hemoglobin of ≤0.5 g/dL is too low to be solely responsible. The increase in GOT, GPT, and CK in the PBH group probably reflects a limited, transient dysfunction of the liver, presumably induced by a flooded reticuloendothelial system.

After infusion of 32.07 ± 4.94 mL/kg of PBH, renal toxicity could not be found in our experiment. A significant increase in urine production during the first 24 h is probably due to osmotic diuresis, caused by hemoglobinuria of monomers and dimers. Using stroma-free hemoglobin in rats, Lee et al. (25) demonstrated that no apparent depression of kidney function is to be expected until an equivalent dose of 150% of circulating blood volume is reached (±75 mL/kg). This reversible toxicity could be diminished by adding bicarbonate. In an exchange transfusion model (≥95% exchange of blood volume by PBH), Vlahakes et al. (16) found only a slight increase in blood urea nitrogen and creatinine on the second day, with return to baseline level at day 3. The mechanism of the transient renal toxicity is still unclear but probably results either from some direct toxic effect of hemoglobin on tubular epithelium or from intratubular precipitation and consequent obstruction (10,12,23).

Both in the HES and the PBH groups, hematocrit and (erythrocytic) hemoglobin returned to prehemorrhage levels within 24 h (Table 2, Figure 2). This rapid recovery is presumably the result of using nonsplenectomized dogs.

The favorable results of stroma-free hemoglobin obtained in this study are in contrast to the data presented by Dawidson et al. (26). In their ischemic intestinal shock model, 6 of 8 rats transfused with stroma-free hemoglobin died within 24 h, whereas 15 of 16 rats infused with either lactated Ringer's solution or 3% albumin in lactated Ringer's solution survived for 7 days. Proposed explanations for the failure of stroma-free hemoglobin are (a) diminished volume expansion compared with the other two fluids, and (b) an increased vascular permeability, possibly due to enhanced production of free radicals. However, when the objective of resuscitation is to optimize tissue perfusion and oxygenation, the infusion of 300 mL/kg stroma-free hemoglobin will result in an enormous increase in hemoglobin content and a concomitant decrease in viscosity. The authors only present hematocrit, without mentioning hemoglobin content. The experiment would have been more realistic if oxygen transport capacities had been the goal of resuscitation.

In conclusion, ultrapurified PBH restored oxygen delivery and consumption after hemorrhagic shock in the same way as infusion with autologous blood. The limited degree of hemorrhage enabled the animals in the HES group to restore oxygen delivery by increasing their cardiac output up to 158% above baseline value. Besides a transient increase in liver enzymes, no apparent organ dysfunction was noticeable after PBH infusion during a 7-day follow-up or at autopsy.

CASE REPORTS

Profound Hemodilution: What Is the Critical Level of Hemodilution at Which Oxygen Delivery-Dependent Oxygen Consumption Starts in an Anesthetized Human?

E. C. S. M. van Woerkens, MD, A. Trouwborst, MD, PhD, and
J. J. B. van Lanschot, MD, PhD

Department of Anesthesiology and General Surgery, University Hospital Dijkzigt, Erasmus University, Rotterdam, The Netherlands

The risks of homologous blood transfusion are well known, and some patients may refuse blood transfusions on religious grounds. Transfusion requirements may be diminished by hemodilution techniques. The critical level of hemodilution in humans, defined as the point at which oxygen consumption (Vo_2) starts to decrease because of insufficient oxygen delivery (Do_2), is not known. With permission of the family, the case history of a Jehovah's Witness patient with a critical level of hemodilution and Do_2-dependent Vo_2, due to excessive blood loss during surgery, is presented.

Case Report

An otherwise healthy 84-yr-old, 60-kg, male Jehovah's Witness had bleeding from the stomach. At admission, the bleeding stopped spontaneously with a hemoglobin concentration of 7.7 g/dL. Examination revealed a malignant tumor of the stomach. Five weeks after admission, the hemoglobin concentration was 10.1 g/dL (hematocrit 31%). Because of the danger of massive and lethal bleeding from the ulcerative tumor, it was decided to perform a total gastrectomy. The patient refused homologous blood products and any form of autologous transfusion. Fully informed consent was obtained for invasive monitoring and for the use of the technique of acute hypervolemic hemodilution (1,2). Because of adhesions between the stomach and spleen, the spleen ruptured during surgery and mobilization of the stomach and massive bleeding followed. At the end of surgery, blood loss was 4500 mL. Twelve hours postoperatively, the patient died. In accordance with medicoethical law in The Netherlands, it was forbidden in this case to administer any blood transfusion.

We now describe the methods and results of our investigations during this case. On the day of surgery, two intravenous cannulas were inserted. The radial artery was cannulated and a thermodilution catheter introduced into a pulmonary artery via the internal jugular vein. Midazolam (2.5 mg IV) was administered before catheter insertion. Heart rate, mean arterial blood pressure, pulmonary artery pressure, and right atrial pressure were monitored continuously. After 30 min of stable cardiovascular status, baseline cardiovascular values were obtained. In addition, arterial and mixed venous blood samples were obtained for measurements of hemoglobin, hemoglobin oxygen saturation, hematocrit, and analysis of blood gases. Systemic vascular resistance, pulmonary vascular resistance, Do_2, Vo_2, and P_{50} (Po_2 at which hemoglobin is 50% saturated with oxygen) were calculated from these acquired data. The oxygen extraction ratio was calculated by dividing Vo_2 by Do_2. P_{50}, corrected to 37°C and pH = 7.40, was calculated (and not measured by in vitro biotonometric technique) from a single measurement of venous pH, Po_2, and oxygen saturation of hemoglobin (3). Anesthesia was induced with fentanyl (5 μg/kg IV), thiopental (5 mg/kg IV), and pancuronium (0.1 mg/kg IV). After tracheal intubation, the lungs were ventilated with 70% nitrous oxide in oxygen, and tidal volume was adjusted to achieve normocapnia. Anesthesia was maintained with fentanyl and enflurane (end-tidal 0.4 vol% throughout the whole surgical procedure) and muscle relaxation maintained with pancuronium (2 mg/h). The bladder was catheterized. Before surgery began, hypervolemic hemodilution was undertaken in three equal steps. Per step, 500 mL of dextran 40 (50 g/L) and 500 mL of lactated Ringer's solution were infused over 10 min. All measurements were repeated after each step. The same variables were recorded after 1500- and 3500-mL blood loss. Peroperatively, lactated Ringer's solution was infused in a volume equal to urine output plus 8 $mL \cdot kg^{-1} \cdot h^{-1}$ (to compensate for fluid loss from the wound). Blood loss was replaced by an equal volume of gelatin solution. Measurements were repeated at the end of surgery (blood loss 4500 mL) and at 1, 2, 4, and 8 h thereafter.

Postoperatively, anesthesia was maintained with continuous intravenous midazolam (0.1 $mg \cdot kg^{-1} \cdot h^{-1}$), and muscle relaxation was achieved with pancuronium (2 mg/h).

The lungs were ventilated with 40% oxygen in air, and body temperature was kept normal. Postoperatively, lactated Ringer's solution was infused at 100 mL/h. The critical level of hemodilution was determined from a plot of V_{O_2} against D_{O_2}. The critical point was defined as the point at which V_{O_2} became dependent on D_{O_2} with further hemodilution. To avoid the investigator bias of selecting this point by eye, the critical point was analytically chosen from the intersection of the two best-fit regression lines determined by a least sum of squares technique, as described previously by Schumacker et al. (4).

The resultant hemodynamic data are summarized in Table 1. Stepwise acute hypervolemic hemodilution, with a change in hematocrit from 31% to 20%, resulted in a decrease in systemic vascular resistance of 53% and an increase in cardiac output of 54%. At a hematocrit of 8%, cardiac output was slightly decreased but still maintained compared with the postinduction of anesthesia value before hemodilution was induced. Mean arterial pressure decreased at hematocrit values of <10% because of slightly decreased cardiac output and further decreased systemic vascular resistance. During extreme hemodilution, heart rate increased only slightly.

The results of systemic oxygenation are shown in Table 2. The critical point of D_{O_2} after which V_{O_2} gradually decreased was analytically chosen from the intersection of the two best-fit regression lines (Figure 1). The D_{O_2} at this critical point was 184 mL·m^{-2}·min^{-1} (4.9 mL·kg^{-1}·min^{-1}). The hemoglobin content at this critical point was 4.0 g/dL (Figure 2), with the oxygen extraction ratio 0.44, the mixed venous P_{O_2} 34 mm Hg, and the mixed venous oxyhemoglobin saturation 56%. The position of the oxyhemoglobin dissociation curve (ODC), corrected for changes in pH and P_{CO_2}, shifted to the right, but not before

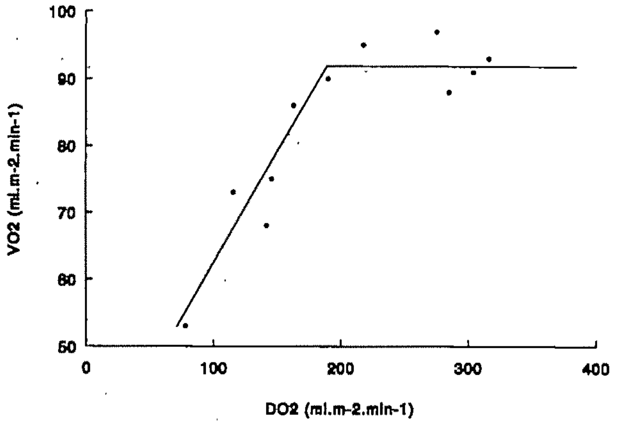

Figure 1. Relationship between oxygen delivery (Do_2) and oxygen consumption (Vo_2) during increasing hemodilution.

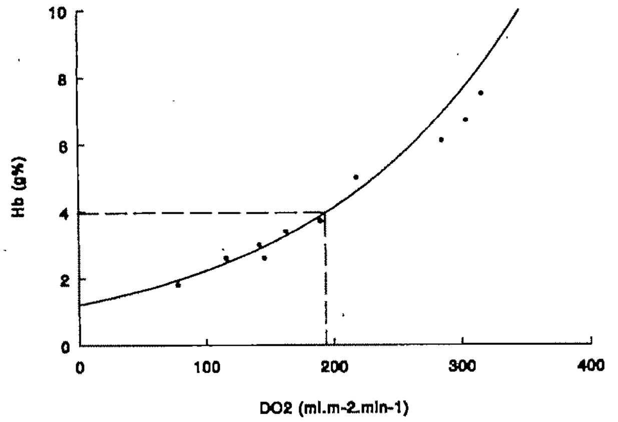

Figure 2. Relationship between oxygen delivery (Do_2) and hemoglobin (Hb) concentration with critical point of Do_2.

hematocrit was 8%. At a hematocrit of 8%, the mixed venous pH decreased, but the arterial pH did not. Twelve hours postoperatively, the patient died at a hemoglobin concentration of 1.6 g/dL.

Discussion

In the present case, values of several variables at the critical point of hemodilution at which Do_2-dependent Vo_2 starts could be recorded. There are no reports in the literature on the systemic oxygenation in humans at such a critical point of hemodilution. The point at which Vo_2 becomes dependent on Do_2 during hemodilution is not established in humans. In our anesthetized patient, Vo_2 started to decline at a Do_2 of 184 $mL \cdot m^{-2} \cdot min^{-1}$ (4.9 $mL \cdot kg^{-1} \cdot min^{-1}$). There are only a few reports concerning critical Do_2 in anesthetized cardiac patients in whom Do_2 was limited, not because of decreased arterial oxygen content but because of decreased cardiac output (5,6). In one study, Vo_2 decreased at Do_2 <330 $mL \cdot m^{-2} \cdot min^{-1}$ and in the other study at Do_2 <300 $mL \cdot m^{-2} \cdot min^{-1}$. The difference in critical Do_2 between our patient and those of the other reports can be easily explained. A decrease in Do_2 by decreased cardiac output of blood with normal hemoglobin content is often accompanied by even more decreased blood flow through the microcirculation, whereas during hemodilution, flows in the microcirculation are accelerated, owing to improved rheologic properties of blood (7). In animal studies, Cain and Chapler (8,9) found a critical Do_2 of 10 $mL \cdot kg^{-1} \cdot min^{-1}$ in anesthetized dogs during anemic hypoxia and when oxygen-supply dependency of Vo_2 started at a hematocrit of 10%. In another study in anesthetized dogs, a critical Do_2 of 7.9 $mL \cdot kg^{-1} \cdot min^{-1}$ was established (10). However, in anesthetized pigs, which are more closely related to humans anatomically and physiologically (11), during hemodilution at a Do_2 of 7.8 $mL \cdot kg^{-1} \cdot min^{-1}$ (the final step of hemodilution in the study protocol), we found that Vo_2 was still well maintained (12). In another pig study, in which the critical Do_2 was not discussed, a critical hemoglobin content (where oxygen supply-dependent Vo_2 started) of 3.9 ± 0.7 g/dL, similar to the present case, was found (13). In other pig studies we also found a critical hemoglobin concentration of 4.0 g/dL (14). In our patient, as in another study using the same anesthesia technique (1), Vo_2 and Do_2 decreased with the induction of anesthesia. Therefore, the values of Do_2 and Vo_2 before induction of anesthesia were not used in Figure 1 to establish the critical point of hemodilution. It is possible that if the patient had been conscious, a different critical level of hemodilution would have been found.

The position of the ODC, corrected for changes in pH and Pco_2, shifted to the right, but not before the hematocrit was 8%. There are no reports concerning the position of the ODC in humans during acute hemodilution, except reports of the ODC during chronic anemia. In two studies in humans, chronically reduced hemoglobin concentration is compensated by improved oxygen unloading, afforded by the shift to the right of the ODC (15,16). In one study in dogs, an acute change in ODC during acute hemodilution occurred but not before the hematocrit decreased below 10% (17), whereas in sedated pigs at every step of hemodilution, the ODC shifted to the right (11,18). In these pig studies, a close relationship was found between the shift in ODC and the decreased mixed venous Po_2 for corrected pH 7.4. Therefore, just as in our case, changes in ODC may play a role in oxygen delivery during acute hemodilution and especially, as stated previously (18,19), when oxygen reserves are minimal.

One might argue that from a single case no meaningful conclusions can be made. However, during the same stages of hemodilution (at the same hematocrit level), the cardiovasular responses to hemodilution of this patient were similar to those in another report on anesthetized humans (1), and this case might therefore be representative for anesthetized humans. Furthermore, the advanced age of the patient could have influenced the critical point of hemodilution. However, in a clinical study there were no differences found between young and elderly patients in hemodynamic compensatory mechanisms during hemodilution (20). Finally, it has been suggested that by calculating Vo_2, rather than measuring Vo_2, and using the same variable (e.g., cardiac output) for calculating Vo_2 and Do_2, the relationship between Do_2 and Vo_2 might be based on mathematic coupling. However, it has been stated that by keeping the range of the independent variables as large as possible (as in our patient), the effects of coupled error are excluded (21).

Insertion of the Laryngeal Mask Airway in Awake Infants With the Robin Sequence

Dorothea A. Markakis, MD, Samuel C. Sayson, MD, and Mark S. Schreiner, MD

Department of Anesthesiology and Critical Care Medicine, The Children's Hospital of Philadelphia, The University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania, and Brooke Army Medical Center, San Antonio, Texas

Since its development and description, the laryngeal mask airway (LMA) has gained rapid acceptance in Europe and Canada (1,2). The LMA has been slow to gain widespread use in the U.S. anesthesia community owing to the lack of availability and, possibly, the concern for risks incurred with the use of any mask airway, including aspiration and laryngospasm.

Apart from its use in patients with normal airway anatomy, several reports have been published advocating the LMA as an alternative to tracheal intubation in patients ranging from neonates to 9 yr of age with severe micrognathia (3–5). Infants with severe forms of the Robin sequence (also known as Pierre Robin syndrome) may present difficulties in maintaining a mask airway in addition to the challenge of tracheal intubation. On the basis of the reported success of the LMA in anesthetized children with micrognathia, we devised an approach for anesthetizing infants with the Robin sequence with severe micrognathia and airway obstruction. We proposed to insert the LMA in the *awake* infant and then to proceed to induce general anesthesia with the inhalation of halothane. This report is based on the first three patients in whom we utilized this approach.

Case 1

A 4.8-kg, 6-wk-old boy with the Robin sequence, a Dandy-Walker cyst, and recurrent airway obstruction was admitted for revision of a glossopexy originally performed at 4 wk of age. Maintenance of an adequate mask fit and patent airway proved difficult during the administration of the first anesthetic, and direct laryngoscopy had failed to provide visualization of the larynx. Oral tracheal intubation was accomplished using the modified lighted stylet technique described by Krucylak and Schreiner (6).

Subsequent anesthesia was managed as follows: preanesthetic medication consisting of oral atropine (0.02 mg/kg) was administered 30 min before induction of anesthesia. The awake infant's oropharynx was sprayed once with 2% lidocaine solution (~2 mg), and a No. 1 LMA lubricated with 2% viscous lidocaine (~4 mg) was inserted. The child tolerated insertion of the LMA well and neither coughed nor gagged but cried with the same intensity as he did when initially entering the operating room. Breathing was audible through the LMA, and auscultation confirmed bilateral breath sounds. After we induced anesthesia with 1.5% halothane in oxygen and demonstrated the ability to manually control ventilation, the patient was paralyzed with 0.1 mg/kg of intravenous vecuronium. The LMA was removed, and the infant's trachea was intubated on the first attempt using a modified lighted stylet.

This infant returned to the operating room 4 mo later for elective hernia repair. After inhaled induction of anesthesia, fiberoptic bronchoscopy was easily performed using the LMA as a guide, as previously described by Benumof (7) and by Maekawa et al. (8).

Case 2

A 3.4-kg, 5-wk-old girl with the Robin sequence associated with arthrogryposis presented for glossopexy after several weeks of trial management with a nasopharyngeal airway had failed to relieve her obstructive apnea. No preanesthetic medication was given. Topical application of 2% lidocaine solution (~2 mg) to the oropharynx preceded insertion of a No. 1 LMA lubricated with 2% viscous lidocaine (~4 mg) in the awake patient. Although the infant cried, the degree of distress appeared to be comparable to that expressed during the insertion of an orogastric tube in the awake child. A smooth inhaled induction of general anesthesia followed, with a mixture of 50% nitrous oxide and 0.5%–2% halothane in oxygen via the LMA. After demonstrating that we could manually control ventilation, intravenous vecuronium was used to facilitate neuromuscular relaxation. Although only the posterior arytenoids were visible with direct laryngoscopy and cricoid pressure, this proved sufficient for successful tracheal intubation. After extubation of the trachea, the patient required placement of a nasopharyngeal airway and application of continuous positive airway pressure to relieve airway obstruc-

tion. Three weeks later, the patient returned to the operating room for an elective tracheostomy because of persistent airway obstruction. The induction of anesthesia was identical to that just described. On this occasion, however, tracheal intubation required the use of the lighted stylet.

Case 3

A 2.9-kg, 16-wk-old girl with the Robin sequence associated with Stickler syndrome (progressive arthro-ophthalmopathy) was admitted for tracheostomy to relieve persistent airway obstruction. Stickler syndrome is the most common genetic cause of the Robin sequence and is associated with mandibular hypoplasia, progressive myopia, retinal detachment, and joint stiffness. A glossopexy performed 2 wk previously failed to relieve the infant's recurrent episodes of upper airway obstruction, even with the aid of a nasopharyngeal airway. During the previous anesthetic, the awake infant's trachea had been intubated under direct laryngoscopy. The anesthesiologist performing the intubation had not visualized the larynx but still successfully intubated the trachea using a styletted endotracheal tube.

Because of persistent severe airway obstruction and previous difficulty with tracheal intubation, we altered our approach. Oropharyngeal topical analgesia was accomplished with a single spray of 2% lidocaine solution (~2 mg). A No. 1 LMA lubricated with 2% viscous lidocaine (~4 mg) was inserted in the awake patient, who tolerated this, crying with breath sounds clearly audible through the LMA. We proceeded to induce general anesthesia while maintaining spontaneous ventilation with the inhalation of 1.5% halothane in oxygen. After demonstrating that we could manually control ventilation, the patient was paralyzed with intravenous vecuronium. Direct laryngoscopy again failed to allow visualization of the larynx, but this time an attempt at tracheal intubation was unsuccessful. The LMA was easily reinserted, and controlled ventilation was resumed. After removal of the LMA, the trachea was intubated using a lighted stylet.

Discussion

The Robin sequence represents a spectrum of anatomic anomalies the common features of which include mandibular hypoplasia, glossoptosis, and cleft palate. Four types of airway obstruction have been described in patients with the Robin sequence; in only 50% is the obstruction totally related to posterior positioning of the tongue (9). Therefore glossopexy will fail to relieve airway obstruction in approximately half of all symptomatic patients with the Robin sequence. This may explain why the use of an oral or nasopharyngeal airway alone may not improve an already difficult mask airway. Patients who fail to improve after glossopexy or nasopharyngeal airway placement, or both, usually require tracheostomy.

During inhaled induction of general anesthesia via a mask in infants and children with abnormal airway anatomy, as seen in Robin sequence, upper airway obstruction is usually anticipated, often encountered, and occasionally extremely difficult to manage. We have described three infants with severe airway obstruction unrelieved by placement of a nasopharyngeal airway. Insertion of an LMA while these infants were still awake secured a patent airway before the induction of general anesthesia. Once the infants were anesthetized, the anesthesiologist could calmly proceed with the task of tracheal intubation. Had the procedures been non-airway related, the LMA would have provided an alternative to tracheal intubation. Reinsertion of the LMA between attempts at tracheal intubation provided excellent airway control.

Visualization of the larynx may prove difficult or impossible in patients with the Robin sequence. Some of the approaches that have proved successful when conventional direct laryngoscopy has failed include direct laryngoscopy with an anterior commissure laryngoscope (10,11), fiberoptic bronchoscopy (7,8,12), and intubation with a lighted stylet (6). Over the past 2 yr, we have had consistent success with intubating the trachea of infants and children with severe micrognathia using a lighted stylet. In teaching this last technique to our less experienced colleagues, we insist that they become comfortable with this technique in healthy children >10 yr old before attempting it in healthy younger children and infants. Only in this fashion can one safely achieve successful intubation of the trachea in smaller patients with a complicated airway anatomy. Although older children can usually be safely sedated and intubated using the fiberoptic bronchoscope alone, in infants this may be more difficult. Bronchoscopes as thin as 2.2 mm in diameter are now available, making fiberoptic bronchoscopy through the LMA (7,8) a viable alternative for those less comfortable with the use of a lighted stylet.

It must be emphasized that all of the complications of mask anesthesia, including emesis and aspiration, can occur with the LMA. Although the most caudal tip of the LMA is positioned in the floor of the hypopharynx (Figure 1), this does not provide protection against active regurgitation. In one report, a patient undergoing a cholecystectomy aspirated stomach contents intraoperatively. This was detected only after removal of the LMA (13). In a second report, vomiting resulting in aspiration pneumonitis developed in a 74-yr-old man undergoing a hip arthroplasty using an LMA (14). The authors attributed the vomiting to inadequate depth of anesthesia. Regurgitated material can be more difficult to recognize when using the LMA; once discovered, the LMA and oropharynx should be suctioned and the LMA

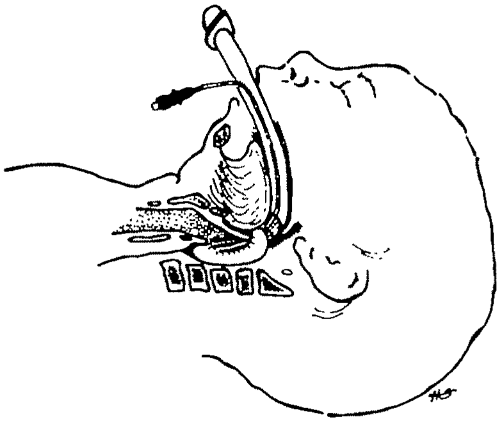

Figure 1. The laryngeal mask airway bypasses the soft tissue obstruction by surrounding the infant's larynx.

removed. The other potential complications of LMA, as seen in mask anesthesia, include laryngospasm, coughing, or breath holding. These complications were not seen in the infants reported here, perhaps because the LMA was inserted while the infants were still awake. Were laryngospasm encountered during the insertion of the LMA, we would recommend the use of succinylcholine and subsequent ventilation through the LMA, striving for a more adequate depth of anesthesia. Malposition of the LMA should be detected if breath sounds are not adequate or if there is a large air leak of the oropharynx.

The three infants cried when the LMA was inserted, but the level of stress appeared comparable to the insertion of an orogastric or nasogastric tube in an awake infant. The infant's reaction did not, therefore, prevent a smooth induction of anesthesia. Although we used both lidocaine solution spray and viscous lidocaine as a lubricant to provide topical anesthesia to the pharynx, it is not clear that both were necessary. To avoid potentially toxic doses of lidocaine in infants, the LMA lubricant might best be lidocaine free, using lidocaine spray alone for topicalization.

One could argue that the use of a shorter acting muscle relaxant than vecuronium might be preferable; however, this might not afford the time occasionally required to intubate using either the lighted stylet or the fiberoptic bronchoscope. Our choice of an intermediate-acting nondepolarizing relaxant reflected our confidence in having secured and confirmed a patent airway before the induction of general anesthesia, our ability to control ventilation after the induction of anesthesia, and our confidence in our ability to easily replace the LMA once it had been removed.

We have demonstrated that in infants with the Robin sequence and severe airway obstruction, the LMA allows a smooth transition from the awake, spontaneously breathing state to the anesthetized state while avoiding episodes of airway obstruction in the interim. After ensuring the ability to provide adequate positive pressure ventilation, neuromuscular blockade can be used if desired. With the patient well ventilated, anesthetized, and paralyzed, optimal conditions exist for successful, atraumatic tracheal intubation.

Extracorporeal Membrane Oxygenation for Perioperative Support During Congenital Tracheal Stenosis Repair

L. Kyle Walker, MD, Randall C. Wetzel, MB, BS, FCCM, and J. Alex Haller, Jr., MD

Departments of Anesthesiology/Critical Care Medicine, Pediatrics, and Pediatric Surgery, The Johns Hopkins Medical Institutions, Baltimore, Maryland

Extracorporeal membrane oxygenation (ECMO) is routinely used for cardiopulmonary support in a wide variety of neonatal diseases, such as meconium aspiration syndrome, respiratory distress syndrome, persistent pulmonary hypertension, sepsis syndrome, and severe pneumonia. Extracorporeal membrane oxygenation is also potentially useful as a component of preoperative care for infants with profound respiratory failure and surgical lesions such as congenital diaphragmatic hernia (1). We recently used ECMO intraoperatively to support a baby with congenital tracheal stenosis (CTS) and continued using ECMO during the postoperative period to avoid trauma to the tracheal anastomosis. Extracorporeal membrane oxygenation was continued for 7 days, after which the patient was safely returned to mechanical ventilation. This hybrid approach is similar to that used in patients with unrepaired congenital diaphragmatic hernia (2).

Neonatal CTS, which presents with severe symptoms in the first days of life, has a high mortality (44%–79%), and sudden death is common (3,4). If the lesion is near or includes the carina or involves >50% of the trachea, repair is both difficult and dangerous. A variety of surgical approaches have been used. The surgical repair of choice is primary tracheal resection and anastomosis (5). Most surgeons believe that up to 50% of the length of the infant trachea can be primarily resected (1). Where the lesion involves >50% of the trachea, tracheal reconstruction has been performed using a variety of materials to fill the defect, including costochondral grafts (3,6), pericardium (7), and esophagus (4).

Regardless of the method of repair, providing ventilation and oxygenation during surgical correction of the trachea is one of the anesthesiologist's greatest challenges. If an endotracheal tube can be advanced through the area of stenosis to the carina or into one lung, ventilatory support can be maintained in a traditional fashion. This is often fraught with technical difficulties and a significant risk of hypoxia, hypercarbia, and neurologic sequelae (1). When the airway cannot be dependably secured, management alternatives include the use of cardiopulmonary bypass (CPB) to maintain CO_2 removal and oxygenation (4,5,7) or jet ventilation (8). Traditional CPB requires a median sternotomy with placement of aortic and right atrial catheters. Patients must undergo heparinization so that extracorporeal circuitry can be used without clotting. In addition, standard CPB cannulation further complicates the surgical approach with large catheters in the operative field. Even if the operation goes smoothly, postbypass ventilation may be difficult or unsuccessful. Recently, in a baby with CTS, we elected to use ECMO to provide perioperative ventilatory support. A form of extracorporeal support was chosen because the pinpoint stenosis was at the carina, and a mainstem bronchus could not be safely intubated. Extracorporeal membrane oxygenation provided secure intraoperative gas exchange and assured a stable postoperative period while minimizing barotrauma and mechanical trauma to the anastomosis.

Case Report

A 2.5-kg full-term infant was twin A, delivered by elective cesarean section at 38-wk gestation. She had Apgar scores of 8 at 1 min and 9 at 5 min. Respiratory distress rapidly developed in the delivery room, with gasping respirations, grunting, and cyanosis. The baby was transferred to the neonatal intensive care unit and the trachea was intubated with a 3.5-mm endotracheal tube. Arterial blood gas revealed pH 6.98, P_{CO_2} 108 mm Hg, P_{O_2} 69 mm Hg, 0.35 fraction of inspired oxygen (F_{IO_2}) ventilatory pressures of 22/3 cm H_2O, and intermittent mechanical ventilation of 60 breaths/min. A chest radiograph before intubation showed hypoinflation. After intubation, marked bilateral hyperinflation with hyperlucent lung fields and flattened dia-

igure 1. Chest radiograph soon after birth, showing the marked yperinflation of the lungs with flattening of the diaphragms. Vhat is also remarkable is the lack of tracheal shadow from the end f the endotracheal tube to the appearance of the mainstem ronchi.

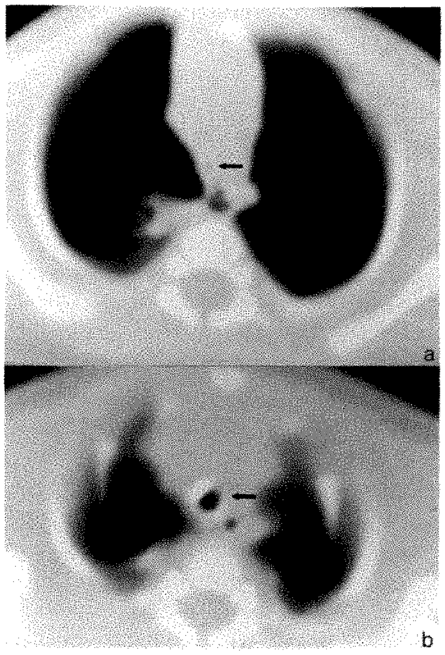

Figure 2. a. Computed tomography scan view showing the narrowed trachea just at the carina (*arrow*). In contrast, just posterior to the trachea is the esophagus with a 5F feeding tube. **b.** Normal trachea just distal to the end of the endotracheal tube (*arrow*). Again, for contrast, just posterior to the trachea is the 5F feeding tube in the esophagus.

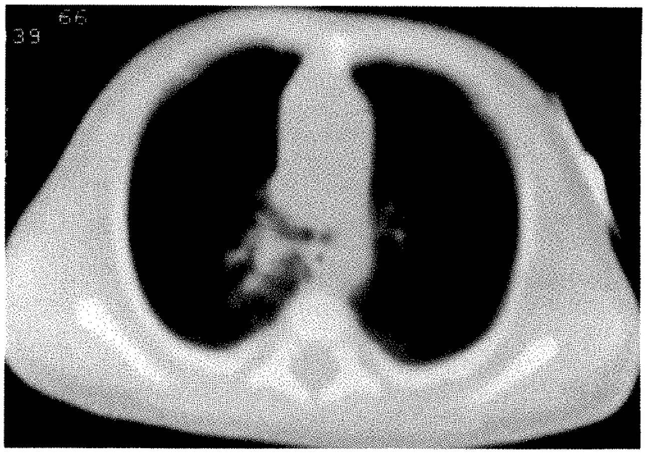

Figure 3. Computed tomography scan view shows the normal caliber mainstem bronchi just distal to the carina.

hragms was evident (Figure 1). Numerous ventilator ianipulations and reintubation with a 4.0-mm endotraheal tube were unsuccessful in resolving the hypercarbia nd hyperinflation.

Bronchoscopy on day 3 of life revealed severe distal acheal stenosis with circumferential narrowing that did ot admit a 3-mm bronchoscope. A high-resolution comuted tomography scan showed a 1.5-cm segment of cirumferential tracheal narrowing approximately 1 mm in iameter, without cartilaginous rings, that extended to the arina but did not appear to involve the mainstem bronchi igure 2). Both mainstem bronchi appeared to be of normal ize just after their origin (Figure 3). An echocardiogram as performed that showed no structural heart disease, nd an ultrasound examination of the brain revealed no emorrhage or structural abnormalities. In the 24 h before urgery, there was a need for increased FIO$_2$ to 0.4. The hest radiograph remained clear, but the lungs were hyperflated.

Because of the location of the stenotic lesion and the aliber of the trachea (1–2 mm), intraoperative extracorpoeal circulation was chosen to facilitate operative repair. enoarterial (VA) ECMO was chosen because it allowed e use of extracorporeal support without a median sternomy and bulky cannulas in a small (2.5 kg) infant. Extrarporeal membrane oxygenation also allowed the use of orter activated clotting times (ACTs) than CPB and alwed the operative repair to be performed from a supraavicular approach without thoracotomy or sternotomy. In ddition, ECMO provided the option of postoperative pport.

The infant was positioned with cervical hyperextension, lowing easy visualization of the trachea. Anesthesia was rovided by 20 μg/kg of fentanyl and muscle paralysis with 0.3 mg of pancuronium bromide. Ventilation was maintained with a Mapelson D circuit and FIO$_2$ was titrated to maintain 95% arterial saturation. End-tidal CO$_2$ monitoring (Raman spectroscopy, aspiration from a distal endotracheal tube) and pulse oximetry saturation were used to guide hand ventilation and FIO$_2$. Careful dissection using meticulous electrocoagulation allowed mobilization of the trachea and identification of the area of tight stenosis. The right common carotid artery and right internal jugular vein were isolated and prepared for cannulation with the ECMO catheters, which were eventually inserted posterior to the sternocleidomastoid muscle. The catheters exited from the primary surgical incision, because making separate stab wounds would increase the likelihood of postoperative bleeding on ECMO. The catheters were compartmentalized from the site of the surgical repair by the sternocleidomastoid muscle. The distal trachea was widely mobilized to visualize the mainstem bronchi. The baby underwent heparinization with 100 U/kg of sodium heparin. The ECMO catheters (BioMedicus, Eden Prairie, Minn.), an 8F arterial and 10F venous, were placed and the position verified by chest radiograph. Venoarterial ECMO support was initiated and stabilized over 15 min. Ventilation through the endotracheal tube was discontinued. The endotracheal tube remained in place, well above the area of repair.

Anesthesia was supplemented with 20 μg/kg of fentanyl, 0.5 mg of midazolam, and an additional 0.5 mg of pancuronium bromide. A heparin infusion was adjusted to maintain ACTs of 180–200 s using the Hemochron (International Technidyne Corporation, Edison, N.J.) system. The platelet count was 160,000/mm^3 before beginning CPB. Aggressive transfusion was used to maintain the platelet count between 150,000 and 200,000/mm^3 to minimize bleeding. Extracorporeal membrane oxygenation flows were maintained at 80 mL·kg^{-1}·min^{-1}. This flow maintained a stable venous saturation of 70% and normalized arterial blood gases. In neonatal ECMO support for respiratory failure, 80–120 mL·kg^{-1}·min^{-1} generally provides excellent gas exchange support without native pulmonary function (9). The stenotic area of trachea was resected, and primary anastomosis was successfully completed. During the repair, the baby remained hemodynamically stable without CO_2 retention, hypoxemia, or acidosis.

The baby was returned to the pediatric intensive care unit on ECMO with continuous positive airway pressure of 5 cm H_2O without ventilation. Extracorporeal membrane oxygenation was continued for 7 days. The baby underwent elective flexible bronchoscopy twice during ECMO to document the patency and stability of the anastomotic site and to remove tenacious secretions that transiently occluded the trachea, resulting in bilateral atelectasis. Blind, deep tracheal suctioning was avoided to minimize trauma to the anastomosis. The endotracheal suction catheters were passed only to the end of the endotracheal tube during routine suctioning. The postoperative course was complicated by large, bilateral pleural effusions that required pleurocentesis just before discontinuing ECMO. Extracorporeal membrane oxygenation was discontinued on the seventh postoperative day, when bronchoscopy revealed a well-healed, open tracheal anastomosis. The operative incision was without bleeding until the last 12–24 h of ECMO. There were no signs of wound infection. Prophylactic antibiotic coverage with oxacillin and gentamicin was maintained during ECMO. There were no episodes of desaturation or hemodynamic instability during ECMO. Eight months after repair, the infant remains dependent on ventilatory support because of tracheomalacia.

Discussion

Neonatal CTS is a life-threatening disease, particularly if it involves a long segment. Before the 1980s, severe tracheal stenosis was nearly always fatal (8). In most recent reports, mortality remains high despite the many surgical advances in therapy (3,4). If the lesion is near or involves the carina, the repair is technically much more difficult. In infants with early symptomatology, the risk of sudden death from tracheal obstruction is significant (3,4), and many survivors have profound neurologic injury as a result of hypoxic insults before or during repair (1,3,8).

Because of the distal location of this stenotic lesion and the degree of carinal involvement, we believed that ventilation through the airway would be extremely difficult, potentially impossible, and would technically complicate the surgical repair. Extracorporeal support greatly facilitated the repair and provided postoperative support. A median sternotomy with intrathoracic catheters for standard CPB would have exposed this small infant (2.5 kg) to added risk and contributed to a crowded operative field. Because extracorporeal support could be easily accomplished through the cervical incision using VA ECMO, this approach to intraoperative support was attractive, albeit unique. Other potential benefits of ECMO included (a) lower heparin requirement for heparinization than CPB, with decreased risk of bleeding; and (b) the option of providing extracorporeal support postoperatively allowed potential protection of the anastomosis from the stresses of mechanical ventilation and suctioning during the early postoperative period.

The major complications of ECMO are neurologic injury, bleeding, embolism, and sepsis. Neurologic injury is related to cannulation and ligation of the common carotid artery and internal jugular vein and bleeding and embolism during bypass. Acute VA ECMO with vessel ligation is generally well tolerated by critically ill infants in severe respiratory failure. Follow-up studies in infants supported with ECMO have shown that developmental outcome is similar to that seen in infants with serious respiratory failure treated conventionally (10). Two extensive neuroimaging follow-up series of neonates who required support with ECMO have failed to demonstrate any difference in the numbers of right-sided (ligated) versus left-sided (unligated) intracranial lesions (11,12). Those infants may, however, have suffered pre-ECMO neurologic injury due to an underlying disease process that required ECMO. One would expect VA ECMO to be better tolerated in an infant without antecedent hypotension or hypoxia. There are alternative sites and strategies for ECMO that include venovenous support or alternative sites for arterial cannulation. It is difficult to provide good oxygenation with venovenous ECMO without some pulmonary contribution, which has made it a less than satisfactory form of support for the operative procedure. In an infant of this size (2.5 kg), other arterial sites are too small. A recent report (13) describes the use of a side-sewn carotid patch that does not require carotid ligation and was described as easily repaired. This could be considered an option.

Risks of prolonged ECMO support include hemorrhage from continued use of heparin, risks of thrombi or emboli from long-term arterial infusion, and infection from continued maintenance of catheters near the operative site. The risk of hemorrhage in this case was greatest at the time and site of surgical repair. The ACTs were maintained in the 180–200-s range, and aggressive postoperative transfusion of platelets achieved an elevated platelet count of 150,000/mm^3 to minimize this risk. The thrombotic or embolic risk is real, but with meticulous care, many hours of prolonged bypass can be performed without incident (14). To prevent or minimize the risk of infection, the perfusion catheters were separated from the operative incision by compartmentalization with the sternocleidomastoid muscle. Prophylactic antibiotics (oxacillin and gentamicin) were also administered.

Intraoperative anesthetic care consisted of routine monitoring for neonatal surgery, including an arterial cannula (15). In addition, ECMO flows and arterial blood gases, as well as ACTs and heparin infusion rates, required meticulous attention. Fentanyl analgesia was titrated to hemodynamic status. Although ECMO patients show rapid development of fentanyl tolerance, this is generally not evident at the initiation of ECMO (16). Standard doses of fentanyl and muscle relaxants can be used, but as bypass is initiated, there is a decrease in plasma opiate levels, and one must be prepared to supplement analgesia as indicated (17). Hemodynamic instability, hypotension or hypertension, and myocardial "stun" manifested as depression of pulsatility can all occur after the initiation of ECMO. Thus, the hemodynamic status requires careful observation and adjustment of ECMO flows. Full, stable ECMO support should be achieved before surgery proceeds.

Initiation of ECMO support and surgical repair were successfully completed with a primary anastomosis of the carinal cuff to the prestenotic trachea. The child was returned, on ECMO, to the pediatric intensive care unit. During the next 7 days, the infant was easily supported on low continuous positive airway pressure (6–7 cm H_2O). Positive pressure ventilation was completely avoided for the first 48 h and then instituted at 5 breaths/min with a pressure limit of 15 cm H_2O to minimize barotrauma to the tracheal anastomosis. Elective bronchoscopy to monitor the site of anastomosis and clear secretions was easily accomplished using a 3-mm flexible bronchoscope. Extracorporeal membrane oxygenation was discontinued on day 7, when the anastomosis was noted to be open and healing well. The lungs were well expanded after thoracentesis. The decision to discontinue support at day 7 was based on two factors. First, a healthy, healing anastomotic site was seen on bronchoscopy; and second, the first evidence of bleeding was observed (1–2 $mL \cdot kg^{-1} \cdot h^{-1}$) from the suprasternal incision. If some bleeding had not begun, we might have considered extracorporeal support for a slightly longer period to assure maximal anastomotic healing.

In this child, ECMO was chosen instead of traditional CPB because median sternotomy and intracardiac cannulation could be avoided, less heparinization was possible, and prolonged (several days) postoperative support could be provided. The prolonged postoperative support was the most significant issue. It was clear that this baby would require mechanical ventilatory support postoperatively. We believed that the benefits of low continuous positive airway pressure without the need for intermittent positive pressure ventilation would enhance anastomotic healing, owing to less stress and tension on the suture line.

In conclusion, intraoperative ECMO provided a safe, controlled method of intraoperative respiratory support while optimizing surgical conditions. In this child with paracarinal CTS, ECMO also provided postoperative support to enhance tracheal healing and pulmonary recovery.

Management of a Difficult Airway in a Patient With Hurler-Scheie Syndrome During Cardiac Surgery

Susan Craig Nicolson, MD, Ann E. Black, MB, BS, and Christine M. Kraras, MD

Department of Anesthesiology and Critical Care Medicine, The Children's Hospital of Philadelphia and The University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania

---

The mucopolysaccharidoses (MPS) are a heterogeneous group of clinically progressive inherited diseases characterized by excessive storage of mucopolysaccharides leading to organ dysfunction and anatomic abnormalities. Even though the MPS are rare disorders, their disabling and progressive nature involves frequent surgical intervention, which is accompanied by an increased risk of perioperative complications, many related to the anesthetic. The major features of these syndromes that have anesthetic implications include progressive airway, craniofacial, and skeletal abnormalities and developmental delay (1–5). We present the use of extracorporeal circulation as an alternative method for managing a known difficult airway in a patient with MPS scheduled for open heart surgery.

Case Report

A 20-yr-old man with Hurler-Scheie syndrome (MPS type V) was scheduled for aortic and mitral valve replacement because of stenosis of both valves. Mucopolysaccharide deposition had required balloon valvotomy of the mitral valve and of both valves 5 and 1 yr, respectively, before surgery. Progressive exercise intolerance, chest discomfort, and dyspnea prompted repeat cardiac catheterization, which demonstrated an aortic valve gradient of 100 mm Hg with a pulmonary artery pressure of 48/36 mm Hg and wedge pressure of 32 mm Hg. The patient reported progressive airway obstruction during sleep over the 4 yr before surgery. Nasal continuous positive airway pressure (10 cm H_2O) and sleeping in the sitting position improved airway patency. The patient had undergone two previous surgical procedures for which he received a general endotracheal anesthetic: an inguinal herniorrhaphy in infancy and an Achilles tendon release at age 6 yr. A carpal tunnel procedure at 9 yr was abandoned because of an inability to intubate the trachea following induction of anesthesia. A subsequent corneal transplant, as well as the balloon valvotomies, was performed with sedation with the patient in the semirecumbent position. Preoperative physical examination revealed an alert, cooperative man with normal mental status who weighed 37 kg and whose height was 127 cm. Arterial blood pressure was 105/70 mm Hg, heart rate was 60 bpm, respiratory rate was 30 breaths/min, and peripheral arterial oxygen saturation measured by a pulse oximeter sensor while breathing room air was 96%. Evaluation of his airway demonstrated a mental to hyoid distance of 1.5 finger breadths, macroglossia, restricted motion of his tempromandibular joints and neck, redundant pharyngeal tissue, and tonsilar hypertrophy.

The patient was orally premedicated with atropine (0.02 mg/kg). After placement of peripheral venous and radial arterial catheters, electrocardiogram leads, and a pulse oximeter sensor, a topical laryngeal block was performed using 4% lidocaine. Two unsuccessful attempts, one via the oral and the other via the nasal route, were made to place an endotracheal tube using a fiberoptic bronchoscope with the patient in the sitting position. Anesthesia was then electively induced with intravenous ketamine (2 mg/kg) and the patient was placed supine. With the patient breathing 100% oxygen via a face mask delivering 10 cm of positive pressure, the right groin was infiltrated with local anesthetic and arterial and venous bypass cannulas were placed in the patient's femoral artery and vein. Cardiopulmonary bypass was instituted using a pump priming volume containing pancuronium (0.2 mg/kg), fentanyl (75 μg/kg), and scopolamine (0.01 mg/kg), after which the heart was exposed via a median sternotomy. Hypothermic circulatory arrest was begun once the patient was cooled to a rectal temperature of 20°C, during which time both valves were excised and replaced. A number of experienced anesthesiologists made several attempts using all available modalities (variety of laryngoscope blades, anterior commissure laryngoscope, lightwand, fiberoptic bronchoscope, blind nasal) to intubate the trachea without success by the time of rewarming after completion of the surgery. A decision had been made for the surgeon to introduce a 75-cm, 0.045-mm wire into a small incision in the thoracic trachea and pass it cephalad to exit the nose. After failing to pass a 6.0-mm cuffed tube, a 5.0-mm uncut cuffed endotracheal tube was guided over the wire and, while keeping the wire taut, the tube was

advanced into the trachea. Visual inspection of lung expansion enabled identification of the carina. The tube was then placed 2 cm proximal to the carina and the cuff inflated. The patient was successfully weaned from bypass and transferred to the intensive care unit where the postoperative chest radiograph showed the nasotracheal tube to be in proper position. The endotracheal tube remained in place, with no attempt made to extubate the trachea for the next 3 days, at which time the patient died for reasons unrelated to his airway.

Discussion

This case illustrates an alternative method for managing a difficult airway in a patient having cardiac surgery with extracorporeal circulation. After preoperative identification of a problematic airway, a plan is devised for the patient to maintain spontaneous ventilation until institution of bypass. Once the patient is on bypass, oxygenation and ventilation are assured and attempts can be made to secure the airway with an endotracheal tube. This approach when properly executed eliminates the potential for inadequate oxygenation and/or ventilation and hemodynamic compromise when placing an endotracheal tube in a patient with a difficult airway. Consideration must be given to the potential risks associated with this technique, including loss of the airway before institution of bypass if sedative medications are used, airway manipulation in an anticoagulated patient, and inability to place an endotracheal tube after institution of bypass. The history of inability to intubate this patient's trachea, the inability of the patient to lie flat without acute dypsnea and upper airway obstruction, and the undesirability of tracheostomy called for careful and innovative management. An anesthetic plan was constructed recognizing that this patient was to undergo surgery requiring cardiopulmonary bypass. A minimal number of attempts to intubate the topicalized airway using conventional modalities were planned while the patient was awake, thus minimizing both trauma to the airway and alterations in hemodynamics. Recognizing that tracheal intubation via this route was not likely to be successful, consideration was given to attempting a technique that had previously been used in a patient with MPS: placement of the tube over a wire inserted into the larynx via the cricothyroid membrane which was passed retrograde (5). Distortion of the anatomy did not allow distinct identification of the cricothyroid membrane in this patient. The intent was to administer medication to allow the patient to lie flat cooperatively while breathing spontaneously during placement of the bypass cannulas in the groin. Ketamine, in a dose of 2 mg/kg, was chosen as it had met similar goals when used in the same dose in this patient during cardiac catheterizations. Institution of cardiopulmonary bypass would then enable additional attempts to intubate the trachea with no stress to the cardiovascular system while oxygenation and ventilation were guaranteed. Recognizing that, despite ideal conditions, the anatomic abnormalities of the airway might preclude both oral and nasal intubation, an attempt would be made to place an endotracheal tube over a wire inserted into the thoracic trachea and passed retrograde. Tracheostomy, although not desirable because of the proximity of the stoma to the fresh median sternotomy, would secure the airway before weaning from bypass if all other routes failed.

Accumulation of mucopolysaccharides in the soft tissue of the oropharynx, the epiglottis, aryepiglottic folds, and tracheal wall, coupled with the presence of a short neck, predispose these patients to anatomic abnormalities of the airway, tracheal rigidity, and a reduced cross-sectional area. This explains the high incidence of perioperative airway problems, some fatal, reported in these patients. King et al. (3) reported one or more airway problems (difficulty visualizing the cords, inability to pass an age-appropriate tube, and airway obstruction) in all but one of eight pediatric patients between 1 and 16 yr of age with MPS receiving an anesthetic. Baines et al. (2) retrospectively reviewed the anesthetic management of 16 patients with MPS undergoing 50 surgical procedures under general anesthesia. Eight patients had airway difficulty during one or more of their procedures. The trachea of one child could not be intubated. One patient's trachea was successfully intubated only during a respiratory arrest that followed a failed elective intubation, and one patient had an elective tracheostomy under local anesthesia. Kempthorne and Brown (5) examined the airway problems encountered in nine children anesthetized for 20 surgical procedures. In addition to confirming the high incidence of airway problems, 65% in this series, their review suggested that airway problems increase with increasing patient age, a finding that is consistent with the progressive nature of these diseases.

Cardiac involvement in patients with Hurler-Scheie syndrome is limited to the coronary arteries and valves and most commonly presents with signs of valvular insufficiency or stenosis. The pattern of valve involvement is the same as that which follows rheumatic fever. The mitral valve is most frequently affected, followed by the aortic and tricuspid with nearly equal frequency. Although a case could be made for avoiding the use of ketamine in patients with aortic stenosis, it was chosen to induce anesthesia in this patient, as it had been used during the recent cardiac catheterization with no adverse hemodynamic effects.

Faced with a patient with a known difficult airway scheduled for surgery requiring cardiopulmonary bypass, consideration should be given to establishing bypass and then securing the airway.

Perioperative Management of Neonatal Ectopia Cordis: Report of Three Cases

James H. Diaz, MD, MHA

Departments of Anesthesiology and Pediatrics, Ochsner Clinic and Alton Ochsner Medical Foundation; and Department of Anesthesiology, Tulane University School of Medicine, New Orleans, Louisiana

Ectopia cordis or heterotopic heart (1) is a rare congenital cardiac anomaly (<0.1% of all congenital heart defects) that has often defied successful surgical repair because of the magnitude of the chest deformity and its associated anomalies, particularly intracardiac defects and omphaloceles (1,2). An increased awareness of ectopia cordis is now indicated, as the early ultrasound diagnosis of the defect can often be made in utero (2). Although the surgical treatment of ectopia cordis continues to be improved and refined (2), the surgical outcome remains dismal, and survivors are rare. Continued advances may, however, soon improve final outcomes for neonates with ectopic hearts. Three cases of ectopia cordis managed at our institution over the past 8 yr are reported. A synopsis of each infant's immediate preanesthetic cardiopulmonary status and any major therapeutic interventions carried out before initial surgery is presented in Table 1. A current classification system for ectopia cordis is also presented (Table 2), associated congenital anomalies are reported (Table 3), and techniques of perioperative management are reviewed (1,2).

Case Reports

Case 1

A 2495-g female neonate delivered vaginally at 38-wk gestation had Apgar scores of 2 at 1 min and 2 at 5 min. An extrathoracic heart with intact anterior abdominal wall had been recognized and was covered with saline-soaked sterile dressings for transfer of the infant to our institution shortly after birth. Direct echocardiography suggested a double-outlet right ventricle with large ventricular septal defect. Within 4 h of birth, the infant was anesthetized with intravenous fentanyl and pancuronium for surgical coverage of the extrathoracic heart. Surgical attempts to reposition the ectopic heart within the thorax were carried out unsuccessfully for the next 4 h. Orthotopic cardiac repositioning produced cardiac tamponade with bradycardia and hypotension, so a synthetic silo was used to cover the exposed heart without producing cardiac tamponade. During transport to the neonatal intensive care unit, the infant developed sudden bradycardia with hypotension that was refractory to cardiopulmonary resuscitation. A transvenous pacemaker did not restore sinus rhythm, and the infant died 8 h after birth. Chromosomal karyotyping was not performed.

Case 2

A 3900-g female neonate with Apgar scores of 5 at 1 min and 7 at 5 min was delivered at 40-wk gestation by emergency cesarean section because of persistent fetal bradycardia in the breech presentation. An anterior thoracoabdominal defect with extrathoracic heart and omphalocele was recognized at birth (Figure 1). At age 16 h, the infant was anesthetized with fentanyl and pancuronium for surgical coverage of thoracoabdominal defects. Each attempt at orthotopic cardiac repositioning caused asystolic cardiac arrest. Sinus rhythm and blood pressure were restored by internal cardiac massage and intravenous therapy with atropine, calcium chloride, sodium bicarbonate, and epinephrine. As the heart and omphalocele could not be reduced and covered primarily, a Silastic silo was tacked to the skin edges to cover the external heart and omphalocele. Synthetic coverage of the defects also triggered cardiac arrest that responded to repeated resuscitative measures as described. The silo was removed, and extensive skin flaps were undermined, raised circumferentially about the defects, and loosely reapproximated without complete closure of the thorax and abdomen. Thirteen hours postoperatively, the patient developed bradycardia with hypotension unresponsive to cardiac massage and resuscitative drugs. The infant died 27 h after birth. Chromosomal karyotype was 46 XX.

Case 3

A 29-yr-old primigravida was referred to our institution at 34 wk of pregnancy after sonographic diagnosis of extrathoracic heart and associated omphalocele. On the day after admission, a 1940-g male neonate with Apgar scores of 2 at 1 min and 4 at 5 min was delivered by primary cesarean

section under general endotracheal anesthesia. A large ventral wall defect containing the heart, the liver, and small bowel loops was recognized. Echocardiographic evaluation demonstrated an intact sternum; a large omphalocele containing the heart, liver, spleen, and small bowel loops; a double-outlet right ventricle; a large ventricular septal defect; valvular pulmonic stenosis; a patent foramen ovale; total anomalous pulmonary venous return; and an absent pericardium. In addition, the heart was noted to be prolapsed through a large midline defect in the diaphragm. Chromosomal karyotype was 46 XX. High-frequency ventilation with 100% inspired oxygen therapy was instituted for progressive respiratory failure with chronic hypoxemia. On the fifth day of life, the infant developed asystolic cardiac arrest and was not resuscitated.

Discussion

With the increasing use of real-time sonography in obstetrics, the diagnosis of ectopia cordis will be made more frequently in the prenatal period (case 3) (2–5). The prenatal diagnosis of ectopia cordis should stimulate a vigorous sonographic search for other associated anomalies, particularly omphaloceles and craniofacial defects such as microcephaly and hydrocephalus (3–5).

The etiology of ectopia cordis is unknown. A weak association with trisomy 18 (one case) has been suggested, and chromosomal karyotyping is now recommended in all cases to improve genetic coun-

Table 3. Specific Anomalies Associated With Ectopia Cordis in Order of Frequency of Occurrence[a]

Sites of anomalies			
Craniofacial	Chest wall	Intracardiac	Abdominal wall
Microcephaly	Cleft sternum	Septal defects	Omphalocele
Hydrocephalus	Bifid sternum	Outflow tract obstructions	Diastasis recti
Cleft palate	Absent sternum	Cardiac diverticuli	Gastroschisis
Cleft lip		Double-outlet right ventricle	
Anencephaly		Anomalies of caval and pulmonary venous return	
Neural tube defect		Transposition of the great arteries	
		Aortic coarctation	
		Truncus arteriosus

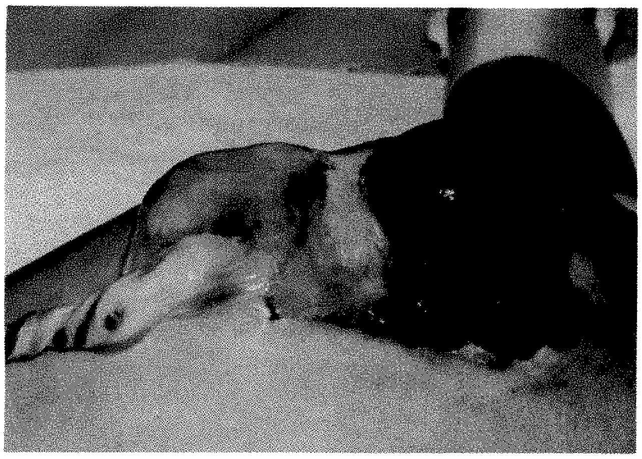

Figure 1. Twelve-hour-old neonate with complete thoracic ectopia cordis and bifid sternum with the entire heart exposed (case 2). Note prominent right and left auricular appendages or diverticuli and associated omphalocele with attached umbilical cord. The right arm is extended for radial artery cannulation (top of photograph).

seling (3,5). Omphalocele and ectopia cordis may both result from the failure of timely fusion of the cephalic anterior body folds and are commonly associated anomalies (6). Some anterior fusion defects and some forms of ectopia cordis may also be caused by the amniotic band syndrome (6).

Early plans may now be made for cesarean delivery of the fetus with ectopia cordis amenable to surgical palliation or repair (2). Vaginal delivery could cause prolonged cardiac compression, damage herniated viscera, or rupture atrial diverticuli or omphalocele sacs (2). After atraumatic abdominal delivery, the neonate with ectopia cordis, omphalocele, and correctable intracardiac anomalies may be considered for staged postnatal repairs (1,2,7). If, however, prenatal echocardiography shows uncorrectable intracardiac lesions, consideration should be given to elective termination of pregnancy in the first or early second trimester (1,3–5,7).

Immediate treatment of an infant with ectopia cordis should begin at birth and consists of covering the lesion with saline-soaked gauze pads and gently wrapping the thorax and trunk circumferentially to prevent heat loss and desiccation of the ectopic heart and omphalocele, if present (2,4). No pressure should be applied over the extrathoracic heart as any compression might reduce venous return to the heart, reduce cardiac filling, and decrease cardiac output. Compression of the omphalocele sac should also be avoided as it may force herniated viscera into a limited abdominal cavity, elevating the hemidiaphragms and restricting alveolar ventilation (8).

After emergency management, more complete preoperative evaluation can be undertaken, such as computerized axial tomography to evaluate thoracic volumes and capacities (6) and echocardiography to confirm the presence or absence of commonly associated intracardiac defects (6) (Table 2). In hemodynamically stable neonates, the extrathoracic heart should then be quickly covered with skin flaps or a synthetic silo or chimney to prevent further fluid loss and cardiac desiccation and to provide soft tissue or synthetic protection of the exposed heart and any associated atrial diverticuli easily ruptured by minor trauma (4).

In a 1982 report, Harrison et al. (2) immediately applied an adherent plastic drape over an intact omphalocele sac in a newborn with thoracoabdominal ectopia cordis. Progressive ligation of the plastic-reinforced sac allowed the omphalocele contents to be gradually reduced by gravity and progressive replacement (2). After temporary coverage of the defect, diagnostic work-up can continue with cardiac catheterization and angiography. Following complete cardiac evaluation after temporary coverage of thoracoabdominal defects, Harrison et al. (2) recommended correction of intracardiac lesions before extensive reconstruction of the chest and abdominal wall, pericardium, and diaphragm. Such extensive operations appear to be poorly tolerated in infants with giant omphaloceles and congenital heart defects (2).

Intraoperative anesthetic management (cases 1 and 2) requires neuromuscular paralysis, controlled hyperventilation for respiratory acidosis, avoidance of high mean airway pressures that could impede biventricular outflows, high inspired O_2 concentrations to improve blood and tissue oxygenation in cases characterized by low cardiac output syndrome and tissue ischemia, and avoidance of nitrous oxide which could distend bowel trapped in omphaloceles. In addition, the hemodynamic instability produced by heart and great vessel dissection contraindicates inhaled anesthetic agents that could promote further myocardial depression in neonates already compromised by extensive fluid losses from herniated viscera, and by respiratory and metabolic acidosis from alveolar hypoventilation and low cardiac output syndrome, respectively. Opiates and ketamine are often the only anesthetics that can be safely used.

Extensive intraoperative monitoring is required, including direct blood pressure measurement by intraarterial cannulas and bladder catheterization for accurate urine outputs. Direct blood pressure measurement by right radial artery cannula is recommended as other arterial sites provide inaccurate blood gas measurements during reestablishment of transitional circulation, which often complicates the postoperative course in neonates with patent ductus awaiting later intracardiac repairs. A pulse oximeter probe on the right hand or right ear also provides continuous preductal monitoring of peripheral perfusion and tissue oxygenation.

Although useful in directing massive volume replacement during thoracic dissection, central venous cannulation for right atrial pressure monitoring may be difficult or impossible because of atrial diverticuli and abnormal systemic and pulmonary venous drainage. Left atrial pressure monitoring may prove just as difficult or impossible for the same reasons. Needle atriotomy with a small-bore catheter through the needle will provide accurate intraoperative central venous pressure monitoring. Transthoracic right atrial cannulation may be helpful after staged repairs of ectopia cordis. Postoperatively, significant artifactual alterations will occur in right atrial waveforms during positive pressure ventilation in infants with either artificially covered or primarily repaired ectopic hearts because of cardiac compression and absence or instability of the anterior chest wall and diaphragm. To limit artifact, right atrial pressures should be measured only at end-exhalation without application of raised airway pressures. In the absence of supravalvular and branch pulmonary artery stenosis, a transthoracic pulmonary artery catheter may be inserted under direct vision through a right ventricular outflow tract ventriculotomy needle. The pulmonary artery catheter may permit better hemodynamic monitoring during low cardiac output states, persistent pulmonary hypertension, or prolonged pulmonary hypoplasia and allow for thermodilution cardiac output determinations postoperatively. As with right atrial pressures, pulmonary arterial pressures should be measured only at end-exhalation without application of raised airway pressures that could induce artifactual fluctuations in waveforms.

Endotracheal tubes should remain in place until infants are conscious and vigorous with normal arterial blood gases, tidal volumes, and ventilatory mechanics, usually several days to weeks postoperatively (9). Tight skin or synthetic-silo closures of the thorax and abdominal wall can significantly restrict spontaneous ventilation and prolong the need for postoperative controlled ventilation (9). Tissue expanders create larger skin and subcutaneous tissue flaps for subsequent defect closures with less restriction of ventilation and may permit earlier tracheal extubation postoperatively (9).

Cardiovascular failure, particularly from undiagnosed or uncorrected associated cardiac anomalies and rupture of cardiac diverticuli (1,7), and cardiorespiratory failure are frequent causes of death in the immediate postoperative period (Figure 1). Although never used in the management of ectopia cordis, extracorporeal membrane oxygenation may provide a better therapeutic bridge between defect coverage and later intracardiac or reconstructive surgery than inotropes alone. Further operations for wound dehiscence, secondary wound closures, or relaxing incisions may be necessary in the first few weeks postoperatively (1,7).

Orthotopic heart transplantation has not been suggested as a viable alternative for the initial surgical management of ectopia cordis probably because associated chest and abdominal wall defects often need several staged repairs in an immunocompetent patient. After successful chest and abdominal wall closures, however, the infant with ectopia cordis and uncorrectable intracardiac defects may become a candidate for orthotopic heart transplantation, provided the recipient's great vessel anatomy and pulmonary venous drainage are amenable to standard donor-recipient vascular anastomoses.

In conclusion, the frequency of accurate in utero diagnosis of ectopia cordis is increasing. The extent of chest and abdominal wall deformities in ectopia cordis has often defied previous attempts at surgical repair. Extensive thoracic dissection to free the great vessels and to create more mediastinal space for a deformed heart that was later compressed by tight silo (case 1) or skin (case 2) closures led to the early postoperative death of patients 1 and 2, respectively, resulting from progressive intravascular volume losses, limitation of venous return, reduction of cardiac output, and pump failure. Prenatal sonographic diagnosis, abdominal delivery, neonatal resuscitation, and temporary and nonrestricting synthetic or skin coverage of thoracoabdominal defects may be followed by intracardiac repair and chest wall reconstruction in neonates with ectopia cordis. These efforts, combined with advances in surgical techniques, infant heart transplantation, and the newer cardiorespiratory support technologies, like extracorporeal membrane oxygenation, may soon improve the likelihood of quality survival in ectopia cordis.

Intraoperative Hypoxemia Complicating Laparoscopic Cholecystectomy in a Patient With Sickle Hemoglobinopathy

Anthony J. Cunningham, MD, FRCPC, and Mark Schlanger, DO

Department of Anesthesiology, Yale University School of Medicine, New Haven, Connecticut

Laparoscopic cholecystectomy has recently become a popular alternative to traditional laparotomy and cholecystectomy in the management of patients with gallbladder disease (1). This new surgical technique retains the benefit of completely removing the gallbladder with the advantages of shorter hospital stay, more rapid return to normal activities, less pain associated with the small, limited incisions, and less postoperative ileus compared with the open laparotomy technique (2–4).

The sickle hemoglobinopathies are inherited hematologic disorders characterized by the presence of hemoglobin S (Hb S) and in vivo sickling of erythrocytes. Chronic hemolytic anemia associated with sickle hemoglobinopathy predisposes the individual to cholelithiasis. The reported presence of cholelithiasis in patients with sickle cell hemoglobinopathies ranges from 4% when diagnosed by routine abdominal radiography and oral cholecystography (5) to 55% when ultrasonography is used (6). Regarding the indications for cholecystectomy, surgical opinion remains divided between those advocating the procedure only for symptomatic patients because of increased operative risks (7) and those recommending elective cholecystectomy for patients with silent gallstones to avoid future complications and diagnostic difficulties differentiating acute cholecystitis from hepatobiliary sickle cell crisis (8).

Early contraindications to the laparoscopic cholecystectomy technique included the presence of large intrabiliary stones, common bile duct stones, evidence of acute inflammation, or pregnancy (9). Morbid obesity and the possibility of adhesions associated with previous intraabdominal surgery were considered relative contraindications. The indications for the laparoscopic technique have become more liberal recently after case reports confirmed its efficacy and safety in patients with acute cholecystitis (10) and during pregnancy (11). A recent report described the safe use of laparoscopic cholecystectomy in nine young patients with sickle hemoglobinopathy (12). However, the presence of preexisting lung disease has not been considered a relative contraindication to laparoscopic cholecystectomy. We present the first report of the necessity for conversion to an open cholecystectomy because of profound and sustained hypoxemia in a patient with sickle cell disease and radiographic evidence of restrictive lung disease.

Case Report

A 37-yr-old, 81-kg woman presented with symptomatic chronic cholelithiasis and was scheduled for elective laparoscopic cholecystectomy. She was admitted as an ambulatory patient on the morning of surgery.

Her past medical history was remarkable in that she was homozygous for sickle cell disease (Hb SS) and she presented with sickle cell anemia since childhood. She required several previous hospital admissions because of recurrent painful crises involving the abdomen, lungs, and joints. These crises necessitated frequent blood transfusions. Clinical manifestations of sickle cell disease in this patient included osteomyelitis of the left tibia and avascular necrosis of the left femur, and complications also included difficult venous access. A right-sided hemopneumothorax had previously complicated an attempted central venous cannulation using the right subclavian vein approach. A left arm arteriovenous fistula was created surgically to facilitate vascular access. Her medications at the time of admission included daily oral folate and meperidine, as needed for pain relief.

Physical examination revealed a heart rate of 82 bpm, supine arterial blood pressure of 120/75 mm Hg, and a grade II/VI systolic ejection murmur that was audible along the left sternal border. Auscultation of the lungs was unremarkable. Preoperative hemoglobin was 9.7 g/dL and hematocrit was 29.6%. The remainder of the hematologic assessment, coagulation screen, renal and liver function

tests, and serum electrolytes were within normal limits. The admission electrocardiogram revealed sinus rhythm and left ventricular hypertrophy. Roentgenographic examination of the chest revealed small lung volume, extensive interstitial infiltrative changes, and biconcave vertebrae with osseous changes of the right fifth rib. Arterial blood gas analysis and pulmonary function tests were not obtained before surgery, and a preoperative blood transfusion regimen was not used.

In the operating room, routine monitors (electrocardiogram, automated noninvasive blood pressure sphygmomanometer, precordial stethoscope, and oximeter) were placed, and an 18-gauge indwelling catheter was inserted in the right internal jugular vein because of limited peripheral venous access. Fentanyl 100 μg was administered intravenously before induction of anesthesia. A heart rate of 82 bpm, arterial blood pressure of 120/70 mm Hg, and oxygen saturation of 97%, while breathing room air, were documented before induction of anesthesia.

Anesthesia was induced with thiopental 4.0 mg/kg IV, and vecuronium 0.1 mg/kg IV was administered to facilitate tracheal intubation. Anesthesia was maintained with 0.5%–1.0% end-tidal isoflurane and nitrous oxide in 50% oxygen, with incremental bolus (1–2 μg/kg) doses of intravenous fentanyl. After induction of anesthesia, urinary bladder catheter and nasogastric tubes were inserted. Intraoperative monitoring included continuous electrocardiogram (leads II and V_5), pulse oximetry, end-tidal capnography, neuromuscular function, inspired oxygen fraction, peak airway pressure, esophageal temperature, and urinary output.

With the patient in a steep Trendelenburg position, a Veress needle was introduced into the peritoneal cavity through an infraumbilical incision, and carbon dioxide was insufflated to an intraabdominal pressure of 15 mm Hg via an electronic variable-flow, pressure-controlled insufflator. Systemic blood pressures ranged between 100 and 140 mm Hg systolic, 70 and 90 mm Hg diastolic, and pulse rates varied between 90 and 100 bpm; arterial oxygen saturations of 97%–99% and peak airway pressures of 25–30 cm H_2O were recorded. Intermittent positive pressure ventilation (IPPV) was employed using an Ohmeda 7810 ventilator, with an inspiratory flow rate of 25 L/min and an inspiratory-to-expiratory (I:E) ratio of 1:2. Minute ventilation was adjusted to maintain end-tidal carbon dioxide tension between 30 and 35 mm Hg.

The patient's position was changed to a steep 20° reverse Trendelenburg with left lateral tilt. During the ensuing 20 min, as the fundus of the gallbladder was retracted and the cystic duct and artery were mobilized, arterial oxygen saturation progressively declined to 86%, with a gradual increase in peak airway pressure to 50 cm H_2O. Nitrous oxide administration was discontinued and IPPV with a fractional inspired oxygen tension (FIO_2) of 1.0 plus 5 cm H_2O positive end-expiratory pressure (PEEP) was commenced. Heart rate, arterial blood pressure, and end-tidal carbon dioxide tensions were essentially unchanged, and no twitch responses were elicited on neuromuscular function monitoring after supplemental vecuronium administration. Chest movement was symmetrical bilaterally, and auscultation of the lungs revealed no abnormality. Access limitations precluded radial artery cannulation for arterial blood gas analysis. Despite IPPV with an FIO_2 of 1.0 and a minute ventilation of 8 L, arterial oxygen saturation of 85% persisted for 5 min. No changes were made in the inspiratory flow rate or the I:E ratio. Because of sustained and moderately severe hypoxemia in a patient homozygous for sickle cell disease, the surgical team was requested to convert the procedure to an open cholecystectomy. The patient was placed in a supine position and the intraabdominal carbon dioxide was vented. Arterial oxygen saturation promptly increased to 99% and peak airway pressure decreased to 25–30 cm H_2O.

The remainder of the open cholecystectomy procedure was uneventful. Neuromuscular block was reversed with 2.5 mg neostigmine plus 0.4 mg glycopyrrolate IV, and the trachea was extubated once the patient was fully awake and following commands. Arterial oxygen saturation >97% was documented in the postanesthesia recovery room throughout the patient's stay. The postoperative chest radiograph was essentially unchanged compared with the preoperative film. The postoperative period was complicated by the development of a painful abdominal Hb SS crisis 3 days after surgery, which required transfusion of 2 U of packed red blood cells. The patient was discharged 6 days after surgery.

Discussion

We report the first case of conversion from laparoscopic to open cholecystectomy because of sustained intraoperative hypoxemia and high airway pressures in a patient with sickle hemoglobinopathy and interstitial lung disease. We speculate that hypoxemia in this case may have resulted from ventilation-perfusion mismatch and intrapulmonary shunting secondary to preoperative decreased lung volumes and extensive interstitial lung disease, coupled with a further decrease in functional residual capacity induced by the creation of the pneumoperitoneum. A list of the factors that could be implicated in the development of intraoperative hypoxemia in this case is included in Table 1.

The preexisting infiltrative lung disease may have contributed to the development of intraoperative hypoxemia in this case. Sickle cell chronic lung disease (SCLD) has been reported to be a prime contributor to mortality in young adults with sickle cell hemoglobinopathy (13). Both perfusion and diffusion defects have been demonstrated, with generalized pulmonary fibrosis and disabling restrictive respiratory failure (14). Powars et al. (15) defined four stages of SCLD based on pulmonary function tests, chest roentgenograms, arterial blood gas analysis, and noninvasive cardiac studies. Patients, similar to the one reported here, were categorized as stage 2, based on chest radiologic findings of diffuse parenchymal fibrosis. Case-control analysis showed that the significant risk factors associated with the disease were

Table 1. Intraoperative Hypoxemia During Laparoscopic Cholecystectomy—Differential Diagnosis

- Pre-existing conditions
  - Cardiopulmonary disease
  - Morbid obesity
- Hypoventilation
  - Patient position
  - Pneumoperitoneum
  - Endotracheal tube obstruction
  - Inadequate ventilation—spontaneous/controlled
- Intrapulmonary shunting
  - Reduced FRC (pneumoperitoneum induced)
  - Endobronchial intubation
  - Pneumothorax
  - Emphysema—mediastinum/subcutaneous
  - Bowel distention (N_2O induced)
  - Pulmonary aspiration of gastric contents
- Reduced cardiac output
  - Hemorrhage—trochar injury
  - Inferior vena caval compression
  - Impaired venous return—pneumoperitoneum
  - Dysrhythmias—hypercarbia/volatile anesthetic agents
  - Myocardial depression—drug-induced/acidosis
  - CO_2 venous embolism

FRC, functional residual capacity.

the total number of acute chest syndrome events in an individual before the onset of SCLD and the presence of sickle cell crises marked by chest pain and aseptic necrosis. Temporal clustering of acute chest syndrome episodes frequently heralds the onset of SCLD.

Intraoperative hypoxemia may have been caused by a reduction in alveolar oxygen tension, an increased alveolar/arterial oxygen tension difference, or a reduction in cardiac output, singly or in combination. A reduction in alveolar oxygen tension may be caused by reduced or absent inspired oxygen concentration and decreased alveolar ventilation. Hypoxemia due to mechanical failure of the oxygen supply system or the anesthetic machine, disconnection of the breathing system from the oxygen supply, and inadvertent excess nitrous oxide administration were all excluded by inspection of the inspired oxygen analyzer, by checking the anesthetic breathing circuit, and by auscultation of the lungs. Kinking of the endotracheal tube, blockade by secretions, or a herniated or ruptured endotracheal tube cuff were excluded by confirmation of symmetrical chest movements and normal breath sounds.

An increased alveolar/arterial oxygen tension difference may lead to intraoperative hypoxemia. This will be most commonly associated with increased intrapulmonary shunting and decreased mixed venous oxygen tension. Inadvertent endobronchial intubation because of frequent positional changes from the Trendelenburg position to the reverse Trendelenburg and left lateral tilt position were excluded by clinical assessment. A tension pneumothorax has been reported as a complication during laparoscopic cholecystectomy after trochar insertion and intraperitoneal carbon dioxide insufflation (16). A congenital defect of the diaphragm (patent pleuroperitoneal canal) through which the insufflated gas passes into the thoracic cavity has been suggested as the underlying mechanism (17). A pneumothorax was excluded by clinical evaluation during surgery and chest x-ray after surgery.

A reduction in functional residual capacity relative to closing volume may be associated with the development of intraoperative atelectasis and intrapulmonary shunting. These changes may be associated with general anesthesia because of a variety of factors: (a) cephalad shift of the diaphragm associated with supine position (18); (b) loss of inspiratory muscle tone; (c) appearance of end-expiratory muscle tone in the abdominal expiratory muscles; (d) changes in intrathoracic blood volume associated with induction of anesthesia (19); and (e) influence of muscle relaxants on diaphragmatic excursion (20). The reduction in functional residual capacity associated with general anesthesia may be compounded by the carbon dioxide-induced pneumoperitoneum during laparoscopic cholecystectomy. A reduced cardiac output secondary to pneumoperitoneum-induced reduction in venous return or drug-induced myocardial depression may have reduced mixed-venous oxygen tension. The larger the intrapulmonary shunt and the greater the reduction in mixed-venous oxygen tensions, the greater the reduction in the arterial partial pressure of oxygen.

A number of case reports have described acute hypotension, hypoxemia, and cardiovascular collapse associated with laparoscopy (21, 22). Postulated causes included hypercarbia due to hypoventilation or absorption of carbon dioxide from the peritoneal surface, inducing dysrhythmias, especially if the myocardium is sensitized by volatile anesthetic agents; reflex increase of vagal tone due to excessive stretching of the peritoneum; compression of the inferior vena cava leading to decreased cardiac output; hemorrhage; and venous gas embolism. The clinical conditions associated with venous carbon dioxide embolism during laparoscopy have been described (23,24). The authors suggested that carbon dioxide could enter a tributary of the portal system during attempts at establishing the pneumoperitoneum. In this case report, the unchanged heart rate, rhythm, blood pressure, and end-tidal carbon dioxide tension suggest that significant cardiac output reduction or venous gas embolism were unlikely mechanisms of the hypoxemia and high airway pressure. Gastric regurgitation has been reported during gynecologic laparoscopic procedures (25). The prompt improvement in arterial oxygen saturation on venting the intraperitoneal carbon dioxide, the absence of visible gastric contents at the time of tracheal extubation, and the unchanged postoperative chest film make aspiration an unlikely mechanism in this case.

The ventilatory effects of carbon dioxide insufflation during laparoscopic cholecystectomy were prospectively evaluated by Liu et al. (26) in a study of 16 otherwise healthy patients undergoing laparoscopic cholecystectomy under general anesthesia. End-tidal carbon dioxide and $Paco_2$ increased from 31.4 ± 0.7 mm Hg to 42.1 ± 1.6 mm Hg, and from 33.3 ± 0.7 mm Hg to 43.7 ± 1.2 mm Hg, respectively, during the course of the procedure. Arterial pH decreased from 7.43 ± 0.01 to 7.34 ± 0.01, and bicarbonate concentration remained constant. Thirteen of 16 patients required increased minute ventilation to correct the hypercarbia detected by capnography. Wittgen et al. (27) compared the ventilatory effects of laparoscopic cholecystectomy in 20 patients with normal cardiopulmonary status (ASA physical status I) to the ventilatory effects in 10 patients with documented cardiac and pulmonary disease (ASA physical status II and III). Patients with preoperative cardiopulmonary disease demonstrated significant increases in arterial carbon dioxide tensions and decreases in pH compared with patients without underlying disease. Conversion to open cholecystectomy was required in two patients who demonstrated persistent hypercarbia and respiratory acidosis, despite vigorous hyperventilation. The patient in this case report had preoperative radiologic evidence of small lung volumes and extensive interstitial lung disease secondary to long-standing sickle cell disease. The creation of the pneumoperitoneum may have resulted in a critical further reduction in functional residual capacity and an increased intrapulmonary shunt leading to progressive arterial oxygen desaturation, which was refractory to increased minute ventilation, PEEP, and supplemental oxygen administration.

The application of PEEP >5 cm H_2O was considered inappropriate because of development of high airway pressures with the potential for pulmonary barotrauma, decreased venous return, and hypotension. An alternative strategy—inverse ratio ventilation—might have improved gas exchange at lower levels of PEEP and peak distending pressures (28). Inverse ratio ventilation could have been used with volume-cycled ventilation and end-inspiratory pause/decelerating inspiratory flow rate or pressure-controlled ventilation applied with a long inspiratory time. However, adverse hemodynamic effects and gas trapping may have followed these ventilatory interventions. The inability to maintain an arterial oxygen saturation >85% despite an Fio_2 of 1.0 plus 5 cm H_2O PEEP in our patient with sickle cell disease was considered sufficient justification for conversion to an open cholecystectomy. Upon deoxygenation, red blood cells containing Hb S change from a biconcave disc to an elongated crescent-shaped or "sickle"-shaped cell (29). The ability of red blood cells to traverse the microcirculation depends, in large part, on their pliability. As the red blood cell sickles, it becomes rigid, and, as a result, may obstruct capillary blood flow. The deoxygenation of blood from patients with sickle cell disease is associated with a marked increase in viscosity and, in this case, the inability to promptly reverse the arterial hypoxemia was of major concern. Arterial oxygen saturation promptly increased, and peak airway pressures decreased, upon changing to the supine position and after venting the intraperitoneal carbon dioxide.

Table 2 details the indications for conversion from laparoscopic to open cholecystectomy in five recently published series (30–34), in which the conversion rates varied from 1.0% to 6.9%. Experience from several institutions suggests that the incidence of common bile duct injuries may be higher with the laparoscopic procedure, and conversion to open cholecystectomy was usually caused by difficulty in identifying and mobilizing the cystic duct, suspected or confirmed common bile duct injury, uncontrolled bleeding from the cystic artery, acute inflammatory changes, or stones present in the common bile duct. Apart from isolated case reports and letters describing the uneventful anesthetic management of such cases (35–37), the anesthesia literature is conspicuous by the absence of data concerning anesthesia-related complications of laparoscopic cholecystectomy (38).

The role of a preoperative transfusion regimen in reducing the morbidity of cholecystectomy in patients with sickle hemoglobinopathy is speculative and must be balanced by the potential hazards of disease transmission and erythrocyte allosensitization (39). In patients with homozygous sickle cell disease, the erythrocytes may contain 80%–95% Hb S, with the remainder consisting of 5%–20% fetal hemoglobin (Hb F). Protocols have been advocated that include the preoperative transfusion of packed red blood cells with hemoglobin A erythrocytes in Hb SS patients to restore the percentage of Hb S to <45%, as determined by quantitative hemoglobin electrophoresis (40). The rationale for this management is to increase the proportion of normal erythrocytes containing Hb A to a level that will inhibit blockage of the microcirculation by sickling cells. However, the efficacy and safety of transfusion therapy in patients with sickle hemoglobinopathy were questioned in a retrospective study by Bischoff et al. (41). Transfusion therapy was administered preoper-

atively in 48 of the 66 patients reviewed. No significant reductions in postoperative sickling complications and increased morbidity related to transfusion adverse events were reported after preoperative transfusion in patients with preoperative hematocrits of <30%.

Based on the limited data available in the literature, and on our own experience with this procedure, we advocate preoperative arterial blood gas analysis and pulmonary function testing for patients undergoing laparoscopic cholecystectomy in whom respiratory risk factors have been identified on routine preoperative evaluation. In this era of cost containment, these patients may not be suitable for admission on the morning of surgery if such ancillary preoperative investigations are not available at the preoperative screening clinic. If hypoxemia, hypercarbia, or respiratory acidosis are documented by preoperative arterial blood gas analysis or if impaired pulmonary function tests are reported, we would express reservations about proceeding with the laparoscopic, rather than the open, cholecystectomy technique. If surgical management involved the laparoscopic technique, we would advocate radial artery cannulation, in addition to end-tidal carbon dioxide monitoring, to assess the adequacy of oxygenation and ventilation after pneumoperitoneum creation (42). This case and the limited published data (26,27) suggest that restrictive or obstructive lung disease may be relative contraindications to a laparoscopic cholecystectomy technique and that anesthesiologists should have a low threshold for recommending conversion from laparoscopic to open cholecystectomy if problems of high airway pressures or refractory hypoxemia are encountered during surgery.

We acknowledge the cooperation of Irving M. Modlin, MD, the attending surgeon in the case, and the assistance of Sorin J. Brull, MD, and Rowena Garcia, RN, in the preparation of this manuscript.

An Unusual Presentation of Spinal Cord Tumor After Epidural Anesthesia

Hugh B. Martin, MD, James J. Gibbons, MD, and Richard D. Bucholz, MD
Department of Anesthesiology, St. Louis University Medical Center, St. Louis, Missouri

The incidence of backache in the peripartum period is 25%–50% with or without epidural block (1–3). Backache is often attributed to ligamentous strain and managed with the conservative therapy of bed rest and analgesics. However, severe and/or persistent back pain or associated neurologic symptoms may indicate pathology requiring timely intervention for optimal outcome. We report an unusual case of an intradural spinal cord tumor presenting as severe, persistent, back pain after epidural anesthesia for cesarean section. This case is unique because the patient presented with back pain without sensory or motor deficits and because a previous epidural anesthetic complicated the interpretation of the magnetic resonance imaging (MRI) scan.

Case Report

An apparently healthy, 31-yr-old woman with no previous history of back pain underwent a cesarean section for prolonged labor under epidural anesthesia at a referring hospital. After her operation, she experienced intermittent, sharp, nonradiating low back pain that slowly abated until 18 mo later when she underwent her second cesarean section under epidural anesthesia, also at the referring institution. The intense back pain that developed immediately postoperatively required 2 wk of bed rest and analgesics. She denied experiencing any weakness or numbness in the lower extremities at any time, nor did she experience any bowel or bladder dysfunction. When pain was present, it was increased by bending forward, coughing, or sneezing. Neurologic examination was unremarkable. An MRI scan demonstrated an abnormality within the thecal sac posterior to the L-4 and L-5 vertebral bodies not typical for a tumor and more suggestive of a localized intrathecal hematoma or inflammatory process (Figures 1 and 2). The radiologist further suggested that the finding "may represent some type of sequela from the previous spinal [sic] anesthesia such as localized intrathecal hemorrhage."

Persistent symptoms led to a repeat MRI scan 6 mo later, which revealed a well-demarcated intradural tumor extending from the superior vertebral plate of L-4 to the inferior aspect of the L-5 vertebral body (Figures 3 and 4). At this time the patient was transferred to our medical center for treatment. She underwent general anesthesia for L-4, L-5 laminectomy, bilateral L-3 hemilaminotomy, and resection of an intradural mass densely adherent to the cauda equina and the filum terminale extending from L-3 to L-5. A total gross removal was accomplished with preservation of all nerve roots. Pathological review of the surgical specimen revealed a myxopapillary ependymoma. No abnormality was detected in the epidural space. The postoperative course was uncomplicated, with preservation of neurologic function. As ependymomas tend to reoccur after surgery, radiation therapy was begun 1 mo postoperatively. At follow-up 1 yr postoperatively, the patient is asymptomatic with no neurologic deficit.

Discussion

Patients often attribute low back pain after delivery to epidural anesthesia; however, the incidence of low back pain after delivery is unrelated to the use of general, epidural, or pudendal anesthesia (1,3–5). Although most patients with low back pain improve with symptomatic therapy, severe and/or persistent low back pain, such as this patient demonstrated, necessitates consideration of etiologies other than the common musculoskeletal injuries. The differential diagnosis of low back pain is extensive, and includes tumor, infection, herniated disks, spinal stenosis, spondylolisthesis, hemorrhage, and ankylosing spondylitis. Also visceral disease, such as endometriosis or nephrolithiasis, may present with back pain as the chief complaint (6,7). This patient's first MRI scan, demonstrating localized hemorrhage, was interpreted to be a result of recent instrumentation of the subarachnoid space. As the patient did not demonstrate neurologic signs, no further assessment or intervention was performed. Repeat MRI clearly demonstrated intradural tumor. Improved communi-

cation between the anesthesiologist and radiologist in this case may have clarified the misconception that a "spinal" anesthetic was administered to this patient. Clarifying that it was an epidural anesthetic may have led to further evaluation of the intrathecal hemorrhage. Fortunately, in this case, a delay in diagnosis did not result in harm to the patient. Although spinal anesthesia is associated with varying degrees of spinal hemorrhage in up to 0.35% of the cases (8), spontaneous spinal subdural hematoma in the absence of tumor or vascular abnormalities is rare (8,9).

Tumor as a cause of low back pain is uncommon. Deyo and Diehl (10) found a 0.66% incidence in 2000 walk-in patients with low back pain. Symptoms preceded the detection of the tumor by an average of 2 yr. Depending on the location of the tumor, local, segmental, or distant signs and symptoms may be the presenting symptoms. Generalized back pain and dermatomal pain tend to be early harbingers. It is unclear why this patient developed acute severe, low back pain after her first cesarean section. One could speculate that an acute shift in tumor position resulted in neuronal compression and thus the development of low back pain. A shift in tumor position could result from an increase in cerebrospinal fluid pressure secondary to injection of epidural local anesthetic, a change in lumbar alignment secondary to motor relaxation, or a decrease in epidural blood volume after delivery (releasing the inferior vena cava compression caused by the gravid uterus). Intradural tumors occur at an incidence of 3–10 per 100,000 population. Approximately 90% of all intradural tumors are benign and potentially resectable. Myxopapillary ependymoma is almost exclusively a tumor of the cauda equina that occurs most often in the fourth decade. The tumor may infiltrate nervous tissue and bone but rarely metastasizes. The prognosis is excellent when the tumor can be completely removed surgically (11).

Usubiaga (12) summarized six case reports of serious sequelae of epidural anesthesia in the presence of occult metastatic spinal osseous tumors. Hirlekar (13) reported paraplegia after epidural anesthesia in the presence of extradural spinal cord tumor. Hirsch et al. (14) used epidural anesthesia for management of labor pain in a patient with an undiagnosed cervical spinal arteriovenous malformation. It was not until 4 wk later that progressive paraplegia developed. Our case is the only one in which an intradural spinal tumor presented in the peripartum period, in association with epidural anesthesia.

The decision to proceed with epidural anesthesia in the presence of low back pain is an individual, patient-physician decision. Most difficulties in identifying the epidural space or threading the catheter are technical problems confronting the anesthesiologist. Renck and Torbergsen (15) have described the findings that might occur when an epidural catheter is inserted in the presence of a spinal cord tumor. There may be resistance to introduction of the catheter, severe paresthesia in one spinal nerve, or a bizarre distribution of sensory analgesia. Difficulty in establishing epidural anesthesia was not noted with our patient. Fortunately, our patient did not suffer major neurologic sequelae after instrumentation of the epidural space. If lumbago or other symptoms possibly related to anesthetic involvement develop, the patient should undergo appropriate evaluation when such symptoms are unrelieved by symptomatic therapy. Failure to detect tumor of this region promptly may result in inadequate resection of the lesion or permanent neurologic deficit.

Transesophageal Echocardiographic Detection of a Right Atrial Thrombus Around a Pulmonary Artery Catheter

Patrick R. Martens, MD, Jacques J. Driessen, MD, PhD, Yves Vandekerckhove, MD, and Luc Muyldermans, MD

Departments of Anaesthesia, Critical Care, and Cardiology, AZ St. Jan Hospital, Brugge, Belgium

Transesophageal echocardiography (TEE) is of substantial value in the diagnosis of cardiac mass lesions (1). Because it is unacceptable that the surface of intravascular catheters induce thrombus formation and embolization, surface heparinization has become standard practice for pulmonary artery catheters (PACs). We recently performed TEE for postoperative assessment of right and left ventricular function, during which time a thrombus was found around a PAC in the right atrium.

Case Report

A 68-yr-old woman with a history of asthma and a previous cataract operation was scheduled for coronary revascularization for two-vessel disease. Left ventricular contractility appeared to be normal on preoperative angiography. (Left end-diastolic pressure was 8 mm Hg before and 16 mm Hg after contrast injection.) A heparin-coated, 7.0F thermodilution PAC (AMC Thromboshield, Baxter Edwards Swan-Ganz) was inserted via the right internal jugular vein through an 8.0F introducer sheath with a side port and a hemostatic valve. During cardioplegic myocardial arrest, the left anterior descending artery was bypassed with the left mammary artery, and a venous graft was implanted on the right coronary artery. Because the first attempt at weaning from extracorporeal circulation was unsuccessful owing to low cardiac output, one more venous graft was performed on a diagonal branch. Immediately after bypass, the patient was in sinus rhythm and required dopamine (5–10 $\mu g \cdot kg^{-1} \cdot min^{-1}$) as inotropic support. At the end of surgery, she had bilateral unreactive, wide pupils but appeared to wake up 4 h later. Myocardial enzymes were elevated the next morning (myocardial fraction of creatinine phosphokinase was 66 IU/L and glutamic oxaloacetic transaminase was 115 IU/L [normal value <40]), and there was electrocardiographic evidence (significant ST-segment elevation in the corresponding leads) of septal myocardial infarction. Transesophageal echocardiography was performed on the second postoperative day because of persisting low cardiac output with pulmonary hypertension (peak systolic pressure 60 mm Hg) that had been present since termination of cardiopulmonary bypass. Apart from a limited area of posteroseptal and anteroseptal akinesia and spontaneous contrast in the right cavities indicative of decreased blood flow, a 2 × 3-cm echodense mass in connection with the PAC was noted in the right atrium, as shown in Figure 1. The mass was fairly mobile and entered the right ventricle through the tricuspid orifice during diastole and returned to the right atrium during systole. The patient did not have atrial fibrillation. Although a thrombopenia of 28,000/mm^3 existed, it was assumed that the irregular lobulated border of this mass was a thrombus associated with the indwelling PAC. Because the pulmonary hypertension could be explained by recurrent pulmonary emboli, our patient underwent heparinization with 25,000 U/day. Thrombolysis was considered contraindicated in this patient. Meanwhile, a norepinephrine infusion was started to maintain an adequate mean arterial blood pressure. A hemothorax on the left side had to be evacuated. Two days later, repeat TEE revealed minor reduction of this mass lesion, which was still situated in the right atrium and attached to the PAC. The PAC with the thrombus sticking to it was temporarily left in place. We believed that the presence of the PAC prevented the entire large thrombus from migrating into the lungs and causing a sudden life-threatening pulmonary embolism. On the seventh postoperative day, the thrombus was resolved to a diameter of 5 mm and appeared as a "string" thrombus in the superior vena cava when the PAC was gently drawn back. It was then decided to remove the flow-directed PAC and the sheath as a unit and to discontinue heparinization. The tip of the catheter was cultured, and there was no remaining clotting visible on the PAC. Over several days, the patient was gradually weaned from mechanical ventilation and was discharged from the intensive care unit on the 16th postoperative day. Eventually, she was discharged to a long-term care facility after a hospitalization of 3 mo for dyspnea during the night and left pleural effusions.

Discussion

A mass in the right atrium was inadvertently detected in a postoperative patient. In such a case, one should

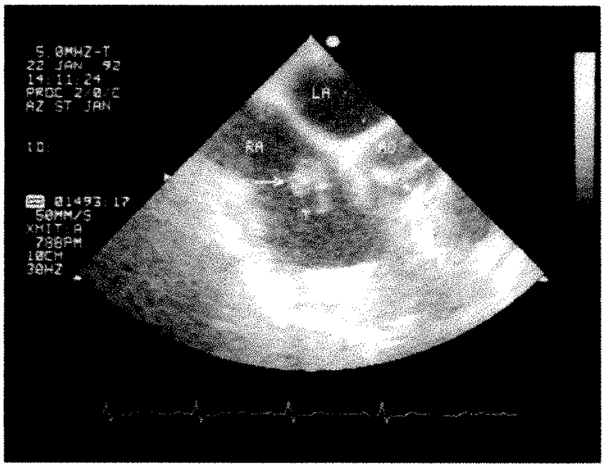

Figure 1. Basal short-axis view at the level of the atria and the aorta in diastole as seen by transesophageal echocardiography (TEE). In the right atrium (RA), a mass (T) is seen in close proximity to the pulmonary artery catheter (*arrow*). LA, left atrium; AO, aorta.

carefully differentiate among Chiari's network and eustachian valves (both normal variants), a myxoma, other tumors, and thrombi. Echocardiographically, the mass had thrombuslike characteristics: laminated appearance, irregular or lobulated borders, and lack of obvious tumor features, such as a narrow stalk or origin from atrial septum (1). Recent reports indicate that TEE is superior to transthoracic echocardiography in diagnosis of an atrial mass and assessment of its size and mobility (2,3). Although it is impossible to prove that a thrombus was induced by the PAC, it is highly probable for the following reasons: first, the mass moved toward the superior caval vein when the catheter was retracted; second, according to a subsequent checkup by our pneumologists, there was no longer evidence of pulmonary emboli, as would be expected if the clot originated in the peripheral venous circulation; and third, the cardiac surgeons who routinely examined the patient's legs preoperatively had no reason to suspect a deep venous thrombosis.

Local thrombus formation around a PAC in the right side of the heart and in the internal jugular or subclavian vein has been described previously (4). In one autopsy study, there were mural thrombi in the chambers on the right side of the heart in approximately one-third of patients with PACs (5). By contrast, a review of PACs in 6245 patients revealed the recovery of a blood clot (weighing ~50 g) in only one patient (6). Those authors advise aspiration on the side port of the sheath during its removal to retain any clot and to prevent its embolization. The rapidity and degree of clot formation depend on the patient's cardiac output and coagulation status, the physician's technique, the length of time the catheter is left in place, and the characteristics of the catheter.

Despite heparin coating, peroperative full heparinization, postoperative thrombopenia, and the absence of atrial fibrillation, clot formation around a PAC may have occurred in this patient. Partial stagnation of blood, together with turbulent flow in the cavities on the right side of the heart during extracorporeal circulation, may have contributed to this phenomenon. Many venous thromboses are not clinically evident; therefore they may be undetected unless they occur suddenly or are sought by radionuclide venography, radiopaque injection, or sonography (7).

Because of the TEE findings, heparinization was instituted in this patient. As a consequence, pulmonary angiography would not have influenced treatment and was not performed. Moreover, easy accessibility of TEE in the operating room and intensive care unit offers distinct advantages over the standard diagnostic techniques (perfusion scanning, pulmonary angiography). In selected cases (e.g., suspected massive pulmonary embolism), TEE may become the procedure of choice (8,9).

Heparin-coated equipment has been used in combination with high-flow cardiopulmonary bypass without systemic heparinization in canine experiments (10). Heparin-coated surfaces belong to the group of ionic-bound heparins and have the advantage that they can be applied to a multitude of surfaces, in contrast to the covalently bound heparins (heparin bonding), which are more limited in this regard. However, the latter show superior retention. Both heparin bonding and heparin coating have been introduced as new approaches to reduce catheter-induced embolization (11).

In conclusion, TEE was not only valuable in the noninvasive evaluation of a postoperative low-output syndrome and the early detection of an intracardiac lesion, most likely a right atrial clot induced by a PAC, but it also influenced clinical decisions (i.e., heparinization and timing of removal of the PAC).

Intraoperative Exacerbation of Parkinson's Disease

Allan P. Reed, MD, and Don G. Han, MD

Department of Anesthesiology, Mount Sinai School of Medicine, New York, New York

Parkinson's disease afflicts approximately 1% of the population over 50 yr old (1). Its associated muscle tremors and rigidity are progressive and become severe enough to debilitate many patients. We summarize a case of advanced Parkinson's disease with an intraoperative exacerbation during regional anesthesia. A discussion of its consequences and treatment follow.

Case Report

A 73-yr-old man with Parkinson's disease required anesthesia for repair of a large recurrent left inguinal hernia. His Parkinson's disease was treated with carbidopa 25 mg and levodopa 100 mg five times a day; amantadine 200 mg three times a day; and selegiline 5 mg each day. Levodopa was administered every 4 h while awake. Delaying or omitting a single dose resulted in severe generalized body tremors and rigidity. He also suffered from congestive heart failure for which he received lanoxin 0.125 mg each day and isordil 20 mg three times a day, as well as sick sinus syndrome for which he had received a permanent pacemaker. Previous anesthetics were limited to one general anesthetic for left inguinal hernia repair and one spinal anesthetic for transurethral resection of the prostate. There were no known anesthetic complications.

He had taken his usual morning medications 2 h before the planned surgery. Physical examination 1 h before surgery revealed masklike facies and poor facial expressions. No bradykinesia or resting tremor were noted. There were no active signs and symptoms of congestive heart failure nor sick sinus syndrome.

No sedative premedication was given. Field block anesthesia was feared to be inadequate for this large, recurrent hernia and therefore was not performed. Spinal anesthesia was agreed to, and the patient was brought to the operating room where his vital signs were an arterial blood pressure of 140/90 mm Hg; heart rate of 70 bpm with a paced rhythm; respiratory rate of 16 breaths/min; and arterial oxygen saturation of 96% while breathing room air. Hyperbaric bupivacaine, 12 mg, plus 10 μg of fentanyl were injected into the cerebrospinal fluid at the L4–5 interspace. Ten minutes later, a T-9 level was achieved and vital signs were essentially unchanged from initial recordings. One hour after initiating spinal anesthesia, and approximately 45 min into the operation, a prominent artifact emerged on the electrocardiogram, which resembled coarse ventricular fibrillation (Figure 1). This event occurred approximately 5 h after his last levodopa dose. The patient remained awake and alert. Arterial blood pressure, heart rate, respiratory rate, and oxygen saturation were essentially unchanged. Examination of the patient's chest and upper extremities revealed fine tremors that progressed to more gross tremors over a 10-min period. The patient reported subjective feelings of discomfort. The constellation of signs and symptoms was similar to manifestations of his Parkinson's disease. Levodopa and carbidopa were given orally with a sip of water while surgery continued. Motor activity and the subjective feelings of discomfort resolved approximately 20 min after initiating therapy. Surgery proceeded during the entire episode and ended shortly after tremors ceased.

In the recovery room, the patient admitted that he would occasionally self-administer additional levodopa without his neurologist's knowledge and that the five times a day dosing schedule had not been as effective as it was initially.

Discussion

The etiologies of Parkinson's disease include carbon dioxide or manganese poisoning; butyrophenone, phenothiazine, or reserpine treatment; central nervous system trauma (1); central nervous system tumors; viral encephalitis (2); and arteriosclerosis (3). Pathophysiologically, Parkinson's disease represents a relative imbalance between dopamine's inhibitory effects and acetylcholine's excitatory properties in the basal ganglion (1). The resultant extrapyramidal stimulation predisposes to bradykinesia, tremor, rigidity, and postural instability—the hallmarks of Parkinson's disease (4).

Treatment goals are to establish proper balance between central dopaminergic and cholinergic activity. Patients with mild disease often receive relief from rest tremors and dystonia with anticholinergics such as trihexyphenidyl and benzotropine (5). Diphenhydramine, an antihistamine possessing central anticholinergic effects (6), is sometimes useful in mild disease. Amantadine, a dopamine agonist, is occasionally helpful for early-stage tremors (1,3).

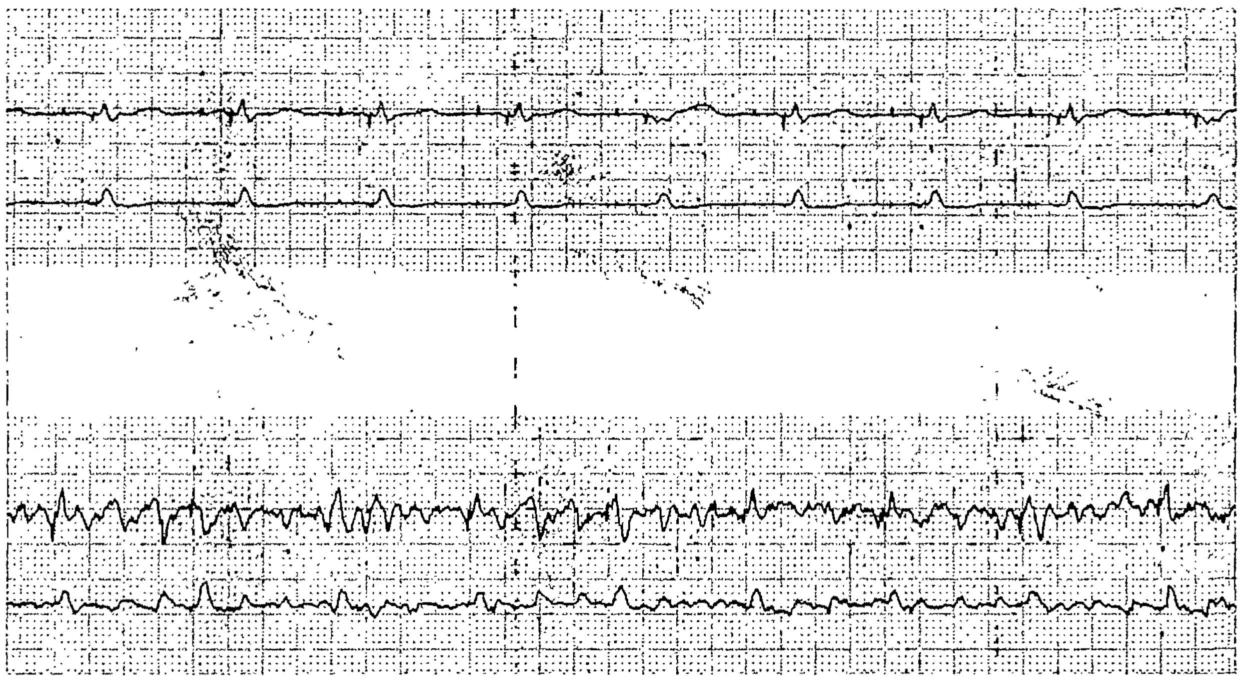

Figure 1. *Upper strip* represents patient's normal paced rhythm. *Lower strip* demonstrates the coarse ventricular fibrillation pattern.

More advanced disease is treated with levodopa, which crosses the blood-brain barrier and reacts with dopa-decarboxylase to form dopamine. To reduce dopamine's peripheral effects such as nausea, orthostatic hypotension, and arrhythmias, levodopa is usually combined with carbidopa, a dopa-decarboxylase inhibitor that does not cross the blood-brain barrier. This combination enhances brain dopamine levels while reducing systemic symptoms (7). Chronic levodopa treatment may result in requirements for increased dosing frequency (3,5). In such cases, bromocriptine, a postsynaptic dopamine receptor agonist, may be useful (5). Selegiline, a monoamine oxidase inhibitor type B (8,9), has been used to slow the progress of Parkinson's disease (10,11).

Most authors recommend continuation of therapy perioperatively (12–14) to avoid laryngospasm (4), aspiration pneumonitis (15–17), obstructive lung disease (17,18), hallucinations (5), and violent tremors—the recognized complications of Parkinson's disease. Patients with Parkinson's disease appear to be at increased risk for these problems in the perioperative period. Violent tremors and rigidity on emergence may also be attenuated or abolished by continuing anti-Parkinson's disease treatment through the perioperative period (13,14). Our patient complied with this recommendation, but due to a delay in the time of surgery, his signs and symptoms recurred intraoperatively. Drugs known to exacerbate extrapyramidal stimulation such as droperidol (19), phenothiazines (20), metoclopramide (20), and reserpine (1) were not administered.

Manifestations began with fine skeletal muscle tremors that were grossly unrecognizable, but were revealed by the electrocardiogram monitor. A coarse fibrillatory pattern was displayed. The initial response to perform electrical defibrillation would have been unnecessary and potentially deleterious. Further investigation revealed arterial blood pressure, palpable pulses, respiratory rate, oxygen saturation, and mental status that were all normal for this particular patient. Fine skeletal muscle tremors produced the observed electrocardiogram pattern. This quickly progressed to a clinically severe episode of tremors and rigidity.

In the absence of parenteral anti-Parkinson's disease medications that are effective in advanced cases, we elected to treat with the "per os" form of the drug and accept the prolonged onset time. Treatment with intravenous atropine was considered but rejected because of the increased risk of tachyarrhythmias in a patient with preexisting sick sinus syndrome, congestive heart failure, and elevated systemic dopamine activity from chronic levodopa, amantadine, and selegeline ingestion. Furthermore, atropine is not known to be effective for the treatment of advanced disease. Diphenhydramine and benztropine had previously failed to relieve this patient's manifestations.

Despite suggestions to stop monoamine oxidase inhibitors (MAOIs) 3 wk before anesthesia (21–24), this patient was continued on his therapy through the morning of surgery. Many patients receiving such drugs up to the time of surgery have been anesthetized without significant complications (8). This patient's MAOI, selegiline (L-deprenyl, phenethylamine), has been used for treatment of Parkinson's disease in the United States since 1989. Selegiline is an MAOI type B, which prevents dopamine degradation and has little or no effect on epinephrine or norepinephrine (25). Although metabolized to amphetamines, there is hope that selegiline will produce less sympathetic overactivity than previous MAOIs (26,27). There is no information regarding the interaction of selegiline and anesthetics.

Postoperative ileus represents a serious problem for patients with severe Parkinson's disease. Presently available parenteral medications such as diphenhydramine and benztropine are oftentimes inadequate to treat advanced disease. Parenteral forms of levodopa are only available experimentally, as of this writing. Lisuride (2,7), a dopamine agonist, is available parenterally in Europe, but not in the United States. Levodopa is absorbed from the proximal small bowel (28,29) and therefore is useless as a suppository. Absorption occurs rapidly from the gastrointestinal tract and can be used in many post-laparotomy patients. For those patients in whom intestinal absorption does not take place, only diphenhydramine and benztropine are available for Parkinson's disease treatment in the United States.

This case report highlights several new aspects of perioperative care for patients with advanced Parkinson's disease. Skeletal muscle activity mimicking ventricular fibrillation has been reported previously in anxious and shivering patients (30). However, Parkinson's disease has never before been documented as a specific disease entity that predisposes to this problem. Heightened awareness of the potential for artifactual electrocardiographic representations of ventricular fibrillation should help prevent unnecessary and potentially dangerous electrical defibrillation. Additionally, skeletal muscle activity progressing to rigors can hinder the quality of surgical repair and prolong the operating time.

Previous recommendations for perioperative treatment have not emphasized the need for synchronizing levodopa administration with the beginning of anesthesia and surgery. Based on the 20-min onset time observed in this patient and the documented 30-min to 2-h time to peak plasma levels (31), we recommend administration of oral levodopa approximately 20 min before the start of anesthesia. Such coordination of drug dosing should provide maximal intraoperative and postoperative protection from Parkinson's disease exacerbations.

When necessary, oral levodopa can be administered intraoperatively and postoperatively to control Parkinson's disease manifestations.

Regional techniques are preferable to general anesthesia methods. Regional anesthesia allows for communication of the subjective feelings accompanying Parkinson's disease attacks, thereby prompting earlier treatment. The muscle-relaxing effects of some general anesthetics and neuromuscular blockers will probably mask the myopotentials, which were the first sign of exacerbation in this patient. Consequently, residual general anesthesia or neuromuscular blocker may delay diagnosis and treatment. The high incidence of nausea and vomiting associated with general anesthesia prevents effective administration of oral medications.

Patients with advanced Parkinson's disease are at risk for exacerbations in the perioperative period. These exacerbations place them in jeopardy for unnecessary electrical defibrillation in addition to previously described complications. Oral levodopa should be administered approximately 20 min before inducing anesthesia and may be repeated intraoperatively and postoperatively in many patients. Regional anesthesia may be preferable to allow for communication of the patient's subjective feelings.

Intraoperative Hypertension During Surgical Excision of Neuroblastoma

Case Report and Review of 20 Years' Experience

Charles M. Haberkern, MD, Peter G. Coles, MD, Jeffrey P. Morray, MD,

Neuroblastomas and pheochromocytomas are derived from neural crest tissue, and both synthesize and release catecholamines (1–3). The ability of pheochromocytomas to produce life-threatening cardiovascular instability before and during surgical removal is well recognized and reviewed in the anesthesia literature (4–7). Published information concerning anesthetic experience with neuroblastoma is restricted to scattered reports of preoperative and intraoperative cardiovascular instability (8–11), including one report of an intraoperative death (12) with an accompanying general description of the anesthetic management for neuroblastoma (13). The incidence of cardiovascular instability during neuroblastoma resection has not been documented previously.

The following case of an infant with a mediastinal neuroblastoma illustrates that significant tachycardia, hypertension, and catecholamine elevation may accompany surgical excision of this tumor. This case prompted a review of the anesthetic experience with this disease in our institution over the past 20 yr.

Case Report

A 4-mo-old girl presented with a 1-mo history of episodes of diaphoresis, agitation and pallor occurring about every other day and lasting several hours. She had been a full-term infant with an otherwise unremarkable past medical history.

On admission to the hospital, the child appeared to be well and without acute distress. Vital signs were temperature 36.3°C, heart rate (HR) 132 bpm, arterial blood pressure (BP) 83/50 mm Hg, weight 5.4 kg, and length 64.5 cm. Serum electrolytes were normal and the hematocrit was 34%. The electrocardiogram was unremarkable, and the chest radiograph revealed a mediastinal mass that was shown by computed tomography to be a left posteromedial mediastinal mass causing displacement of the trachea.

Soon after admission, episodes of diaphoresis and agitation were observed along with increased BP (maximum 164/92 mm Hg) and HR (maximum 162 bpm). Urine analysis demonstrated elevated concentrations for several catecholamines: vanillylmandelic acid 107 mg/g creatinine (normal 5.1–16.3 mg/g creatinine); homovanillic acid 121 mg/g creatinine (normal 6–30 mg/g creatinine); and norepinephrine 162 µg/24 h (normal 7.2–14 µg/24 h). Serum concentrations of epinephrine, norepinephrine, and dopamine were also elevated (Table 1). A bone scan showed uptake at the tumor site only. Initially, the hypertensive episodes were treated with nifedipine (2.5 mg orally) as needed. Two days after admission, treatment with parenteral hydration and phenoxybenzamine (0.2 mg·kg^{-1}·day^{-1}) was instituted, and phenoxybenzamine was increased to a maximum of 1.7 mg·kg^{-1}·day^{-1} over 10 days until the episodes of diaphoresis were eliminated and hypertension was controlled.

Two weeks after admission, the patient was brought to the operating room for thoracotomy and tumor excision. Preoperative BP was 95/45 mm Hg, HR 115 bpm, weight 6.4 kg. Serum electrolytes remained normal and the hematocrit was 32%. After sedation with intravenous thiamylal, routine noninvasive monitors were applied and an arterial catheter was inserted. Anesthesia was induced with oxygen and isoflurane, and the trachea was intubated without difficulty while the patient was breathing spontaneously. Central venous and urinary catheters were then placed. Anesthesia was maintained with oxygen, air, isoflurane (0.4%–0.5% end-tidal), fentanyl, and vecuronium. The anesthetic course was uneventful until tumor manipulation, which resulted in transient but distinct hypertension and tachycardia (BP increased from 80/40 to 135/80 mm Hg, HR increased from 120 to 140 bpm); the hypertension was controlled with intravenous sodium nitroprusside. The tumor was a well-encapsulated, 4–6-cm mass that was easily removed except for a small residuum that extended

into the second intercostal space. Estimated blood loss for the procedure was 50 mL, and fluid losses were replaced with the intravenous administration of 350 mL of crystalloid solution. After tumor excision, vital signs remained stable. At the termination of the procedure, the infant was awakened and her trachea extubated without complication; no tachycardia, hypertension, or hypotension occurred throughout the postoperative period.

Pathologic examination confirmed the diagnosis of stage II neuroblastoma. Sequential determinations of serum catecholamines in the perioperative period demonstrated a marked elevation of the serum norepinephrine concentration at the time of tumor manipulation and a return to baseline postoperatively (Table 1). The patient has been followed up without additional therapy and has no evidence of recurrent disease 16 mo postoperatively.

Methods

We reviewed the hospital records of 127 children who underwent resection of neuroblastoma at Children's Hospital and Medical Center, Seattle, Washington, between January 1971 and January 1991. Nineteen children underwent biopsy of tumor only and their records were deleted from further analysis. The records of the remaining 108 children were reviewed for preoperative symptoms, HR, BP, and urine or serum catecholamine levels; type of surgical procedure and anesthetic management; intraoperative HR and BP, including maximum sustained BP (recorded at two or more consecutive 5-min intervals) during tumor removal and minimum sustained BP after tumor removal; and final histologic diagnosis. Preoperative BP was considered to be elevated if it was greater than two standard deviations above the mean for age (14). Intraoperative BP and HR were considered to be significantly elevated if they were ≥25% above their postinduction values, and intraoperative BP was considered to be significantly reduced if it was ≤25% of the postinduction value.

Results

There were 55 male and 53 female patients with an average age at the time of surgery of 2.6 yr (range 4 days to 14 yr). Twenty-seven children were asymptomatic and were discovered to have a mass on routine fetal or postnatal examination; 19 children presented with nonspecific symptoms; and 53 presented with symptoms or signs directly related to the mass effect of the tumor. Only nine of the children (8% of the total study population) had a history of symptoms or signs suggestive of increased catecholamine secretion, including flushing, diaphoresis, diarrhea, and hypertension. Two of these nine children had a well-documented history of hypertension, including the child reported here. Fifteen other children with no history suggestive of increased catecholamine secretion had mildly elevated resting systolic BPs on admission to the hospital. Of the 94 children who had preoperative determination of urine and/or serum catecholamines, 81 had elevated levels. Eight of the nine symptomatic children had preoperative catecholamine determinations, all of which were elevated. Thirteen of the 15 children with incidental increased BP on admission had preoperative catecholamine determinations, all of which were elevated. None of the children except the one reported here received antihypertensive therapy preoperatively.

Surgical resection of tumor was preceded by chemotherapy and/or radiation therapy in 36 of the children. Tumor sites were neck (2), thorax (27), abdomen (74), and spinal cord (5). The average duration of anesthesia was 4 h (range 1.5–10.2 h). Forty-six of the children were anesthetized with a volatile agent-based technique; 53 with a opioid-based technique; and 9 with a combined regional-general technique. No problems with airway management were encountered in those patients with mediastinal tumors.

Intraoperative hypertension and tachycardia accompanying tumor manipulation were extremely uncommon in the study population (<3%). In addition to the child described above, these changes occurred in only two other children, both of whom had elevated baseline catecholamine levels. One was a 10-mo-old boy with stage III neuroblastoma who presented with a history of excessive diaphoresis, progressive weakness in the lower extremities, and bowel and bladder dysfunction.

During emergency laminectomy for decompression, tumor manipulation was associated with an increase of HR from 135 to 180 bpm, an increase of BP from 90/60 to 135/90 mm Hg, and an increase of rectal temperature from 35.5 to 38.8°C. During a repeat laminectomy 2 mo later, an intraoperative elevation of serum epinephrine was documented. The other child was a 3.5-yr-old girl who presented with hip pain and was found to have stage IV neuroblastoma. After chemotherapy, she underwent adrenalectomy, during which tumor manipulation was accompanied by a 40%–50% increase in both HR and BP that was treated with propanolol.

Whereas combined tachycardia and hypertension during tumor manipulation was uncommon, other intraoperative vital sign changes did occur in our review population. Twenty-nine percent of the children had a significant increase in HR during tumor dissection without change in BP or temperature. Forty-five percent of the children had a significant decrease in systolic BP after tumor excision. In most of these cases, BP was restored with infusions of blood and/or crystalloid; no patient required vasopressor therapy. No intraoperative dysrhythmias were noted in any patient, including the 71 patients who received halothane.

Our review population included the full range of clinical stages and pathologic variations of neuroblastoma. Final clinical staging of the tumors demonstrated that 35% were stage IV, 5% were stage IVS, and the rest were evenly distributed among stages I–III. Final pathologic characterization of the tumors demonstrated that 70% were neuroblastoma, 23% ganglioneuroblastoma, and 6% ganglioneuroma. The distribution of clinical stages and pathologic types was similar for the nine symptomatic patients as for the population at large, and, as noted above, all three children with intraoperative hypertension had neuroblastoma (stages II–IV).

Discussion

Neuroblastoma is the most common solid tumor of infancy and the third most common malignancy of childhood (15). Along with the related tumors ganglioneuroblastoma and ganglioneuroma, neuroblastoma is an embryonal tumor of neural crest origin that may arise at any site in the sympathetic nervous system, especially the paravertebral sympathetic ganglia, adrenal medulla, and preaortic retroperitoneal paraganglia. Metastases are present in more than half the cases at the time of diagnosis, particularly in bone cortex, bone marrow, and lymph nodes. The tumor is staged (I–IV) according to degree of local extension and metastasis, stage IVS specifying remote disease in liver, skin, and/or bone marrow. As shown by our study population, the clinical presentation is extremely varied and is often directly related to the site of origin of the tumor. The clinical diagnosis of neuroblastoma is confirmed by radiologic and chemical studies, including urine and/or serum catecholamines (norepinephrine, epinephrine, dopamine) and their metabolites (vanillylmandelic acid and homovanillic acid); some elevation of catecholamines is found in 80%–90% of patients (15,16). Primary surgical resection of neuroblastoma is reserved for stages I and II; for the more advanced stages, treatment may entail chemotherapy, radiation therapy, and even bone marrow transplantation (17).

The release of catecholamines by neuroblastoma tumors may produce fever, diaphoresis, flushing, diarrhea, and hypertension. The latter sign has been reported in as many as 35% of cases (15,18). In our review population of 108 patients, only 9 children had signs or symptoms suggestive of catecholamine release, including 2 children with a history of well-documented hypertension. Fifteen additional children had mild elevation of blood pressure on admission without other related signs or symptoms.

Our study suggests that the incidence of clinically important cardiovascular signs indicative of catecholamine release during tumor resection is <3%. Although tachycardia and hypertension may accompany surgical manipulation of any tumor in the chest or abdomen, the association of acute vital sign changes with the marked increase in serum norepinephrine concentration in our reported patient strongly indicates that these are indeed catecholamine-related changes. In contrast to patients with neuroblastoma, virtually all patients with pheochromocytoma demonstrate intraoperative hypertension if α-adrenergic blocking drugs are not given before surgery (19). However, as demonstrated by our case report, patients with neuroblastoma may mimic those with pheochromocytoma, and clinically adequate preoperative treatment with α-adrenergic blocking therapy may not preclude intraoperative hypertension.

The relative infrequency of clinical evidence of catecholamine excess in patients with neuroblastoma resection compared to those with pheochromocytoma may be due to a variety of factors. Neuroblastoma tissue may lack the enzyme that *N*-methylates norepinephrine to produce epinephrine (20). The tumor may also have a variable mixture of both adrenergic and cholingeric cells (21) and a variable concentration of the enzyme responsible for the conversion of dopamine to norepinephrine (β-hydroxylase) (16). Finally, neuroblastoma tissue often has a paucity of intracellular storage granules in which synthesized catecholamines are stored (22–24). Quantitative analysis of the neurosecretory granules in a tumor may be, in fact, difficult as the density of these may vary greatly within areas of a given tumor and between different microscopic fields. When a large number of secretory granules in the cells of neuroblastoma tissue are present, a clinical response during tumor resection similar to that of pheochromocytoma can be seen (25). All three of the children with intraoperative hypertension in our study population had tumors that were rich in neurosecretory granules.

Apparent also from this review is the high proportion of patients who had clinically important episodes of hypotension after removal of neuroblastoma tumor (45%). Although hypotension due to blood loss and caval compression during tumor excision from the chest or abdomen would be anticipated, this high incidence of hypotension after tumor excision is noteworthy. In all cases, BP was restored with adjustments of anesthetic management, with infusion of fluids, and without vasopressor therapy. Previous experience with the anesthetic management of patients with pheochromocytoma supports the use of volume repletion rather than vasopressor therapy in the treatment of hypotension after tumor resection (19). Possible explanations for the commonly observed hypotension after tumor removal in this series of patients with neuroblastoma include a contraction of intravascular volume due to surgical fluid losses, excess of anesthetic depth during surgical closure, or vasodilation associated with a decrease in catecholamine levels.

Our findings have implications concerning the anesthetic management of patients undergoing resection of neuroblastoma. For the vast majority of these patients, signs of intraoperative catecholamine excess are not encountered, although the need to restore intravascular volume after tumor resection can be anticipated. Patients who have marked hypertension and other preoperative signs and symptoms of catecholamine excess may develop intraoperative problems typical of patients with pheochromocytoma. These patients, like those with pheochromocytoma, should undergo preoperative intravascular volume repletion and control of hypertension with α-adrenergic blocking agents until clinical signs and symptoms are controlled (7,19). Once α-adrenergic block is established, β-adrenergic block may be instituted to control secondary tachycardia and tachydysrhythmias. Preoperative treatment with adrenergic blocking agents should blunt, if not ablate, cardiovascular responses to surgical stress and tumor manipulation. Intraoperative hypertensive episodes that do occur can be managed with sodium nitroprusside or with a short-acting α-adrenergic blocking agent such as phentolamine.

There is no evidence from this study or other reports to support the use of one anesthetic agent or technique over others. Successful intraoperative management of patients with pheochromocytoma has been reported using all the volatile agents and opioids (5,6,19). Our experience here confirms the safety of these agents, as well as the safety of a combined regional-general anesthetic technique, in the management of patients with neuroblastoma. In patients with a clinical picture similar to that of the infant described here, it may be prudent to anticipate the potential adverse effects of exogenous epinephrine and to avoid epinephrine-containing local anesthetic agents. Finally, although mediastinal neuroblastomas are generally located in the posterior compartment and do not pose significant problems for airway management, it is important to recognize possible consequences of any tumor that compresses the airway (26,27) as well as the ability of this specific tumor to cause significant compromise to the airway (28).

In conclusion, we report a case of neuroblastoma resection that was associated with intraoperative hypertension despite preoperative treatment with an α-adrenergic blocking agent. The review of our anesthetic experience with neuroblastoma over the past 20 yr indicates that the actual incidence of intraoperative hypertension associated with tumor manipulation is <3%. By contrast, hypotension that follows tumor resection is a common occurrence during the anesthestic management of neuroblastoma.

Letters to the Editor

Propofol in Cardiac Catheterization

To the Editor:

We read with interest the article by Lebovic et al. (1) on the comparison of propofol versus ketamine for anesthesia in pediatric patients undergoing cardiac catheterization. We agree that propofol may well be an alternative to ketamine, but we must reemphasize the cautionary note sounded by the authors—propofol is a myocardial depressant (2,3), and it should be used with this side effect borne in mind.

Although mentioned in their article, Lebovic et al. (1) did not emphasize that their method of inducing anesthesia with propofol differs substantially from that commonly used in adults or children (4,5). Usually, a dose of 2–2.5 mg/kg of propofol is used and administered over a total of 40–60 s. Lebovic et al. (1) used 0.5-mg/kg increments, a relatively small dose, with each increment administered over 60 s. The hemodynamic effects of this method of administration may differ substantially from when the usual dose is administered more rapidly, as is usually the case. Another point that we feel must be stressed is patient selection: until more data are available, it is probably not only prudent but logical to avoid propofol in critically ill pediatric patients presenting for cardiac catheterization. Larger doses will contribute to alterations in cardiac output, with reversal of shunt flow causing much more significant alterations in cardiorespiratory variables than those described by Lebovic et al. (1).

To the Editor:

We read with interest the clinical research report by Lebovic et al. (1) on the usage of propofol as an anesthetic in pediatric patients presenting for cardiac catheterization. The authors indicated that this was the first presentation to describe the use of propofol in pediatric congenital cardiac diseases and further concluded that "propofol anesthesia is a practical alternative for pediatric patients undergoing elective cardiac catheterization and may be preferable to ketamine because of the significantly shorter recovery time." This recommendation must be qualified before wide application. We would like to address the following two points.

First, congenital heart disease is not a single disease but a vast array of anatomic anomalies. Each anomaly is associated with a set of distinctive clinical features. The clinical course and the physiologic responses to different pharmacologic interventions, as well as the homeostatic reflex to various stimuli during the administration of anesthetics, can be extremely diverse. Propofol is known to cause myocardial depression. In the investigation described by Lebovic et al. (1), it was discovered that 7 of 10 patients developed decreased mean arterial pressure after they were given a propofol infusion. In certain congenital heart diseases (e.g., aortic stenosis), a pharmacologically induced decrease in arterial blood pressure can precipitate adverse patient outcome (2). The use of propofol in patients with aortic stenosis must therefore be considered contraindicated. The notion that one anesthetic can be prescribed for a group of diverse cardiac diseases seems imprudent.

Second, the demographic data of the patients enrolled in the study mostly matched when age, body weight, arterial blood oxygen saturation range, and duration of catheterization were compared in the two groups (propofol and ketamine). However, the most important clinical feature in patients undergoing cardiac catheterization is not age, body weight, arterial oxygen saturation, or duration of catheterization, but diagnosis. The diagnosis of congenital cardiac defect, unfortunately, did not match in the two groups. For example, three patients in the ketamine group, but none in the propofol group, were diagnosed as having truncus arteriosus. (The number of patients in the study, 10 in each group, is too small for meaningful statistical analysis among the different diagnoses.)

In conclusion, we strongly believe that there is no single anesthetic that is ideal for providing sedation for cardiac catheterization. The result of the comparison between propofol and ketamine is probably not valid, because clinical diagnoses between the two groups of patients did not match.

In Response:

The cautionary note sounded by Drs. Lippmann and Ginsburg is appropriate. We would add, however, that only a small fraction of pediatric cardiac catheterization patients would be expected to experience arterial desaturation or hemodynamic decompensation in response to propofol. Obviously, the principle of slowly administering lower doses of depressant anesthetics applies to all patients with cardiac disease, especially those with right-to-left shunting.

Drs. Kao and Norton are correct in pointing out that congenital heart disease represents a wide spectrum of anatomic and physiologic abnormalities and that patients with certain lesions may respond adversely to propofol anesthesia. This point was also emphasized in the discussion section of our article and is a point that is well understood by the readership of this journal. However, we disagree with their contention that the presence of three patients with truncus arteriosus in the ketamine group invalidates the results of the study. They could just as easily have argued that there was only one patient with a double-outlet right ventricle in the propofol group. A study of several hundred patients would be necessary to achieve "statistical" equity between the groups. It is not necessary or economical to proceed with such a massive study to prove what is obvious from our limited study. The point of the study is not that propofol should be used in all patients with congenital heart disease; rather, in properly selected patients, it is a satisfactory anesthetic agent with markedly improved recovery characteristics.

In reviewing our further experience with propofol in the cardiac catheterization laboratory, it is being used as the primary anesthetic agent in approximately 70% of cases. We currently induce anesthesia using 1-mg/kg bolus doses of propofol, which is repeated once if necessary. Our initial infusion rate is 100 $\mu g \cdot kg^{-1} \cdot min^{-1}$, which is titrated upward or downward as necessary. Anesthesiologists, as well as pediatric cardiologists and postanesthesia care unit staff, are pleased with the recovery characteristics of propofol. It is likely that propofol will be used more commonly in the future, given the current emphasis on ambulatory care.

Propofol for Radiation Therapy in Small Children

To the Editor:

We agree with Martin et al. (1) that propofol is an excellent anesthetic for small children with indwelling central lines undergoing radiation therapy. However, we have found that when propofol is titrated by small bolus doses or continuous infusion, children are able to maintain their natural airway in both the supine and prone positions, and repeated endotracheal intubation can be avoided. A retrospective chart review of a 1-yr period showed that we had used intravenous anesthesia for 153 of the 156 high-voltage radiation therapy procedures for which anesthesia was requested. Propofol was used as the sole anesthetic in 72 cases and in combination with other anesthetics (midazolam, ketamine, droperidol) in 62 cases. In none of these 153 procedures was the trachea intubated. The radiation procedure itself is painless, and only light levels of anesthesia are needed to keep the child motionless. Patients were monitored with a pulse oximeter, electrocardiograph, respiratory inductane monitor, and an automated oscillometer for automatic arterial blood pressure measurement. Monitors were visible through a window in the treatment room. The children were observed indirectly via videocamera when the anesthesiologist left the room for the 3–7 min required for the treatment. Intravenous anesthesia without endotracheal intubation eliminates the need for an anesthesia machine and waste gas scavenging in a remote location and eliminates the risk of laryngeal trauma from repeated instrumentation. Propofol can be titrated to achieve adequate sedation without undue respiratory or cardiovascular depression. When propofol is used alone, recovery is rapid, and patients are alert before transport. Those patients undergoing daily treatments were able to continue normal daily activities and maintain nutrition. As with all potent anesthetics, careful observation and monitoring of the patient are required, and appropriate equipment and supplies must be available for the management of adverse drug effects or reactions.

In Response:

We appreciate the interest that Drs. Setlock and Palmisano have shown in our case report with regard to the use of propofol in pediatric patients outside the operating room (1). We agree with them that propofol is an excellent anesthetic for small children undergoing procedures remote from the operating room and that it has several distinct advantages over previously utilized techniques. We also recognize that airway management for these cases is somewhat a matter of preference. However, this decision must be made in the context of the individual institution. As stated in our article, we chose to carefully intubate the tracheas of our patients for several reasons: (a) one patient had to be transported to several different locations for multiple radiologic procedures; (b) our radiologic suites are very distant from the operating room should assistance be required; and (c) the patients had to be placed in multiple positions (supine, prone, and lateral). We had no evidence of airway trauma from repeated airway instrumentation when appropriate care was taken. As stated in the article, more experience with this anesthetic technique may demonstrate that oral intubation may not always be necessary. As Drs. Setlock and Palmisano have demonstrated, we also have found that in selected cases, carefully titrated infusions of propofol achieve adequate levels of sedation for these painless procedures and that patients are able to maintain their natural airways. However, each and every procedure must be planned with the particular institution's personnel, facilities, and limitations in mind. We therefore believe that the method of airway management must be left to the individual anesthesiologist, who clearly has an understanding of the local environment in which he or she is working.

Myelopathy and Back Pain —Take Heed

To the Editor:

Two articles in sequential issues of *Anesthesia & Analgesia* should have alerted anesthesiologists to the fact that local anesthetics are not innocuous drugs (1,2). However, these articles did not address other issues that anesthesiologists also should be aware of.

Rigler et al. (1) state that "Despite its long history, clear guidelines for safe administration of local anesthetics via an indwelling catheter remain to be established." A review of the most recent textbooks confirms this statement (two contained nothing on the subject and five only a paragraph) (3–9). Evidently, these books reflect the clinical situation, namely, that intermittent-injection spinal anesthesia has been little used or taught during the past 20 yr. Nevertheless, since 1940, both tetracaine and procaine have been used safely in intermittent-injection spinal anesthesia (10–16). However, tetracaine was not administered as in the one case cited by Rigler et al. (1). Futhermore, 5% lidocaine in 7.5% glucose or dextrose, which was used in the other three cases cited by Rigler et al. (1), is intended for use in the single-injection technique. Package inserts for this preparation of lidocaine state that "If the technique is properly performed and the needle is properly placed in the subarachnoid space, it shouldn't be necessary to administer more than one ampule (100 mg)" (17). It contains no statement about plastic tubing (catheter). Finally, one wonders why for spinal anesthesia, intermittent-injection rather than single-injection techniques were used. Compared with the single-injection technique, intermittent injection is fraught with more complications. All four cases cited by Rigler et al. (1) required only a sensory dermatome level to the tenth thoracic dermatome and durations of 1, 2.5, 3, and 3.5 h. A single injection of no more than 10 mg of hyperbaric tetracaine with duration extended by the addition of 0.2 mg of epinephrine (4–5 h) or 5 mg of phenylephrine (5–7 h) would have sufficed.

Hynson et al. (2) suspected "local irritation of the muscles and soft tissues" from chloroprocaine. When chloroprocaine was reintroduced for epidural block in 1971, it contained sodium bisulfite, a known tissue irritant (18,19); however, myelopathy from it did not surface until 1980 (20). In 1988, the bisulfite in chloroprocaine was replaced with the chelating (stabilizing) agent disodium ethylenediaminetetraacetate (EDTA) (21). After injection of this stabilizer into the subarachnoid space of rabbits, it was concluded that the investigation ". . . suggested EDTA has neural blocking effects and may cause complications" (22). One wonders what would happen if 20 mL or more was injected unintentionally into the subarachnoid space of patients? Perhaps nothing, but then, time will tell. Nine years (1971–1980) elapsed before myelopathy from chloroprocaine containing sodium bisulfite surfaced.

Hopefully, these two articles (1,2) have notified physicians that trespassing clinically with local anesthetics that have not been carefully and thoroughly researched for the techniques for which they are to be used, can result in significant complications.

In Response:

We appreciate Dr. Moore's comments. As we have previously stated (1), the purpose of our article was to alert clinicians to a potential risk, to suggest an etiology for the four cases of cauda equina syndrome, and to begin to establish guidelines for the safe administration of local anesthetic through an indwelling subarachnoid catheter (2).

Dr. Moore agrees that clear guidelines for continuous spinal anesthesia (CSA) do not exist. Nonetheless, he suggests that since 1940, tetracaine and procaine have been used safely for intermittent-injection spinal anesthesia. However, his citation of the literature is incomplete. For example, the cited report by Schuhmacher and Eversole (3) provides only a description of the technique used for CSA at the Lahey Clinic during the late 1930s and early 1940s; it does not report results nor review complications. The citations do not include the subsequent report published 4 yr later by Nicholson and Eversole (4) that did review the Lahey Clinic experience during that same period and documented five cases of neurologic complications among 21,000 tetracaine spinals. Of these five cases, three occurred with a continuous spinal technique, two of which were classified as cauda equina syndrome. (Unfortunately, the report does not indicate the relative number of cases performed with a single-injection or a continuous technique.) Dr. Moore's references also do not include other reports in which neural injury was associated with CSA performed with procaine or tetracaine (5,6). Furthermore, the relationship between injury and anesthetic agent may not always be appreciated—as we noted in our article, the three cases of severe urinary retention described in Apgar's (6) series of 422 cases of CSA performed with procaine likely reflect local anesthetic neurotoxicity. Thus, the use of tetracaine or procaine for CSA as described by these early investigators cannot be viewed as entirely safe.

In the four cases of cauda equina syndrome reported in our article (2), there was evidence of a focal sensory block, and to achieve adequate anesthesia, a dose of local anesthetic was administered that was greater than that usually used with a single-injection technique. We postulated that the combination of maldistribution and a relatively high dose of local anesthetic exposed neural tissue to a toxic concentration of anesthetic. We have been able to demonstrate in a model of the subarachnoid space that when maldistribution occurs, the concentrations achieved with repeated administration of hyperbaric local anesthetic are potentially neurotoxic (7).

However, prior to our report of the four cases, concerns with regard to neurotoxicity from high doses of local anesthetic were confined primarily to chloroprocaine (8). The dosages of local anesthetics commonly administered intrathecally have been tailored to achieve an appropriate dermatomal level and duration, not to avoid neurotoxicity. Previous reports of CSA often have commented on the wide variability in anesthetic requirement and suggested, as in the Lemmon (9) article cited by Dr. Moore, that the "dose should be given as needed." Although the package insert for 5% lidocaine indeed does suggest that 100 mg should be sufficient, it fails to state that this dose should not be exceeded nor caution that neural injury might result. Conversely, higher doses of lidocaine have often been recommended or administered. For example, the textbook by Lund (10), which Dr. Moore cites, suggests a dose of "100 to 150 (or more) mg for upper abdominal procedures," whereas Mörch et al. (11), using a catheter technique, administered doses of 150 to 550 mg, with doses as high as 250 mg administered to establish the initial block.

Dr. Moore believes that 5% lidocaine in 7.5% dextrose is for use in a single-injection technique, noting that the package insert does not mention administration of the anesthetic through a catheter. This view is inconsistent with his belief that tetracaine and procaine are appropriate for CSA, because neither the insert for procaine (12) nor for tetracaine (13) refers to such use. It is also inconsistent that Dr. Moore cites Lund (10) but fails to acknowledge Lund's conclusion that "Any local anesthetic agent which is suitable for [single-injection] spinal anesthesia may be used for [CSA]." Of note, Mörch et al. (11), one of the first to report 5% lidocaine in 7.5% dextrose to be "a safe, potent and satisfactory agent for spinal anesthesia," delivered the anesthetic through a catheter. However, a major point in our article was that neurotoxic injury resulted from the combination of maldistribution and a high dose of relatively concentrated local anesthetic. Consequently, we suggested that the lowest effective concentration of local anesthetic be used. This recommendation is based on data indicating that the risk of neurologic injury is, at least in part, concentration dependent (14). If maldistribution occurs, the concentration of local anesthetic will not be adequately diluted by cerebrospinal fluid. Therefore, we recommend that 5% lidocaine not be used—this concentration is in excess of that needed for adequate blockade. We suggest that lower concentrations be selected for single-injection spinal anesthesia as well: the appropriateness of injecting a particular local anesthetic into the subarachnoid space should not be based on whether it is to be administered through a needle or a catheter, nor with a single-injection or a continuous technique, but, rather, the intrinsic characteristics of the anesthetic solution.

We also recommended that a test dose should be administered, after which the extent of blockade should be assessed; if maldistribution of anesthetic is suspected, maneuvers such as changing patient position, altering the lumbosacral curvature, switching to a different baricity of local anesthetic, or manipulating catheter position should be used; if these maneuvers fail to correct the problem, the technique should be abandoned. We have suggested that similar cautions be applied when repeating single-injection spinals that have failed to provide adequate analgesia (15). Maldistribution *can occur* with a single-injection technique, and there is the potential (albeit less than with an indwelling catheter) for repeat injections to distribute in the same restricted pattern; this restricted distribution could result in neurotoxic concentrations of local anesthetic—a review of the closed-claim database appears to support these concerns (15).

We do not agree with Dr. Moore that, in comparison with a single-injection technique, CSA is fraught with complications. Conversely, the continuous technique offers potential advantages. With CSA, the duration of anesthesia can be controlled by administering incremental doses of short-acting local anesthetics, and there is evidence to suggest that anesthesia can be maintained for extended periods without prolonging recovery. In a preliminary study, we observed that the length of stay in the postanesthesia care unit was unrelated to the duration of the surgical procedure (16). Although the single-injection technique also can provide anesthesia for extended periods (e.g., addition of a vasoconstrictor to tetracaine), the inability to predict anesthetic duration or surgical time accurately can lead to failure of the spinal technique or to prolonged recovery. In addition, CSA allows greater control of the extent of blockade, which, in a preliminary study, has been shown to correlate with hypotension, bradycardia, and nausea and vomiting (17); additional preliminary data suggest that patients receiving a continuous technique have a lower requirement for vasopressors (18).

We appreciate and share Dr. Moore's concern that the renaissance in regional anesthesia flourish; and we do hope, as Dr. Moore suggested, that our article will serve to alert clinicians that "local anesthetics are not innocuous drugs."

Epidural Hematoma: Was Catheter Removed During Complete Anticoagulation?

To the Editor:

A recent case report linked the occurrence of an epidural hematoma to the presence of a congenital spinal arteriovenous abnormality (1). However, review of the case presentation raises a basic question—did removal of the epidural catheter while the patient was still undergoing anticoagulation therapy result in the epidural hematoma?

A 71-yr-old man underwent a carotid endarterectomy under cervical epidural anesthesia. Heparin (5000 U) was administered intravenously. The epidural catheter was removed at the end of the procedure, approximately 120 min after the dose of heparin, without checking coagulation studies. Approximately 30 min later, the patient began complaining of discomfort in the chest, arm, and back. Emergent surgical exploration revealed a cervical epidural hematoma and an "extensive plexus" of veins covering the dura. Coagulation studies were performed approximately 260 min after the heparin dose and were normal.

Other cases have been reported in which an epidural catheter was removed from a patient undergoing anticoagulation therapy, who went on to develop an epidural hematoma (2–4). In one case, heparin (5000 U) was administered 70 min before the epidural catheter was removed. At 2 h, a Lee-White clotting time remained elevated (21 min; normal 5–15 min) (3).

Recommendations exist with regard to the removal as well as the insertion of epidural catheters. One group recommended "frequent activated clotting time analyses" to ensure neutralization of heparin activity before epidural catheter removal (5). An editorial published in the newsletter of the American Society of Regional Anesthesia stated that one should "leave the epidural catheter in place until all systemic anticoagulation is neutralized or reversed" (6).

Therefore, the presence of a congenital spinal arteriovenous abnormality may predispose a patient to an epidural hematoma; but the removal of an epidural catheter when a patient remains in an anticoagulated state will do so as well. An epidural catheter should be left in place until anticoagulation has been corrected. Removal can then be accomplished safely.

In Response:

Dr. Stevens asks a fair question: "was the epidural catheter removed during complete anticoagulation?" There were no clinical signs of excess bleeding or delayed clot formation during the carotid endarterectomy. Blood samples that were obtained at the onset of symptoms did clot. The hematologist found no clotting defects. It remains that this does not rule out continuing anticoagulation activity. The wormlike nest of veins in the epidural space at surgery associated with the hemangioma on the chest wall still remains a possible cause for the hematoma and the reason for the original report. I agree that the coagulation status must be established before removal of the epidural catheter.

Long-Distance Anesthesia

To the Editor:

I should like to agree with Dr. Boyd and coworkers (1) concerning "long-distance anesthesia," which I also use in ophthalmic anesthesia. There may, however, be a problem with standard calculated minute volume (Vmin) and tidal volume (Vt).

The anesthetic dead space is from the Y-piece to the tip of the endotracheal tube. There is, however, further effective dead space. This further dead space is in the compliance of the ventilatory tubing. Most tubing in use has a compliance of 3–5 mL/cm H_2O at room temperature (20°C); therefore, with an airway pressure of 20 cm H_2O, there is 60–100 mL of fresh gas used in the expansion of the tubing. If the tubing is doubled in length, then the expansion volume rises to 120–200 mL.

The Vt measured at the inspiratory or expiratory port of the ventilator will be patient tidal volume plus expansion volume. When measured at the Y-piece, only patient tidal volume is measured. It is possible to measure Vt at the Y-piece by an electronic spirometer or, more easily, by an in-line vane-type or resistance flowmeter.

It is therefore important in long-distance anesthesia to either know the compliance of the tubing used or to measure Vt at the Y-piece. Alternatively, end-tidal CO_2 measured at the Y-piece also confirms adequate alveolar ventilation despite the length of the tubing.

For ophthalmic anesthesia, I have been using a closed-circuit anesthesia system with ventilatory tubing 2 m in length (4 m overall). This allows full access to the patient's head for surgical purposes. Knowing the compliance of the tubing, I can calculate the actual tidal volume that the patient is receiving. I confirm adequate alveolar ventilation by monitoring end-tidal CO_2 and hemoglobin O_2 saturation.

I would agree with Dr. Boyd and coworkers that there appears to be a perception that the patient must be close to the ventilator. However, assuming that all of the above are taken into account, then there is no reason why the ventilator cannot be a reasonable distance from the patient, yet still be in a safe location and provide surgical access.

In Response:

We were encouraged by Dr. Dunphy's letter with regard to our article on long-distance anesthesia, which he also utilizes.

We certainly concur with his statements about the compliance of the ventilator tubing as a factor in calculating the delivered tidal volume. To compensate, we usually add approximately 100 mL to the estimated tidal volume required by the patient. The volume is then adjusted for an end-tidal CO_2 of 35 mm Hg. Furthermore, the hemoglobin O_2 saturation is monitored in every patient.

This was an omission on our part, and we appreciate Dr. Dunphy's comments.

An Atraumatic Oral and Nasotracheal Intubation Guide Probe

To the Editor:

I would like to comment on the case report by Knuth and Richards (1). Tracheal intubation via the nasal approach is not a rare event. In children, nasal intubation is used for amygdalectomy or to adequately fix the endotracheal tube when the child's head is too far from the anesthesiologist. In adult surgery, nasal intubation is performed in otolaryngology—head and neck surgery and in oral and dental surgery.

In our university clinic, we always use a tube with a flexible guide probe and a blunt extremity for all oral or nasal endotracheal intubation (Figure 1). This probe, which is well adapted to the endotracheal tube diameter, has two advantages: (a) it facilitates oral intubation without larynx trauma when laryngoscopy is difficult, and it can be used together with the Magill forceps to facilitate intubation; (b) it prevents the inhalation of foreign bodies and keeps anatomic structures (adenoids or turbinate) out of the airway. This probe also prevents insufflation in the airway of an object set in the endotracheal tube. The tube is easy to use and without risk for the patient because the probe is always plastic, and its extremity is blunt. The close fit of the probe and the endotracheal tube is important, because it prevents a foreign body from coming between the probe and the endotracheal tube.

More on Epidural Fentanyl Analgesia

To the Editor:

In their discussion of epidural fentanyl analgesia, Glass et al. (1) comment as follows: "Using the epidural route, the concentration and volume of the fentanyl dose as well as the site of the epidural catheter in relation to the site of surgery is important in providing optimal analgesia with the smallest dose." I suggest that volume and concentration are not important. I do believe that epidural placement site is important in providing superior analgesia with smaller doses of fentanyl and wonder why, considering the above statement, Glass et al. decided to place catheters in the low lumbar epidural space. It would have been more appropriate to place the catheters in a low thoracic interspace, because the opiate receptors are found in the spinal cord, which ends at L-2.

As residents, anesthesiologists learn epidural therapy using bolus doses of local anesthetic for anesthesia. Now we are using continuous infusions of narcotics for epidural analgesia. One cannot consider these to be equivalent in theory or practice. I believe that a slow, continuous infusion, for example, either 3 mL/h (0.05 mL/min) or 6 mL/h (0.1 mL/min) to administer 60 μg/h of fentanyl, presents an inconsequential difference of volume to structures in the dynamic epidural space. The argument is that dose is important and concentration (volume) less critical. The finding of an optimal concentration for bolus epidural fentanyl by Welchew (2) does not necessarily apply to a continuous fentanyl infusion.

Glass et al. (1) claim that intravenous and epidural fentanyl provide equivalent analgesia when administered by patient control. In their study, catheters were placed in the lumbar epidural space. The epidural space has a large potential volume in the lumbar region compared with the thoracic region. With narcotics administered in the lumbar epidural space, which is dynamic and filled with adipose tissue and blood vessels, one would assume that very little if any of the analgesic effect would be neuraxial. The obvious reason is that the epidural structures would distribute lipophilic opioids systemically. Thus, I agree with Glass et al. (1) that intravenous fentanyl is probably equivalent to lumbar epidural fentanyl. Perhaps morphine, which is hydrophilic, is the only opioid appropriate for analgesia with lumbar catheter placement.

Nonetheless, I use fentanyl as my drug of choice for epidural analgesia, with catheter placement determined by the dermatomal origin of pain. There is support for this technique by at least one clinical study. In an abstract by Bodily et al. (3), it is reported that fentanyl epidural analgesia for postthoracotomy pain is influenced by the site of epidural catheter placement. Those patients who had lumbar catheters were not as comfortable as those who had thoracic catheters, even though they received 50% more fentanyl. I draw two conclusions: (a) epidural fentanyl provides segmental analgesia; and (b) there is a significant neuraxial component of analgesia with thoracic epidural administration of fentanyl. The Glass et al. (1) research might have confirmed the Bodily et al. (3) study had they placed their catheters appropriately.

To the Editor:

Glass et al. (1) presented an interesting approach to postoperative pain management with the use of patient-controlled administration of fentanyl via the epidural and intravenous routes. However, we believe that their conclusion, that analgesic effects of fentanyl in the epidural space are due to plasma concentrations, is somewhat misleading. In view of the site of infusion, one should not be surprised that the analgesic effect of fentanyl is due primarily to systemic rather than neuraxial antinociceptic activity. An alternative conclusion that one may draw from this study is that for a drug such as fentanyl to be effective, one must place it close to its dermatomal site of desired action.

In support of this, and in contrast to Glass et al. (1), we find epidural fentanyl infusions to be very effective in low doses (i.e., 1.0 $\mu g \cdot kg^{-1} \cdot h^{-1}$) in the control of postoperative pain in patients with upper abdominal and flank incisions. Pharmacokinetic work by Gourlay et al. (2) very clearly defined the potential limitations when using epidural fentanyl for postoperative pain control. Infusions via an L3-4 catheter demonstrated that fentanyl, being very lipophilic, would not diffuse well in a cephalad direction. As a consequence, to achieve good pain control with epidural fentanyl, one must place it at the appropriate dermatomal level, as Wolfe et al. (3) did and as we do.

Opioid activity in the spinal cord is primarily the result of nociceptive inhibition at the dorsal horn level of entry (i.e., for an upper abdominal incision at the T8-10 dermatomal level). One must place a catheter at that level to expect a good result when using highly lipophilic opioids, such as fentanyl, sufentanil, or alfentanil. Our experience with over 600 epidural infusions demonstrates that low-dose fentanyl/bupivacaine infusions (5 μg/mL and 0.125%, respectively) at rates of 6–12 mL/h give excellent relief for postoperative pain.

Patient satisfaction with our continuous infusion technique is very high, especially at night. This technique does not require that patients awaken in pain before giving themselves a dose of analgesic, as would patient-controlled analgesia. In theory, continuous epidural infusions may permit the use of lower doses of narcotics, in part due to the maintenance of steady-state drug concentrations at the dorsal horn. However, patient comfort is the primary goal, not necessarily saving doses of narcotic drugs.

In conclusion, we have found epidural infusions to be both highly effective for control of postoperative pain as well as very safe for use on general surgical wards. We offer this as a respectable alternative to the use of epidural patient-controlled analgesia.

In Response:

Drs. Nicholson and Rowlingson and Dr. Hubbard all raise a very important issue with regard to positioning the epidural catheter when administering epidural fentanyl. It is true that the same principles pertaining to the administration of epidural local anesthetics cannot be extrapolated to the administration of epidural opioids. Local anesthetics act on nerve roots as they pass through the epidural space, whereas opioids have to traverse the dura and cerebrospinal fluid to reach the dorsal horn of the spinal cord to reach their site of action. Because the spinal cord ends at L-1 in the adult, a lumbar epidural catheter at or below this level will increase the distance that the opioid has to traverse, compared with a catheter placed at the thoracic level. The implication is therefore that using an epidural catheter placed at the lumbar level would require a larger dose of fentanyl to provide effective analgesia than an epidural catheter placed over the involved dermatome at the thoracic level. This supposition has not been systematically investigated. A recent study did compare lumbar with thoracic epidural administration of fentanyl after thoracic surgery (1). The investigators were unable to show a significant difference between the two routes of administration in either quality of analgesia, dose, or fentanyl plasma concentrations. It is also interesting to note that Drs. Nicholson and Rowlingson recommend an infusion of 30–60 μg/h of fentanyl (in combination with 0.125% bupivacaine). This hourly dose of fentanyl is the same as that (40–50 μg/h) required intravenously by the patients in our study (2) (as well as others [3]) to achieve very satisfactory analgesia. It should also be noted that the less lipid-soluble opioids will tend to migrate cephalad in the cerebrospinal fluid. Therefore when an opioid (especially one like morphine) is administered in the lumbar epidural space, the onset of analgesia may be altered but not the efficacy of the dose.

It is common for a physician to insert a lumbar epidural catheter for the administration of local anesthetics intraoperatively and then utilize this same catheter for postoperative pain management. Thus, the results of our study are pertinent for normal clinical practice and enable the clinician in such instances to make a more rational choice as to either the drug (fentanyl vs morphine) or mode of its administration (epidural vs intravenous) that is optimal for patient postoperative pain management.

Malignant Hyperthermia During Sevoflurane Anesthesia

To the Editor:

We read with interest the article by Ochiai and colleagues (1) describing the possible association between the administration of sevoflurane and the development of malignant hyperthermia (MH). Because of the important implications of such findings, we believe that a critical examination of their case reports is necessary. We agree that sevoflurane may be associated with MH, as we had previously reported (2).

In the first case report by Ochiai et al. (1), the findings are consistent with the development of MH; but we also note that impairment of CO_2 absorption by sevoflurane may also cause several of the findings (e.g., increased heart rate, end-tidal CO_2). The relative contribution is difficult to discern. In the second case, we question more strongly the association between sevoflurane administration and MH. Whereas it is not certain whether the malfunction of the vaporizer suspended or overevaporated the isoflurane, the exposure to sevoflurane for only 30 min is not likely to have provoked MH. It has been shown that sevoflurane is a less potent trigger of MH than other volatile anesthetics (3). The late onset of MH by volatile anesthetics must be considered when establishing the etiology of MH (2). Also, lethal MH occurred in this patient, who had a history of general anesthesia without a previous problem. In addition, warm skin or muscle rigidity was not shown, and the ineffectiveness of dantrolene is worthy of notice. Muscle biopsy or a postmortem examination of the hypothalamus (4), or both, would have been informative.

These cases are also of interest because of the potential anesthetic interactions that may produce undesirable effects. In our institute, we have used sevoflurane frequently to induce anesthesia in children because of its rapid onset of action. Usually, isoflurane is then used for maintenance of anesthesia. The interactions between these anesthetics and others must therefore be studied, because such combinations may be used, owing to the rapid uptake and elimination of sevoflurane.

Cannulation of Vessels Using a Spring-Loaded Device

To the Editor:

Cannulation of blood vessels is an important part of managing seriously ill patients, especially neonates and infants. The procedure requires very fine hand control and considerable practice. Although it is an operation performed many times, it can be a daunting experience for some (1).

Intravenous cannulas are designed with an introducer needle that is slightly longer and narrower than the cannula. Difficulties are usually encountered once the vessel has been punctured by the needle, and the cannula is advanced. The needle may bend considerably during insertion, making manipulation difficult (2). Additionally, the needle tip may be accidentally advanced or prematurely withdrawn, resulting in failure.

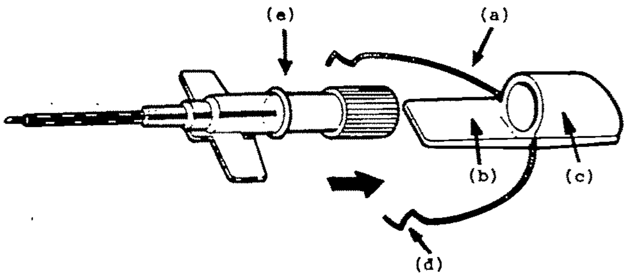

Figure 1. (a) Central venous pressure line guide wire used as spring; (b) rectangular plastic base; (c) tube to hold the hub of the cannula; (d) "Z"-shaped hook; (e) intravenous cannula with wings.

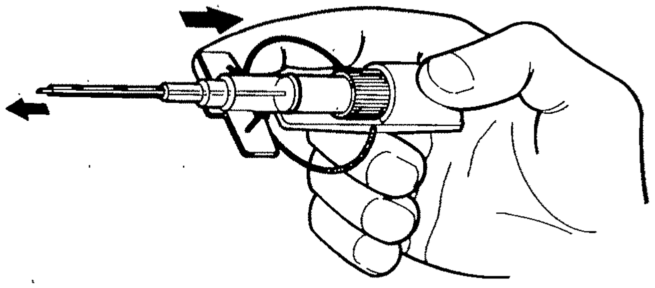

Figure 2. Cannula held with the device spring in tension.

By experiment, I have found that spring-loading the cannula greatly eases this procedure. The spring is put under tension before the vessel is punctured. Once the vessel is punctured, release of the spring pushes the cannula forward in a swift, smooth motion, avoiding the problems normally encountered.

The device (Figure 1) is constructed using a central venous pressure line guide wire that acts as a spring. While the cannula is held in place on the needle with a finger on one of the wings, the free ends of the wire are hooked over the near side of each wing (Figure 2). This puts forward pressure on the cannula. The cannula is held with the wire under tension, and the vessel is pierced as usual. Once the needle is within the lumen, signaled by a "flashback" of blood (3), the resisting finger can be released, and the cannula moves forward into the blood vessel. The spring and the needle are withdrawn, leaving the cannula in situ.

This technique was assessed in 50 infants (92% weighing <4 kg) when cannulation by the conventional method had failed. Cannulation was successful in 47 (94%) of these infants on the first attempt; only 3 (6%) required a second attempt.

By adopting this concept, a new generation of spring-loaded cannulas, long lines, and central venous pressure lines could be constructed.

Use of Transesophageal Echocardiogram for Intracardiac Thrombus Related to Postoperative Atrial Fibrillation

To the Editor:

We describe a case in which a patient developed postoperative atrial fibrillation due to an intracardiac thrombus.

The patient was a 68-yr-old man with a history of insulin-dependent diabetes mellitus and previous myocardial infarction who underwent an emergent embolectomy of the right subclavian artery. The anesthesia was performed by field block using 2% plain lidocaine (200 mg) with intravenous sedation using midazolam 3 mg and fentanyl 100 μg. At the start of the procedure, a heparin infusion was started at a rate of 1000 U/h. The patient had an unremarkable intraoperative course, and the heparin infusion was discontinued at completion. On arrival at the postanesthesia recovery room, the patient's telemetry (lead II) had converted from normal sinus rhythm to atrial fibrillation. Electrocardiogram confirmed the atrial fibrillation, and no ischemic changes were noted. At this time, the patient had experienced no chest pain and was hemodynamically stable. Digitalis (1.0 mg) was administered intravenously over 4 h along with verapamil (7.5 mg) in 2.5-mg doses over 2 h. Heparin therapy was restarted at 1000 U/h after a 7500-U intravenous bolus. The patient was transferred to the coronary care unit, and a transthoracic echocardiogram was obtained to determine the etiology. This revealed mild hypokinesis with an ejection fraction of 40%. However, the transesophageal echocardiogram also revealed the additional presence of an intracardiac thrombus. Heparin therapy was reinstituted, and the cardiac rhythm converted to normal sinus 24 h later.

The purpose of this report was to demonstrate that an intracardiac thrombus is a treatable cause of atrial fibrillation in the postanesthesia recovery room and that transesophageal echocardiography was shown to be superior to the transthoracic echocardiogram in its detection (1,2).

Book Reviews

The Obstetric Anesthesia Handbook

S. Datta. St. Louis: Mosby Yearbook, 1992, 353 pp, $34.95.

This textbook has two relatively unique features that are obvious on initial inspection. First, this book is written by one author, with the sole exception of the final chapter on the legal aspects of obstetric anesthesia, written by Robert M. Knapp, DO, JD. Second, this book is truly a handbook whose size, shape, and length fit the definition of a handbook. Both of these factors make a significant contribution to the success of this work.

There is complete uniformity of style, with little overlap and repetition, as well as a general theme and tone that prevails throughout the text. There is no doubt that this book grew out of routine lectures to students, residents, and research fellows. The text clearly and simply puts into words in an organized manner the kind of information that is passed along by a senior clinician to the next generation. The information is presented in a format that is easy to read and provides enough general discussion and controversies, yet comes to a conclusion and leads to potential management decisions. Although many of the topics discussed in this book have resulted in lengthy book chapters elsewhere (if not books in and of themselves), here the material is condensed in a very thoughtful and practical way. (The current trend seems to be that manuals grow into major books, and books grow into multiple volumes, if not seriously large tomes.) Although larger, more extensive texts clearly have their place as both teaching tools and as basic references, this handbook fills a unique need by providing practical, realistic information in a very accessible format.

When considering such a text, one must accept the obvious drawback that both the length and style do not permit lengthy descriptions of problems. On the other hand, for such a text it houses an incredible wealth of information that is both well organized and accessible. The index is particularly helpful in locating the information one wants quickly. This book is also unique in that it serves both as a truly excellent introduction to the area of obstetric anesthesia for the beginner and as an excellent reference for the occasional obstetric anesthesia practitioner who wishes to review a particular subject or unusual clinical problem. Its very brevity and straightforward nature make it ideal for both purposes. There are also adequate references, so that one can further explore particular problems in some detail. Surely this text is an excellent starting point for any number of controversial issues or specific problems.

The material covered is standard but complete. The introduction on maternal physiologic changes d
pregnancy, labor, and the postpartum period is ade
without being cumbersome. Even in sections tha
exceedingly brief—for example, local anesthetic pharm
ogy—the material presented is appropriate and exceed
current. The chapter on drug interactions and obs
anesthesia is particularly extensive and well organized
chapter on spinal opiates, although exceedingly
packs a great deal of information into very few p
However, it would have benefited from some sp
recommendations concerning monitoring of patients
have received spinal narcotics. Although there is appr
ate mention of delayed respiratory depression and
cerns with monitoring and caring for these patients,
cific recommendations are avoided.

In several sections of the text, there is solid inform
concerning the effects of anesthesia on the newbor
cluding neurobehavioral effects and the general probl
the effects of local anesthetics on the newborn. Throu
the text, be it systemic narcotics to newborn resuscit
there is appropriate emphasis and information pro
concerning the fetus and the newborn. Similarly, are
controversy are presented, with the several sides
considered. Very appropriate and practical comment
made concerning the use of a test dose in the "real wo
with several choices presented. On the other hand,
considering preeclampsia and the probable platelet
function, the author fails to present very specific guid
concerning the use of bleeding time and placeme
regional anesthetic in this group of patients. There a
course, benefits to presenting controversies without
ing to firm conclusions, particularly when there i
obvious firm answer to the problem. However, the clin
often seeks more specific guidelines or a stronger
point, both of which are occasionally missing in this

In conclusion, this is a well-written text that be
from a single author's viewpoint, style, and long hist
clinical experience. This book manages to be both exte
in scope and exceedingly practical and brief in pres
tion, without leaving the reader lost or simply read
glossary of terms. This book is a particularly worthy
tion to the library of the new resident or a pract
clinician who wants a quick and handy reference text

Anesthesia and Organ Transplantation. Volume 29, No. 3 of the International Anesthesia Clinics

L. Firestone, ed. Boston: Little Brown, 1991, 159 pp, $81.00 (annual subscription of four issues).

Anesthesia and Organ Transplantation is a tightly written, enjoyable monograph that makes a valid effort to cover a broad area of anesthesia. Perhaps it is an oxymoron to say that this is a "comprehensive monograph," owing to the limitations of the medium; yet, the increase in transplantation procedures impacts greatly on common practice, and it is publications such as this that help keep us all up to date.

The opening chapter on organ donor care is excellent and suitably explains the hemodynamic and endocrine perturbations. Anesthesiologists play a key role in maintaining organ function, and the concept of the human body as an intensive care unit for the harvested organs is well related.

Subsequent chapters examine individual organ systems and their unique transplantation strategies: kidney, lung, heart, liver, pancreas. It is extremely interesting to observe techniques from other centers, although the distinct limitation of having one author for each chapter appears to segregate viewpoints. There is little reference to neighboring centers' techniques and a strong emphasis on the "Pittsburgh way." The sections on lung and liver transplantation are fascinating, and even the "nontransplant" anesthesiologist will learn key facts relating to common practice. The study of end-organ failure gives one a strong appreciation for intact physiology.

This is a valuable text; yet it would have been more complete with a review of basic immunology concepts to reacquaint the reader with relevant transplantation immunology. This could have led into a discussion of new immunosuppressive drugs; only a small paragraph is devoted to new work being done with FK506. Another area that was excluded from the book was a discussion of preservative solutions, an area that has impacted greatly on timing and outcome of transplantation operations.

Anesthesia and Organ Transplantation is a worthy monograph that covers a smattering of topics and techniques. Its brevity makes this a "quick" read but illustrates the incompleteness of the monograph style.

Todd Pilch, MD
Duke University Medical Center
Durham, North Carolina

Anesthesia for Organ Transplantation: A Society of Cardiovascular Anesthesiologists' Monograph

J. A. Fabian, ed. Philadelphia: J. B. Lippincott, 1992, 194 pp, $49.95.

The continued growth of organ transplantation and the increased longevity of transplant recipients will have an impact on many anesthesiologists. Those practicing in academic centers are often involved in the care of patients undergoing transplant surgery. As the population of transplant recipients grows, many will require surgical care in community hospital settings. This trend will make familiarity with the issues concerning the care of transplant patients requisite knowledge for all practicing anesthesiologists.

This monograph comprises 10 chapters by 22 contributors, including the editor. The chapters range in approach from a "cookbook" look at cardiac transplantation in children, as practiced at one institution, to a fascinating review of investigations into the physiologic alterations in the postcardiac transplant patient. The book fails to live up to its title by the lack of chapters on kidney or pancreas transplantation. Kidney transplantation, perhaps the least complicated transplant procedure, is certainly the most commonly performed currently. The monograph addresses heart and heart lung transplants; pediatric cardiac transplants; cardiovascular physiology after cardiac transplantation; mechanical cardiac assist devices and the total artificial heart; physiologic changes in the brain-dead organ donor; single-lung transplants; liver transplantation; immunosuppression; the use of cardiopulmonary bypass for organ transplantation; and, finally, ethical issues in organ transplantation.

The chapter on anesthetic considerations for liver transplantation is particularly well written. It includes a look at the altered physiology of the cirrhotic patient and a nice, concise review of the issues and concerns of each of the four stages of hepatic transplantation.

The chapter on ethical issues highlights recent developments that relate not to anesthesia, but rather to transplantation: Does unfairness result from allocating scarce organs based on criteria biased toward patients of white, European ethnicity? What are the implications of securing organs by means other than altruism? Do recipients perceive a change in their sense of self after organ transplantation, particularly recipients of animal organs? Should animals serve as organ donors? The chapter author addresses these issues well in terms of fairness and justice.

The monograph might have been improved with the inclusion of chapters on kidney and pancreas transplants and the deletion of a very superficial chapter on the use of cardiopulmonary bypass in organ transplantation. The book will serve as a good introduction to the field of anesthesia for organ transplantation and as a good starting point for further reading in this fast-growing area of our specialty.

A Handbook of Paediatric Anaesthesia

Stephen J. Mather and David G. Hughes, eds. New York: Oxford University Press, 1991, 304 pp, $65.00.

This book is a short manual of pediatric anesthesia written by anesthetists in Bristol, England. The American reader will recognize some differences in the practice of pediatric anesthesia across the ocean, but by and large, these differences are small and not of major clinical significance, although, for the reader unfamiliar with British terminology, some of the names and terms will be difficult.

The value of this book is that it presents in 300 pages a well-written synopsis of much of the field of pediatric anesthesia. A glance at the chapter headings indicates that the usual topics are covered, including anatomy and physiology; pharmacology; pediatric anesthesia apparatus; monitoring in pediatric anesthesia; basic concepts of pediatric anesthesia practice; medical conditions with relevance to anesthesia; anesthesia for cardiac surgery; anesthesia for specialist surgery; day case anesthesia; anesthesia for radiologic procedures; pain management in children; acute airway problems; transport of critically ill children; and cardiopulmonary resuscitation. The information that is presented is sound and conforms in a general way with standard practice in the United States.

The disadvantage of this book, however, is the limited amount of material that can be presented in such a short space. Trainees who use the book are faced with a dilemma. They will find one approach for dealing with a problem but may not understand the rationale for the approach that is presented or the arguments advanced by others for the use of different techniques. Thus, if residents relied on this book alone, they would come away with a fairly "cookbook" approach to practicing pediatric anesthesia without understanding the principles on which sound medical judgments are made. In addition, the selection of references is spotty. In some cases, the original references are included, but this is not always the case. This reviewer believes that it would be difficult for the reader to delve deeply into any particular area on the basis of the references listed.

There are omissions of important material, partly as a result of trying to compress a complex field into a short space. For instance, there is no discussion of masseter spasm after succinylcholine. In other instances, statements are made without a reference for that statement; for example, if a child is anesthetized with a viremia, myocarditis can occur. Other important omissions are the failure to mention the use of phenylephrine or other techniques to raise blood pressure in patients who are having tetralogy of Fallot (Tet) spells, and the difference between primary and secondary ventricular septal defect.

In some areas, the British approach will be unfamiliar; examples are the use of cyclopropane for induction of anesthesia and the lack of use of oral midazolam. The discussion on anesthesia apparatus will be difficult for the American reader, because it largely concerns British apparatus, especially ventilators.

In summary, this book is well written and touches on the highlights of pediatric anesthesia. The problems center on the differences between British and American terminology and practice and the limited depth that is possible in a book of this length and type.

Donald C. Tyler, MD
Children's Hospital and Medical Center
Seattle, Washington

The Management of Acute Pain

G. Park and B. Fulton. New York: Oxford University Press, 1991, 166 pp, $59.95, ISBN 0-19-263016-4.

Much has been published recently on the management of acute pain, including journal articles, monographs, and texts aimed at comprehensive instruction in this area. Much less, though, has been written with the beginner in mind. *The Management of Acute Pain* is aimed at this audience. The authors describe the book as providing "simple, practical guidance" for junior medical students and nursing staff. Although the book effectively follows these guidelines, international differences in practice, drug names, and availability may limit its usefulness in the United States.

The book is structured in a logical fashion, with the first five chapters serving as an introduction. These chapters are well organized, well written, and easily read in a brief period of time, and they lay a solid groundwork for the chapters that follow. Several good tables are included that summarize and clarify the text (the one comparing various routes of drug administration is particularly useful).

The next several chapters in the book deal with the pharmacology and clinical application of opioid analgesics, presenting a very good overview of this area. Specific precautions and guidelines for each route of opioid administration are provided and reinforce the need for an organized and educated staff to care for patients receiving this therapy. The problem in this section and in subsequent pharmacology chapters is inherent in a book aimed at the British market. Drug names and drug availability are different than in this country. Also, the listed dose range for intrathecal morphine (0.5–1.0 mg) is higher than that usually used in the United States. This may explain why the authors caution against the use of intrathecal morphine, except in an intensive care unit-like setting.

The next chapter discusses the nonsteroidal antiinflammatory drugs in a brief but effective format. The advantages and disadvantages of this drug group are discussed, and comparative information on specific agents is included.

A chapter on local anesthetic pharmacology is well written and clinically relevant and includes the necessary section on the recognition and treatment of local anesthetic toxicity. Analgesic techniques involving local anesthetics are then briefly reviewed; however, nursing guidelines for "epidural top-up procedures" with local anesthetics describe a practice different from that common in the United States.

A discussion of the roles of nitrous oxide, transcutaneous nerve stimulation, and acupuncture in pain management completes the review of the most common pain-relief methods. The chapter on antiemetic drugs is well done, but, again, only a few of the drugs included are either available in the United States or in common usage. Some agents widely used in this country, such as hydroxyzine, are not even mentioned.

The book concludes with chapters on case studies in pain management and pain control in special situations. The discussion for each of the case studies is rather narrow and limited, with not enough emphasis on the advantages and disadvantages of various analgesic methods in a particular setting. A better written chapter could have effectively brought into focus the preceding content of the book, but as is, it is disappointing.

The final chapter on pain control in special situations deals with obstetrics and pediatrics. The pediatric section is useful, with a brief overview that discusses important differences in adult and pediatric pain. The obstetric pain section serves best to emphasize international differences in clinical practice. A description of the use of systemic opiates for managing the pain of labor and delivery makes up the bulk of this section, whereas epidural anesthesia is presented as a long list of disadvantages, with little positive said in its favor. This is certainly a misleading viewpoint for trainees in the United States.

The references in this book consist of chapter-specific reading lists rather than individual references. For the most part, these are well selected and reasonably recent.

In summary, consistent with the authors' aims, most of this book could be quite useful to medical students, junior housestaff, and nurses as an introduction to acute pain management. Georgette Love, RN, nurse specialist on the Acute Pain Service, University of Utah, summarized her opinion of the book by saying, "In general, I liked it. It has information that could have been useful to me when I started learning about pain. I will probably buy the book. . . . Lastly, the price tag ($59.95) is well above that expected for a book of this type; $30–$35 would seem reasonable."

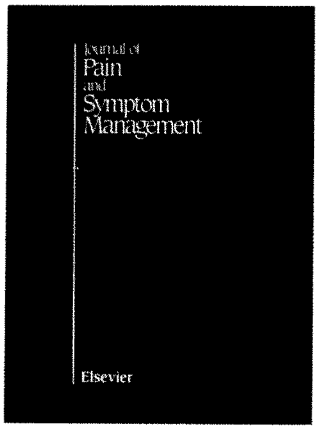
Journal of Pain and Symptom Management is a peer-reviewed, internationally respected forum for the exchange of ideas and information among clinicians and researchers working in pain and symptom management. It publishes original articles, review articles, clinical reports, letters, information exchanges, topical supplements, and media reviews.



The **Journal**'s original articles focus on the full spectrum of patient care: how to treat the patient presenting with pain; how to help the family cope and assist; and how to form and manage a strong medical team that will work as a unit. The **Journal**'s clinical reports discuss methods for symptom identification and pain management, and examine both pharmacologic and psychologic methods of treatment.

Broad in scope, the **Journal** will be of special benefit and interest to oncologists, anesthesiologists, neurologists, pharmacologists, nurses, therapists, psychologists, and psychiatrists. Be sure to subscribe today!

Abstracted and Indexed in: *Excerpta Medica; Psychological Abstracts; MEDLINE; Child Development Abstracts and Bibliography; Nursing Abstracts; Current Awareness in Biological Sciences; International Nursing Index; Oncology Information Service;* and *Cumulative Index to Nursing & Allied Health Literature (CINAHL).*

DIRECTOR OF PAIN MANAGEMENT

The University of Pennsylvania Department of Anesthesia seeks an individual with the skills, experience and potential to lead a group of faculty, fellows and house officers in the areas of acute and chronic pain management. The program includes acute and chronic pain management services at the Hospital of the University of Pennsylvania, and chronic pain management services at the Philadelphia Veterans Affairs Medical Center (located on the same campus) and a suburban Penn outpatient facility. The Section of Pain Management is a major program that includes both clinical and research faculty, and several fellows and residents. The program is central to the mission of the Department, and we seek candidates at the Associate Professor or Professor rank who have the knowledge and skills to direct the clinical, research and educational efforts of this Section. The University of Pennsylvania is an Equal Opportunity/Affirmative Action Employer, and we encourage applications by women and minorities. Please send Curriculm Vitae and the names of three references to:

David E. Longnecker, M.D.
Robert Dunning Dripps
Professor and Chairman
Department of Anesthesia
4 Dulles Building/HUP
3400 Spruce Street
Philadelphia, PA 19104-4283

Critical Care Physicians Harvard Medical School/Brigham & Women's Hospital

We are seeking a Co-Director of Surgical ICU/Director of the Critical Care plus four staff for the Critical Care Division of the Department of Anesthesia at the Brigham and Women's Hospital/Harvard Medical School.

Interested candidates should be Board Certified in Anesthesiology, or other primary specialty, with at least one year of Critical Care training in an ACGME certified program. Candidates should be Board certified or eligible in Critical Care.

Salary is competitive with an excellent benefit package. Qualified individuals should send curriculum vitae to:

Simon Gelman, M.D., Ph.D.
Chairman Department of Anesthesia
Brigham & Women's Hospital
Harvard Medical School
75 Francis Street
Boston, MA 02115

Harvard Medical School/Brigham & Women's Hospital are Equal Opportunity Employers.

International Trauma Anesthesia and Critical Care Society

1993

RESEARCH AWARDS

AREAS OF ELIGIBILITY

Within the general field of perioperative trauma anesthesia and critical care, including basic science clinical research, clinical management, education, or administration.

- Prehospital/EMS/Field
- In Hospital
  - —Pre-Op Stabilization/Resuscitation
  - —Anesthetic Preparation/Induction
  - —Intraoperative Anesthesia
  - —Post-Op Critical Care: PACU/ICU
  - —Pain Management: Pre-Op/Post-Op/Field
- Administration/Organization of Trauma Anesthesia Services

CATEGORIES OF AWARD

- **Prospective Project Award** (up to $US 5,000.00)
  - —Official application must be used
  - —Applications must be received no later than **15, February 1993**
  - —Where relevant, applications must include institutional approval of human studies and/or animal research
  - —Applications must be accompanied by a budget list, copies of previously published material in the area, and any supporting documents to assess project viability
  - —Applications are invited from the international community. Applicants must be members *ITACCS*
- **Retrospective Awards**
  - —Best Scientific Free Paper ($US 2,000.00)
  - —Best Scientific Poster ($US 2,000.00)
  - —Same rules apply as for Prospective Project, except non-ITACCS members are also eligible

Final judgements will be made during the "Sixth Annual Trauma Anesthesia and Critical Care Symposium," to be held in Baltimore, Maryland, USA, 20–22 May, 1993. For details on the symposium contact the Office of International Development, 410 W. Lombard St., Suite 416, Baltimore, MD, 21201, USA, Telephone 410-328-2399 FAX 410-328-0501

For application forms, detailed guidelines and other information on Research Awards, contact:

ITACCS
ATTN: Enrico M. Camporesi, M.D.
Chairman, ITACCS Research Committee
P.O. Box 4826

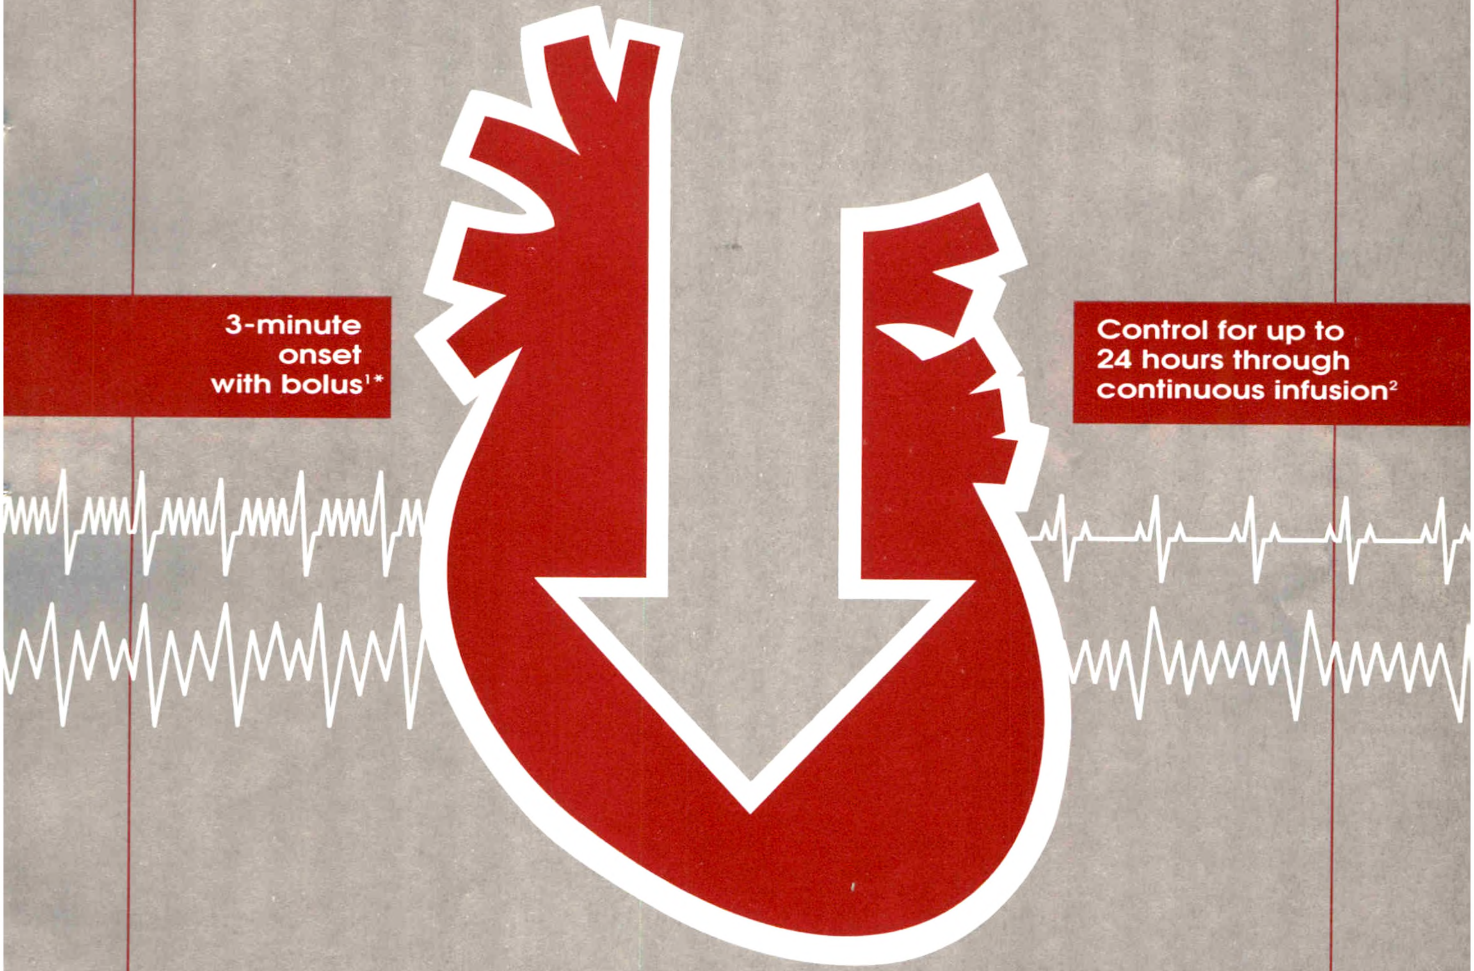
FAX 410-935-8084

Now for heart rate control during atrial fibrillation and flutter

CARDIZEM® Injectable
(diltiazem hydrochloride)
BOLUS INFUSION
5 mg/mL



3-minute onset with bolus[1]*

Control for up to 24 hours through continuous infusion[2]

Heart rate control that is

FAST, SAFE, AND CONTINUOUS[1,2†]

Cardizem Injectable is indicated for temporary control of rapid ventricular rate during atrial fibrillation and flutter; rarely converts to normal sinus rhythm; should be used with continuous monitoring of ECG and blood pressure to avoid hypotension or bradycardia. Infusion rate/dose should be regulated accordingly. A defibrillator and emergency equipment should be readily available.

*Symptomatic hypotension (3.2%) or flushing (1.7%) occurs most often during or immediately following bolus injection.
†Contraindications: atrial fibrillation and flutter patients with WPW or short PR syndrome; sick sinus syndrome or second- or third-degree AV block, except with a functioning pacemaker; severe hypotension or shock; hypersensitivity; recent IV beta-blockers; ventricular tachycardia.

Please see the brief summary of prescribing information on an adjacent page.

CIVAH497/A8114

6491E2

CARDIZEM® Injectable
(diltiazem hydrochloride)
BOLUS INFUSION

CONVENIENT DOSAGE

1 Beginning treatment as

BOLUS: 0.25 mg/kg actual body weight **over 2 minutes**

20 mg average patient

2 If response is inadequate, wait 15 minutes

BOLUS: 0.35 mg/kg actual body weight **over 2 minutes**

25 mg average patient

3 Treatment as

INFUSION:
10* to 15 mg/hr

*5 mg/hr may be appropriate starting infusion for some patients.

BRIEF SUMMARY

CARDIZEM® Injectable
(diltiazem hydrochloride)

INDICATIONS AND USAGE

CARDIZEM Injectable (diltiazem hydrochloride) is indicated for the following:

1. ***Atrial Fibrillation or Atrial Flutter.*** Temporary control of rapid ventricular rate in atrial fibrillation or atrial flutter. It should not be used in patients with atrial fibrillation or atrial flutter associated with an accessory bypass tract such as in Wolff-Parkinson-White (WPW) syndrome or short PR syndrome.
2. ***Paroxysmal Supraventricular Tachycardia.*** Rapid conversion of paroxysmal supraventricular tachycardias (PSVT) to sinus rhythm. This includes AV nodal reentrant tachycardias and reciprocating tachycardias associated with an extranodal accessory pathway such as the WPW syndrome or short PR syndrome. Unless otherwise contraindicated, appropriate vagal maneuvers should be attempted prior to administration of CARDIZEM Injectable.

The use of CARDIZEM Injectable for control of ventricular response in patients with atrial fibrillation or atrial flutter or conversion to sinus rhythm in patients with PSVT should be undertaken with caution when the patient is compromised hemodynamically or is taking other drugs that decrease any or all of the following: peripheral resistance, myocardial filling, myocardial contractility, or electrical impulse propagation in the myocardium.

For either indication and particularly when employing continuous intravenous infusion, the setting should include continuous monitoring of the ECG and frequent measurement of blood pressure. A defibrillator and emergency equipment should be readily available.

In domestic controlled trials in patients with atrial fibrillation or atrial flutter, bolus administration of CARDIZEM Injectable was effective in reducing heart rate by at least 20% in 95% of patients. CARDIZEM Injectable rarely converts atrial fibrillation or atrial flutter to normal sinus rhythm. Following administration of one or two intravenous bolus doses of CARDIZEM Injectable, response usually occurs within 3 minutes and maximal heart rate reduction generally occurs in 2 to 7 minutes. Heart rate reduction may last from 1 to 3 hours. If hypotension occurs, it is generally short-lived, but may last from 1 to 3 hours.

A 24-hour continuous infusion of CARDIZEM Injectable in the treatment of atrial fibrillation or atrial flutter maintained at least a 20% heart rate reduction during the infusion in 83% of patients. Upon discontinuation of infusion, heart rate reduction may last from 0.5 hours to more than 10 hours (median duration 7 hours). Hypotension, if it occurs, may be similarly persistent.

In the controlled clinical trials, 3.2% of patients required some form of intervention (typically, use of intravenous fluids or the Trendelenburg position) for blood pressure support following CARDIZEM Injectable.

In domestic controlled trials, bolus administration of CARDIZEM Injectable was effective in converting PSVT to normal sinus rhythm in 88% of patients within 3 minutes of the first or second bolus dose.

Symptoms associated with the arrhythmia were improved in conjunction with decreased heart rate or conversion to normal sinus rhythm following administration of CARDIZEM Injectable.

CONTRAINDICATIONS

CARDIZEM Injectable is contraindicated in:

1. Patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker.
2. Patients with second- or third-degree AV block except in the presence of a functioning ventricular pacemaker.
3. Patients with severe hypotension or cardiogenic shock.
4. Patients who have demonstrated hypersensitivity to the drug.
5. Intravenous diltiazem and intravenous beta-blockers should not be administered together or in close proximity (within a few hours).
6. Patients with atrial fibrillation or atrial flutter associated with an accessory bypass tract such as in WPW syndrome or short PR syndrome.

   As with other agents which slow AV nodal conduction and do not prolong the refractoriness of the accessory pathway (eg, verapamil, digoxin), in rare instances patients in atrial fibrillation or atrial flutter associated with an accessory bypass tract may experience a potentially life-threatening increase in heart rate accompanied by hypotension when treated with CARDIZEM Injectable. As such, the initial use of CARDIZEM Injectable should be, if possible, in a setting where monitoring and resuscitation capabilities, including DC cardioversion/defibrillation, are present (see OVERDOSAGE). Once familiarity of the patient's response is established, use in an office setting may be acceptable.
7. Patients with ventricular tachycardia. Administration of other calcium channel blockers to patients with wide complex tachycardia (QRS $\geq$ 0.12 seconds) has resulted in hemodynamic deterioration and ventricular fibrillation. It is important that an accurate pretreatment diagnosis distinguish wide complex QRS tachycardia of supraventricular origin from that of ventricular origin prior to administration of CARDIZEM Injectable.

WARNINGS

1. **Cardiac Conduction.** Diltiazem prolongs AV nodal conduction and refractoriness that may rarely result in second- or third-degree AV block in sinus rhythm. Concomitant use of diltiazem with agents known to affect cardiac conduction may result in additive effects (see Drug Interactions). If high-degree AV block occurs in sinus rhythm, intravenous diltiazem should be discontinued and appropriate supportive measures instituted (see OVERDOSAGE).
2. **Congestive Heart Failure.** Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function and in patients with a compromised myocardium, such as severe CHF, acute MI, and hypertrophic cardiomyopathy, have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). Administration of oral diltiazem in patients with acute myocardial infarction and pulmonary congestion documented by x-ray on admission is contraindicated. Experience with the use of CARDIZEM Injectable in patients with impaired ventricular function is limited. Caution should be exercised when using the drug in such patients.
3. **Hypotension.** Decreases in blood pressure associated with CARDIZEM Injectable therapy may occasionally result in symptomatic hypotension (3.2%). The use of intravenous diltiazem for control of ventricular response in patients with supraventricular arrhythmias should be undertaken with caution when the patient is compromised hemodynamically. In addition, caution should be used in patients taking other drugs that decrease peripheral resistance, intravascular volume, myocardial contractility or conduction.
4. **Acute Hepatic Injury.** In rare instances, significant elevations in enzymes such as alkaline phosphatase, LDH, SGOT, SGPT, and other phenomena consistent with acute hepatic injury have been noted following oral diltiazem. Therefore, the potential for acute hepatic injury exists following administration of intravenous diltiazem.
5. **Ventricular Premature Beats (VPBs).** VPBs may be present on conversion of PSVT to sinus rhythm with CARDIZEM Injectable. These VPBs are transient, are typically considered to be benign, and appear to have no clinical significance. Similar ventricular complexes have been noted during cardioversion, other pharmacologic therapy, and during spontaneous conversion of PSVT to sinus rhythm.

PRECAUTIONS

General. CARDIZEM (diltiazem hydrochloride) is extensively metabolized by the liver and excreted by the kidneys and in bile. The drug should be used with caution in patients with impaired renal or hepatic function (see WARNINGS). High intravenous dosages (4.5 mg/kg tid) administered to dogs resulted in significant bradycardia and alterations in AV conduction. In subacute and chronic dog and rat studies designed to produce toxicity, high oral doses of diltiazem were associated with hepatic damage. In special subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes in the liver, which were reversible when the drug was discontinued. In dogs, oral doses of 20 mg/kg were also associated with hepatic changes; however, these changes were reversible with continued dosing.

Dermatologic events progressing to erythema multiforme and/or exfoliative dermatitis have been infrequently reported following oral diltiazem. Therefore, the potential for these dermatologic reactions exists following exposure to intravenous diltiazem. Should a dermatologic reaction persist, the drug should be discontinued.

Drug Interactions. Due to potential for additive effects, caution is warranted in patients receiving CARDIZEM Injectable concomitantly with any agent(s) known to affect cardiac contractility and/or SA or AV node conduction (see WARNINGS).

As with all drugs, care should be exercised when treating patients with multiple medications. CARDIZEM undergoes extensive metabolism by the cytochrome P-450 mixed function oxidase system. Although specific pharmacokinetic drug-drug interaction studies have not been conducted with single intravenous injection or constant rate intravenous infusion, coadministration of CARDIZEM Injectable with other agents which primarily undergo the same route of biotransformation may result in competitive inhibition of metabolism.

Digitalis: Intravenous diltiazem has been administered to patients receiving either intravenous or oral digitalis therapy. The combination of the two drugs was well tolerated without serious adverse effects. However, since both drugs affect AV nodal conduction, patients should be monitored for excessive slowing of the heart rate and/or AV block.

Beta-blockers: Intravenous diltiazem has been administered to patients on chronic oral beta-blocker therapy. The combination of the two drugs was generally well tolerated without serious adverse effects. If intravenous diltiazem is administered to patients receiving chronic oral beta-blocker therapy, the possibility for bradycardia, AV block, and/or depression of contractility should be considered (see CONTRAINDICATIONS). ***Oral*** administration of diltiazem with propranolol in five normal volunteers resulted in increased propranolol levels in all subjects and bioavailability of propranolol was increased approximately 50%. In vitro, propranolol appears to be displaced from its binding sites by diltiazem.

Anesthetics: The depression of cardiac contractility, conductivity, and automaticity as well as the vascular dilation associated with anesthetics may be potentiated by calcium channel blockers. When used concomitantly, anesthetics and calcium blockers should be titrated carefully.

Carcinogenesis, Mutagenesis, Impairment of Fertility. A 24-month study in rats at oral dosage levels of up to 100 mg/kg/day, and a 21-month study in mice at oral dosage levels of up to 30 mg/kg/day showed no evidence of carcinogenicity. There was also no mutagenic response in vitro or in vivo in mammalian cell assays or in vitro in bacteria. No evidence of impaired fertility was observed in a study performed in male and female rats at oral dosages of up to 100 mg/kg/day.

Pregnancy. Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Administration of oral doses ranging from five to ten times greater (on a mg/kg basis) than the daily recommended oral antianginal therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In the perinatal/postnatal studies there was some reduction in early individual pup weights and survival rates. There was an increased incidence of stillbirths at doses of 20 times the human oral antianginal dose or greater.

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. Diltiazem is excreted in human milk. One report with oral diltiazem suggests that concentrations in breast milk may approximate serum levels. If use of CARDIZEM is deemed essential, an alternative method of infant feeding should be instituted.

Pediatric Use. Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

The following adverse reaction rates are based on the use of CARDIZEM Injectable in over 400 domestic clinical trial patients with atrial fibrillation/flutter or PSVT under double-blind or open-label conditions. Worldwide experience in over 1,300 patients was similar.

Adverse events reported in controlled and uncontrolled clinical trials were generally mild and transient. Hypotension was the most commonly reported adverse event during clinical trials. Asymptomatic hypotension occurred in 4.3% of patients. Symptomatic hypotension occurred in 3.2% of patients. When treatment for hypotension was required, it generally consisted of administration of saline or placing the patient in the Trendelenburg position. Other events reported in at least 1% of the diltiazem-treated patients were injection site reactions (eg, itching, burning)—3.9%, vasodilation (flushing)—1.7%, and arrhythmia (junctional rhythm or isorhythmic dissociation)—1.0%.

In addition, the following events were reported infrequently (less than 1%):

Cardiovascular:	Atrial flutter, AV block first degree, AV block second degree, bradycardia, chest pain, congestive heart failure, sinus pause, sinus node dysfunction, syncope, ventricular arrhythmia, ventricular fibrillation, ventricular tachycardia.
Dermatologic:	Pruritus, sweating.
Gastrointestinal:	Constipation, elevated SGOT or alkaline phosphatase, nausea, vomiting.
Nervous System:	Dizziness, paresthesia.
Other:	Amblyopia, asthenia, dry mouth, dyspnea, edema, headache, hyperuricemia.

Although not observed in clinical trials with CARDIZEM Injectable, other reactions associated with oral diltiazem may occur.

Product information as of October 1991

CARDIOVASCULAR FELLOWSHIP OPPORTUNITY

The Department of Anesthesiology and Critical Care Medicine at the University of New Mexico School of Medicine has openings at the CA-4 level for advanced training in cardiovascular anesthesiology. The fellowship is a 2-year comprehensive program designed to train the fellow for a career in cardiovascular anesthesiology. Research in cardiovascular physiology and anesthesia, provision of clinical care for complex adult and pediatric cases, participation in conference, and teaching responsibilities are part of the fellowship experience. Interested individuals should send CV or contact Jorge A. Estrin, MD, PhD, Professor and Chairman, Department of Anesthesiology, University of New Mexico School of Medicine, Albuquerque, NM 83131-5216, (505) 272-2610, FAX (505) 277-1300. The University of New Mexico is an Equal Opportunity/Affirmative Action Employer.

912F/L

THE UNIVERSITY OF NEW MEXICO

Department of Anesthesiology and Critical Care Medicine has immediate faculty positions at the Instructor, Assistant Professor, Associate Professor, and Professor levels for candidates with experience in cardiac, obstetric, neurosurgical, and pediatric anesthesia and critical care medicine. Responsibilities include the teaching of medical students and residents and the provision of clinical care in a busy tertiary referral center. Opportunities to pursue research interests will be provided. It is expected that candidates who apply for CCM positions will have or be eligible for subspecialty certification. Qualified candidates should send CV or contact Jorge A. Estrin, MD, PhD, Professor and Chairman, Department of Anesthesiology, University of New Mexico School of Medicine, Albuquerque, NM 87131-5216, (505) 272-2610, FAX (505) 277-1300. The University of New Mexico is an Equal Opportunity/Affirmative Action Employer.

913F/L

Immediate opening for a BC/BE anesthesiologist to join six MD anesthesiologists in a fee-for-service practice in a 350-bed hospital in a retirement community in Sun City, Arizona. No OB, open heart, trauma, or pediatrics. Send replies to Box 923GHIJ.

923GHIJK

CALIFORNIA

University of California, Irvine: Openings for faculty positions in the Department of Anesthesiology. (1) Assistant or associate professor level in the in-residence series. Responsibilities include teaching and research. (2) Clinical instructor and assistant professor level in the clinical series. Responsibilities include teaching and clinical service. Participation in research is highly desirable but not mandatory

Rank and pay commensurate with skills and experience. Faculty will serve at both a tertiary-care university hospital and a VA Medical Center. Candidates must be ABA certified, or in the examination process, and be eligible for a California state license. An Affirmative Action, Equal Opportunity Employer. Address correspondence with references and curriculum vitae to Steven J. Barker, PhD, MD, Chair, Department of Anesthesiology, University of California, Irvine Medical Center, 101 City Drive South, Route 81A, Orange, CA 92668.

930G/L

LOUISIANA STATE UNIVERSITY MEDICAL CENTER—SHREVEPORT

Faculty positions available for board certified/eligible anesthesiologists. Duties include patient care, resident and student teaching, supervision of CRNAs, research, and administrative responsibilities. Faculty rank and salary commensurate with experience. Please send curriculum vitae and names of three references to D. Richard Davis, II, MD, Associate Professor and Chairman, Department of Anesthesiology, LSU Medical Center—Shreveport, 1501 Kings Highway, Shreveport, LA 71130-3932. We are an Equal Opportunity/Affirmative Action Employer.

931G/L

ANESTHESIOLOGIST

Multispecialty group of 43 physicians adjacent to 165-bed hospital in need of BC/BE anesthesiologist. Located in West Texas City of 80,000 with excellent recreational activities. Salary guarantee with bonus based on production. Send CV to West Texas Medical Associates, 3555 Knickerbocker Road, San Angelo, TX 76904.

CLASSIFIED ADS

Anesthesia & Analgesia makes available classified advertising space for those interested in obtaining positions or wishing to announce meetings, postgraduate courses, or other pertinent events. We require that all advertisements be relevant to the practice of anesthesia and analgesia, and we reserve the right to refuse advertisements that are not relevant.

Specifications. Ads should be typewritten on letterhead stationery; the text should be double-spaced, with the title or key phrase typed in capital letters. Enclose two photocopies with each ad. Display space (minimum ¼ page) is available through Pharmaceutical Media, Inc., 440 Park Avenue South, 14th floor, New York, NY 10016, telephone: (212) 685-5010, FAX: (212) 685-6126.

Rates. Ads cost $1.50 per word per insertion, with a minimum of 20 words. Abbreviations, dates, initials, post office box numbers, telephone numbers, years, and zip codes are considered one word each. There is an additional fee of $18.00 per insertion for box number ads.*

Payment. Full payment or institutional purchase order must accompany the copy for each ad. Ads received without a check or purchase order will be returned. (Make checks payable to Elsevier Science Publishing Company, Inc.)

Deadline. Copy must be received 7 weeks before publication date (i.e., by January 1 for the March issue); multiple-insertion ads are welcome. Ads may run up to 6 months per purchase order/payment. Please specify in which issue(s) your advertisement is to appear.

Send all ad copy, payments, and correspondence to: *Anesthesia & Analgesia*, Classified Ads, Desk Editorial, Elsevier Science Publishing Co., Inc., 655 Avenue of the Americas, New York, NY 10010.

*When responding to a box number ad, include the box number on all correspondence.

NEW ORLEANS

Louisiana State University Medical Center, Department of Anesthesiology, is seeking a board-certified anesthesiologist who is interested in directing publications and research. Outstanding opportunities for clinical studies are available. No night call, weekends, or holidays are required. Excellent salary and fringe benefits. Eligibility for Louisiana licensure is prerequisite. Please send curriculum vitae to M. Naraghi, MD, Professor and Chairman, LSU Department of Anesthesiology, 1532 Tulane Avenue, New Orleans, LA 70140. LSUMC is an EEO/AA employer.

937H/A

POSTDOCTORAL FELLOWSHIP

Background in clinical medicine or clinical research required for studies with patients with heart disease undergoing surgery. Cardiac function and ischemia assessed with ECG, Holter, and echocardiography monitoring. Working with cardiologists, epidemiologists, and anesthesiologists. Send CV and names of three references to Dennis T. Mangano, PhD, MD, Professor and Vice Chairman, Department of Anesthesia, University of California, San Francisco, 4150 Clement Street (129), San Francisco, CA 94121.

949H/L

BC/BE anesthesiologist for a 500-bed tertiary hospital in a Florida coastal city. Immediate opening. Liberal salary and early partnership. Send resume to Box 956I/L.

956I/L

BOISE, IDAHO—PAIN MANAGEMENT

MD/CRNA group seeking additional BC/BE anesthesiologist with pain fellowship or extensive pain experience for expanding pain clinic. Growing 250-bed hospital soon to be adding a Cancer Institute and Open Heart program. No OB. Great opportunity in progressive community (130,000) located in the foothills. Excellent for family and all types of year-round recreation. Partnership after 1 year. Please respond to William G. Binegar, MD, 6054 Emerald, Boise, ID 83704-8863.

957I/K

COASTAL NEW JERSEY—
ANESTHESIOLOGIST DESIRED

Immediate opening for BC or BE MD/DO to join an expanding group practice of 10 MDAs and 9 CRNAs covering a 500-bed regional medical center composed of two hospitals performing over 9000 anesthetics. All types of anesthesia except OH. Great opportunity for energetic well-trained individual. Unlimited opportunity and outstanding lifestyle in a family-oriented seashore community. Very competitive financial package. Please reply with CV to S. Hernberg, DO, Chairman, Department of Anesthesiology, 1925 Pacific Avenue, Atlantic City, NJ 08401.

958I/L

Anesthesiologist to join group consisting of eight anesthesiologists and two CRNAs. Must be board eligible or board certified. Established PC with many fringe benefits in effect. Send CV to Associated Anesthesiologists of Saginaw, PC, 3121 Davenport, Saginaw, MI 48602 or call (517) 791-2150.

959I/K

PHILADELPHIA, PA.

BC/BE anesthesiologist to join physician/CRNA group in a private, university-affiliated, center-city, tertiary-care hospital. No obstetrics, trauma, or pediatrics. Fellowship experience in open heart anesthesia required. Competitive salary, benefits, and potential for partnership is included. Respond with CV to Box 965I/K.

965I/K

UCSF PEDIATRIC ANESTHESIOLOGY FELLOWSHIP

The Departments of Anesthesia at the University of California, San Francisco and Children's Hospital of Northern California, Oakland, California are jointly offering two 1-year clinical fellowship positions (CA-4) in pediatric anesthesiology beginning *July 1993*. The fellowship will include extensive operating room experience in all pediatric subspecialties in both institutions and critical care medicine exposure for both neonates, older infants, and children. The fellows will spend 6 months in each institution. Send inquiries to Dolores Scholz, Postdoctoral Coordinator, Department of Anesthesia, University of California, San Francisco, Box 0648, San Francisco, CA 94143-0648.

967I/L

ANESTHESIOLOGIST

Department of Anesthesiology at the SUNY Health Science Center in Syracuse, N.Y. is recruiting faculty at the instructor and assistant and associate professor levels. Qualified individuals with a strong academic commitment in all types of anesthesia, critical care, and pain management are sought. SUNY Health Science Center is a tertiary-care center and provides clinical services also to the Syracuse Veterans Administration Hospital. Rank and salary are commensurate with experience. Must be board certified or board eligible and possess a New York State medical license. Please send letter, curriculum vitae, names, addresses, and phone numbers of three references to Enrico M. Camporesi, MD, Professor and Chairman, Department of Anesthesiology, SUNY Health Science Center, Syracuse, NY 13210. The State University of New York Health Science Center is an Equal Opportunity/AA Employer.

968I/K

UNIVERSARY OF CALIFORNIA, DAVIS—
Assistant Professor/Associate Professor/Full Professor

Department of Anesthesiology, University of California, Davis, Medical Center is recruiting for two (2) faculty positions at all ranks. These positions require experience in teaching and clinical training, as well as clinical research. Both positions require demonstrated experience, training, and certification in (1) Critical Care to join two other faculty covering ICU 2–3 months per year; (2) Transplant; and (3) General Anesthesia. These positions are in the non-tenured track. Rank and salary are commensurate with experience and based on the UCD School of Medicine Faculty Compensation Plan. Must be board certified or board eligible in anesthesiology, and a California medical license is required. Send curriculum vitae, bibliography, copies of publications, and *the names of three (3) references* to: Dennis Fung, MD, Acting Chairman, Department of Anesthesiology, University of California, Davis, 2315 Stockton Boulevard, Room 2304, Sacramento, CA 95817. Positions are open until filled but not later than December 31, 1992. The University of California, Davis is an Equal Opportunity/Affirmative Action Employer with a strong institutional commitment to the achievement of diversity among its faculty and staff. In that spirit, we are particularly interested in receiving applications from persons of under-represented groups, including women, ethnic minorities, disabled veterans, Vietnam-era veterans, and handicapped persons.

970I/K

PAIN FELLOWSHIP

The Pain Evaluation and Treatment Institute of the University of Pittsburgh Medical Center is offering 1-year CA-4 pain fellowships beginning January or July 1993. The fellowship offers experience, teaching, and research opportunities in outpatient and hospital-based pain therapy. Invasive, pharmacologic, and nonpharmacologic modalities are employed in a wide variety of clinical settings with emphasis on interdisciplinary management. Rotations in a regional anesthesia clinic, acute pain service, cancer pain service, and outpatient chronic pain rehabilitation program provide collaboration with a variety of dedicated pain specialists.

Direct inquiries to Brett Stacey, MD, Medical Director, Pain Evaluation and Treatment Institute, Baum Boulevard at Craig Street, Pittsburgh, PA 15213.

998K

UNIVERSITY OF PITTSBURGH MEDICAL CENTER

The Pain Evaluation and Treatment Institute is seeking additional faculty for our expanding in- and out-patient pain services. We manage acute, chronic, and cancer pain patients in an interdisciplinary fashion, utilizing all modalities of treatment. Teaching and research activities are well funded and supported by the department and university. Clinical anesthesia commitments are flexible depending on the needs of the applicant. Applicants must have completed a pain fellowship or have a similar background, be board certified or board eligible, be able to obtain a Pennsylvania license, and be interested in teaching and clinical research.

Direct inquiries to Brett Stacey, MD, Medical Director, Pain Evaluation and Treatment Institute, Baum Boulevard at Craig Street, Pittsburgh, PA 15213.

999K

Pleasant semirural midwest community of 20,000. Please respond with cover letter, CV, and names of references to Debra K. Schuster, MD, Department of Anesthesiology, Marshfield Clinic, 1000 North Oak Avenue, Marshfield, WI 54449 or call collect at (715) 387-7179. EOE/AAM/F/H/V.

1002K

CHAIRMAN—DEPARTMENT OF ANESTHESIOLOGY

The Deborah Heart and Lung Center, a 155-bed acute care facility specializing in cardiac, pulmonary, and vascular diseases, is seeking applicants for the position of Chairman of the Department of Anesthesiology. Position entails overseeing the clinical activities of an 8 MD/8 CRNA/4 resident-fellow group, maintaining academic university affiliation, and stimulating research endeavors. The applicants must be board certified in anesthesiology, licensed in the state of New Jersey, and experienced in the administration of an active clinical service dealing with complex pediatric and adult cardiac patients. Skills in research and resident education also desired. Send your CV and the names and addresses of three academic references to Vladir Maranhao, MD, Vice President, Medical Affairs Deborah Heart and Lung Center, Browns Mills, NJ 08015.

1003K

PEDIATRIC ANESTHESIOLOGIST: FACULTY POSITIONS

The Department of Anesthesiology, Baylor College of Medicine and its Pediatric Anesthesiology Division at Texas Children's Hospital are recruiting faculty. 8500 cases per year span the range of pediatric anesthesia. Our training program is for CA-2 level and beyond. Qualified pediatric anesthesia specialists can combine clinical/academic practice in a growing, academically oriented division with hospitable living in the economically resurgent climate of Houston, Texas. Successful applicants will be board certified in anesthesiology or in the board examination process and eligible for a Texas license. A minimum of 1-year pediatric anesthesia specialty training at the CA-4 level or beyond is expected. Equivalents are these: current clinical practice limited to pediatric anesthesia or BC, pediatrics. Research interests desirable with encouragement through appropriate amounts of nonclinical time. Salary levels are competitive. Baylor is an Equal Opportunity Employer. Send CV and three references to Burdett S. Dunbar, MD, Chief, Pediatric Anesthesiology, Texas Children's Hospital, 6621 Fannin, Mail Code 2-1495, Houston, TX 77030.

1004K

FELLOWSHIP TRAINING, PEDIATRIC ANESTHESIOLOGY

Baylor College of Medicine, Department of Anesthesiology and its Pediatric Anesthesiology Division at Texas Children's Hospital offer 1- or 2-year subspecialty training in pediatric anesthesiology beginning January 1993. Texas Children's Hospital, a 300-bed facility, is a primary academic affiliate of Baylor College of Medicine. Current case load, 8500 cases per year, spans the range of pediatric anesthesia. Opportunities exist for experience in neonatal critical care, critical care medicine, operating room, pain medicine, and research. Requirements: satisfactory completion of AMA-RRC approved residency; currently in the ABA certification process; eligibility for unrestricted medical license, Texas. Salary: $30,000. Send current CV and three references to Burdett S. Dunbar, MD, Chief, Pediatric Anesthesiology, Texas Children's Hospital, 6621 Fannin Street, Mail Code 2-1495, Houston, TX 77030.

1005K

FELLOWSHIP—PEDIATRIC ANESTHESIOLOGY

The Department of Anesthesiology for the Medical College of Wisconsin is accepting applications for 12-month subspecialty training in pediatric anesthesiology beginning July 1, 1993 (CA-3 and CA-4 positions are available). Experience and training will include all aspects of pediatric anesthesiology including cardiac anesthesia and pain management. Opportunity also is provided for clinical research and critical care experience. Inquiries, CV, and references should be sent to Stephen P. Pontus, MD, Section of Pediatric Anesthesiology, Children's Hospital of Wisconsin, PO Box 1997, MS 735, Milwaukee, Wisconsin 53201. Equal Opportunity/Affirmative Action Employer M/F/D.

1008KL

YALE UNIVERSITY DEPARTMENT OF ANESTHESIOLOGY, NEW HAVEN, CONNECTICUT

Written Board Review

Lectures and written exam seminars

- February 2-7 and April 12-17
- Home-study keywords with discussions and questions with answers.
- Six-day lecture with syllabus.
- Seminars for written exam questions.

Oral Board Review

Mock oral exams and lectures

- February 2-7 and April 12-17
- Home-study, oral-exam stem cases with pre-op, intra-op and post-op questions.
- Six-day lectures with syllabus and concurrent mock oral exams most hours.
- **Registration includes one mock oral.**
- Extra public mock oral exam ($80), private mock oral exam ($110).

Oral Board Tutorial Days

Choose any days – groups limited to 24

- February 12-15 and every weekend January 9-April 20: call for schedule
- Home-study, oral-exam stem cases with pre-op, intra-op and post-op questions.
- Mock oral exams in groups **limited to 24.**
- **Includes one public mock oral per day.**
- Extra public mock oral exams ($80), private mock oral exams ($110).

Two-Part Board Review

Nine mock orals in any two courses

- Any course in 1993, plus any other within three years. One course may be up to six Oral Board Tutorial days of your choice.
- Choose between lectures and concurrent mock orals or written exam discussions.
- **Nine mock oral exams in groups limited to 24 participants.**

Unconditional Guarantee

- If you fail the next Anesthesiology Board Exam you take after taking one of these courses, we will refund half of your last course registration fee and allow you to repeat the course once for FREE.

Alfenta®
(alfentanil HCl) Injection CII

Before prescribing, please consult complete prescribing information, of which the following is a brief summary.

CAUTION: Federal Law Prohibits Dispensing Without Prescription
DESCRIPTION: ALFENTA is a sterile, non-pyrogenic, preservative free aqueous solution containing alfentanil hydrochloride equivalent to 500 µg per ml of alfentanil base for intravenous injection. The solution, which contains sodium chloride for isotonicity, has a pH range of 4.0-6.0.
CONTRAINDICATIONS: ALFENTA (alfentanil hydrochloride) is contraindicated in patients with known hypersensitivity to the drug.
WARNINGS: ALFENTA SHOULD BE ADMINISTERED ONLY BY PERSONS SPECIFICALLY TRAINED IN THE USE OF INTRAVENOUS AND GENERAL ANESTHETIC AGENTS AND IN THE MANAGEMENT OF RESPIRATORY EFFECTS OF POTENT OPIOIDS. AN OPIOID ANTAGONIST, RESUSCITATIVE AND INTUBATION EQUIPMENT AND OXYGEN SHOULD BE READILY AVAILABLE. BECAUSE OF THE POSSIBILITY OF DELAYED RESPIRATORY DEPRESSION, MONITORING OF THE PATIENT MUST CONTINUE WELL AFTER SURGERY. ALFENTA (alfentanil hydrochloride) administered in initial dosages up to 20 µg/kg may cause skeletal muscle rigidity, particularly of the truncal muscles. The incidence and severity of muscle rigidity is usually dose-related. Administration of ALFENTA at anesthetic induction dosages (above 130 µg/kg) will consistently produce muscular rigidity with an immediate onset. The onset of muscular rigidity occurs earlier than with other opioids. ALFENTA may produce muscular rigidity that involves all skeletal muscles, including those of the neck and extremities. The incidence may be reduced by: 1) routine methods of administration of neuromuscular blocking agents for balanced opioid anesthesia; 2) administration of up to ¼ of the full paralyzing dose of a neuromuscular blocking agent just prior to administration of ALFENTA at dosages up to 130 µg/kg; following loss of consciousness, a full paralyzing dose of a neuromuscular blocking agent should be administered; or 3) simultaneous administration of ALFENTA and a full paralyzing dose of a neuromuscular blocking agent when ALFENTA is used in rapidly administered anesthetic dosages (above 130 µg/kg). The neuromuscular blocking agent used should be appropriate for the patient's cardiovascular status. Adequate facilities should be available for postoperative monitoring and ventilation of patients administered ALFENTA. It is essential that these facilities be fully equipped to handle all degrees of respiratory depression.
PRECAUTIONS: DELAYED RESPIRATORY DEPRESSION, RESPIRATORY ARREST, BRADYCARDIA, ASYSTOLE, ARRHYTHMIAS AND HYPOTENSION HAVE ALSO BEEN REPORTED. THEREFORE, VITAL SIGNS MUST BE MONITORED CONTINUOUSLY.
General: The initial dose of ALFENTA (alfentanil hydrochloride) should be appropriately reduced in elderly and debilitated patients. The effect of the initial dose should be considered in determining supplemental doses. In obese patients (more than 20% above ideal total body weight), the dosage of ALFENTA should be determined on the basis of lean body weight. In one clinical trial, the dose of ALFENTA required to produce anesthesia, as determined by appearance of delta waves in EEG, was 40% lower in geriatric patients than that needed in healthy young patients. In patients with compromised liver function and in geriatric patients, the plasma clearance of ALFENTA may be reduced and postoperative recovery may be prolonged. Induction doses of ALFENTA should be administered slowly (over three minutes). Administration may produce loss of vascular tone and hypotension. Consideration should be given to fluid replacement prior to induction. Diazepam administered immediately prior to or in conjunction with high doses of ALFENTA may produce vasodilation, hypotension and result in delayed recovery. Bradycardia produced by ALFENTA may be treated with atropine. Severe bradycardia and asystole have been successfully treated with atropine and conventional resuscitative methods. The hemodynamic effects of a particular muscle relaxant and the degree of skeletal muscle relaxation required should be considered in the selection of a neuromuscular blocking agent. Following an anesthetic induction dose of ALFENTA, requirements for volatile inhalation anesthetics or ALFENTA infusion are reduced by 30 to 50% for the first hour of maintenance. Administration of ALFENTA infusion should be discontinued at leas 10-15 minutes prior to the end of surgery. Respiratory depression caused by opioid analgesics can be reversed by opioid antagonists such as naloxone. Because the duration of respiratory depression produced by ALFENTA may last longer than the duration of the opioid antagonist action, appropriate surveillance should be maintained. As with all potent opioids, profound analgesia is accompanied by respiratory depression and diminished sensitivity to CO_2 stimulation which may persist into or recur in the postoperative period. Intraoperative hyperventilation may further alter postoperative response to CO_2. Appropriate postoperative monitoring should be employed, particularly after infusions and large doses of ALFENTA, to ensure that adequate spontaneous breathing is established and maintained in the absence of stimulation prior to discharging the patient from the recovery area.
Head Injuries: ALFENTA may obscure the clinical course of patients with head injuries.
Impaired Respiration: ALFENTA should be used with caution in patients with pulmonary disease, decreased respiratory reserve or potentially compromised respiration. In such patients, opioids may additionally decrease respiratory drive and increase airway resistance. During anesthesia, this can be managed by assisted or controlled respiration.
Impaired Hepatic or Renal Function: In patients with liver or kidney dysfunction, ALFENTA should be administered with caution due to the importance of these organs in the metabolism and excretion of ALFENTA.
Drug Interactions: Both the magnitude and duration of central nervous system and cardiovascular effects may be enhanced when ALFENTA is administered in combination with other CNS depressants such as barbiturates, tranquilizers, opioids, or inhalation general anesthetics. Postoperative respiratory depression may be enhanced or prolonged by these agents. In such cases of combined treatment, the dose of one or both agents should be reduced. Limited clinical experience indicates that requirements for volatile inhalation anesthetics are reduced by 30 to 50% for the first sixty (60) minutes following ALFENTA induction. The concomitant use of erythromycin with ALFENTA can significantly inhibit ALFENTA clearance and may increase the risk of prolonged or delayed respiratory depression. Perioperative administration of drugs affecting hepatic blood flow or enzyme function may reduce plasma clearance and prolong recovery.
Carcinogenesis, Mutagenesis and Impairment of Fertility: No long-term animal studies of ALFENTA have been performed to evaluate carcinogenic potential. The micronucleus test in female rats and the dominant lethal test in female and male mice revealed that single intravenous doses of ALFENTA as high as 20 mg/kg (approximately 40 times the upper human dose) produced no structural chromosome mutations or induction of dominant lethal mutations. The Ames *Salmonella typhimurium* metabolic activating test also revealed no mutagenic activity.
Pregnancy Category C: ALFENTA has been shown to have an embryocidal effect in rats and rabbits when given in doses 2.5 times the upper human dose for a period of 10 days to over 30 days. These effects could have been due to maternal toxicity (decreased food consumption with increased mortality) following prolonged administration of the drug. No evidence of teratogenic effects has been observed after administration of ALFENTA in rats or rabbits. There are no adequate and well-controlled studies in pregnant women. ALFENTA should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.
Labor and Delivery: There are insufficient data to support the use of ALFENTA in labor and delivery. Placental transfer of the drug has been reported; therefore, use in labor and delivery is not recommended.
Nursing Mothers: In one study of nine women undergoing post-partum tubal ligation, significant levels of ALFENTA were detected in colostrum four hours after administration of 60 µg/kg of ALFENTA, with no detectable levels present after 28 hours. Caution should be exercised when ALFENTA is administered to a nursing woman.
Pediatric Use: Adequate data to support the use of ALFENTA in children under 12 years of age are not presently available.
ADVERSE REACTIONS: The most common adverse reactions, respiratory depression and skeletal muscle rigidity, are extensions of known pharmacological effects of opioids. See CLINICAL PHARMACOLOGY, WARNINGS and PRECAUTIONS on the management of respiratory depression and skeletal muscle rigidity. Delayed respiratory depression, respiratory arrest, bradycardia, asystole, arrhythmias and hypotension have also been reported. The reported incidences of adverse reactions listed in the following table are derived from controlled and open clinical trials involving 1183 patients, of whom 785 received ALFENTA. The controlled trials involved treatment comparisons with fentanyl, thiopental sodium, enflurane, saline placebo and halothane. Incidences are based on disturbing and nondisturbing adverse reactions reported. The comparative incidence of certain side effects is influenced by the type of use, e.g., chest wall rigidity has a higher reported incidence in clinical trials of alfentanil induction, and by the type of surgery, e.g., nausea and vomiting have a higher incidence in patients undergoing gynecologic surgery.

Percent	ALFENTA (N=785)	Fentanyl (N=243)	Thiopental Sodium (N=66)	Enflurane (N=55)	Halothane (N=18)	Saline Placebo* (N=18)
Gastrointestinal						
Nausea	28	44	14	5	0	22
Vomiting	18	31	11	9	13	17
Cardiovascular						
Bradycardia	14	7	8	0	0	0
Tachycardia	12	12	39	36	31	11
Hypotension	10	8	7	7	0	0
Hypertension	18	13	30	20	6	0
Arrhythmia	2	2	5	4	6	0
Musculoskeletal						
Chest Wall Rigidity	17	12	0	0	0	0
Skeletal Muscle Movements	6	2	6	2	0	0
Respiratory						
Apnea	7	0	0	0	0	0
Postoperative Respiratory Depression	2	2	0	0	0	0
CNS						
Dizziness	3	5	0	0	0	0
Sleepiness/ Postoperative Sedation	2	8	2	0	0	6
Blurred Vision	2	2	0	0	0	0

*From two clinical trials, one involving supplemented balanced barbiturate / nitrous oxide anesthesia and one in healthy volunteers who did not undergo surgery.

In addition, other adverse reactions less frequently reported (1% or less) were: Laryngospasm, bronchospasm, postoperative confusion, headache, shivering, postoperative euphoria, hypercarbia, pain on injection, urticaria, and itching. Some degree of skeletal muscle rigidity should be expected with induction doses of ALFENTA.
DRUG ABUSE AND DEPENDENCE: ALFENTA (alfentanil hydrochloride) is a Schedule II controlled drug substance that can produce drug dependence of the morphine type and therefore has the potential for being abused.
OVERDOSAGE: Overdosage would be manifested by extension of the pharmacological actions of ALFENTA (alfentanil hydrochloride) (see CLINICAL PHARMACOLOGY) as with other potent opioid analgesics. No experience of overdosage with ALFENTA was reported during clinical trials. The intravenous LD_{50} of ALFENTA is 43.0-50.9 mg/kg in rats, 72.2-73.6 mg/kg in mice, 71.8-81.9 mg/kg in guinea pigs and 59.5-87.5 mg/kg in dogs. Intravenous administration of an opioid antagonist such as naloxone should be employed as a specific antidote to manage respiratory depression. The duration of respiratory depression following overdosage with ALFENTA may be longer than the duration of action of the opioid antagonist. Administration of an opioid antagonist should not preclude immediate establishment of a patent airway, administration of oxygen, and assisted or controlled ventilation as indicated for hypoventilation or apnea. If respiratory depression is associated with muscular rigidity, a neuromuscular blocking agent may be required to facilitate assisted or controlled ventilation. Intravenous fluids and vasoactive agents may be required to manage hemodynamic instability.
DOSAGE AND ADMINISTRATION: The dosage of ALFENTA (alfentanil hydrochloride) should be individualized in each patient according to body weight, physical status, underlying pathological condition, use of other drugs, and type and duration of surgical procedure and anesthesia. In obese patients (more than 20% above ideal total body weight), the dosage of ALFENTA should be determined on the basis of lean body weight. The dose of ALFENTA should be reduced in elderly or debilitated patients (see PRECAUTIONS). Vital signs should be monitored routinely. Protect from light. Store at room temperature 15°-30° C (59°-86° F).

CRUCIAL PARAMETERS IN SELECTING A NEUROMUSCULAR BLOCKING AGENT

	Norcuron® (vecuronium bromide) for injection	Atracurium besylate
HEMODYNAMICS	No significant variations in blood pressure, cardiac output, or systemic vascular resistance.[1]	Statistically significant variations in blood pressure, cardiac output, and systemic vascular resistance.[1] ($P<.05$)
HISTAMINE	Available clinical experience indicates that reactions commonly associated with histamine release are unlikely to occur.[1-4]	Precautions advised for patients in whom substantial histamine release would be hazardous (eg, clinically significant cardiovascular disease, asthma).[5]
RECOVERY To 25% of control To 95% of control	 25-40 min[3] 45-65 min[3]	 35-45 min[5] 60-70 min[5]
DOSING FLEXIBILITY	The initial recommended dose is 0.08-0.1 mg/kg. Dose can be increased up to 0.28 mg/kg for long cases without significant histamine release or related cardiovascular side effects.[1,3,4]	Initial recommended dose is 0.4-0.5 mg/kg. A moderate histamine release and significant falls in blood pressure have been seen following a dose of 0.5 mg/kg ($P<.05$) and 0.6 mg/kg.*[2,5,6]
STORAGE & SHELF LIFE	2-year shelf life in lyophilized form at room temperature.† Can be reconstituted with various IV solutions including Lactated Ringers.‡	2-year shelf life under constant refrigeration.† Upon removal from refrigeration to room temperature storage, use within 14 days even if rerefrigerated.[5]

* Dose of atracurium above 0.5 mg/kg is not recommended.
† As originally supplied by the respective manufacturers.
‡ Storage after reconstitution varies with solution. See package insert.

Norcuron®

(vecuronium bromide) for injection

A LOGICAL CHOICE FOR NEUROMUSCULAR BLOCKADE

See following page for brief summary of prescribing information.

Organon

ORGANON INC.
WEST ORANGE
NEW JERSEY 07052

Norcuron®

(vecuronium bromide) for injection

Before prescribing, please consult complete product information, a summary of which follows:

THIS DRUG SHOULD BE ADMINISTERED BY ADEQUATELY TRAINED INDIVIDUALS FAMILIAR WITH ITS ACTIONS, CHARACTERISTICS, AND HAZARDS.

CONTRAINDICATIONS: Norcuron® is contraindicated in patients known to have a hypersensitivity to it.

WARNINGS: NORCURON® SHOULD BE ADMINISTERED IN CAREFULLY ADJUSTED DOSAGE BY OR UNDER THE SUPERVISION OF EXPERIENCED CLINICIANS WHO ARE FAMILIAR WITH ITS ACTIONS AND THE POSSIBLE COMPLICATIONS THAT MIGHT OCCUR FOLLOWING ITS USE. THE DRUG SHOULD NOT BE ADMINISTERED UNLESS FACILITIES FOR INTUBATION, ARTIFICIAL RESPIRATION, OXYGEN THERAPY, AND REVERSAL AGENTS ARE IMMEDIATELY AVAILABLE. THE CLINICIAN MUST BE PREPARED TO ASSIST OR CONTROL RESPIRATION. TO REDUCE THE POSSIBILITY OF PROLONGED NEUROMUSCULAR BLOCKADE AND OTHER POSSIBLE COMPLICATIONS THAT MIGHT OCCUR FOLLOWING LONG-TERM USE IN THE ICU, NORCURON® OR ANY OTHER NEUROMUSCULAR BLOCKING AGENT SHOULD BE ADMINISTERED IN CAREFULLY ADJUSTED DOSES BY OR UNDER THE SUPERVISION OF EXPERIENCED CLINICIANS WHO ARE FAMILIAR WITH ITS ACTIONS AND WHO ARE FAMILIAR WITH APPROPRIATE PERIPHERAL NERVE STIMULATOR MUSCLE MONITORING TECHNIQUES (see PRECAUTIONS). In patients who are known to have myasthenia gravis or the myasthenic (Eaton-Lambert) syndrome, small doses of Norcuron® may have profound effects. In such patients, a peripheral nerve stimulator and use of a small test dose may be of value in monitoring the response to administration of muscle relaxants.

PRECAUTIONS:

Renal Failure: Norcuron® is well tolerated without clinically significant prolongation of neuromuscular blocking effect in patients with renal failure who have been optimally prepared for surgery by dialysis. Under emergency conditions in anephric patients some prolongation of neuromuscular blockage may occur; therefore, if anephric patients cannot be prepared for non-elective surgery, a lower initial dose of Norcuron® should be considered.

Altered Circulation Time: Conditions associated with slower circulation time in cardiovascular disease, old age, edematous states resulting in increased volume of distribution may contribute to a delay in onset time, therefore dosage should not be increased.

Hepatic Disease: Limited experience in patients with cirrhosis or cholestasis has revealed prolonged recovery time in keeping with the role the liver plays in Norcuron® metabolism and excretion. Data currently available do not permit dosage recommendations in patients with impaired liver function.

Long-term Use in I.C.U.: In the intensive care unit, in rare cases, long-term use of neuromuscular blocking drugs to facilitate mechanical ventilation may be associated with prolonged paralysis and/or skeletal muscle weakness that may be first noted during attempts to wean such patients from the ventilator. Typically, such patients receive other drugs such as broad spectrum antibiotics, narcotics and/or steroids and may have electrolyte imbalance and diseases which lead to electrolyte imbalance, hypoxic episodes of varying duration, acid-base imbalance and extreme debilitation, any of which may enhance the actions of a neuromuscular blocking agent. Additionally, patients immobilized for extended periods frequently develop symptoms consistent with disuse muscle atrophy. The recovery picture may vary from regaining movement and strength in all muscles to initial recovery of movement of the facial and small muscles of the extremities then to the remaining muscles. In rare cases recovery may be over an extended period of time and may even, on occasion, involve rehabilitation. Therefore, when there is a need for long-term mechanical ventilation, the benefits-to-risk ratio of neuromuscular blockade must be considered. Continuous infusion or intermittent bolus dosing to support mechanical ventilation has not been studied sufficiently to support dosage recommendations.

IN THE INTENSIVE CARE UNIT, APPROPRIATE MONITORING, WITH THE USE OF A PERIPHERAL NERVE STIMULATOR TO ASSESS THE DEGREE OF NEUROMUSCULAR BLOCKADE, IS RECOMMENDED TO HELP PRECLUDE POSSIBLE PROLONGATION OF THE BLOCKADE. WHENEVER THE USE OF NORCURON® OR ANY NEUROMUSCULAR BLOCKING AGENT IS CONTEMPLATED IN THE ICU, IT IS RECOMMENDED THAT NEUROMUSCULAR TRANSMISSION BE MONITORED CONTINUOUSLY DURING ADMINISTRATION AND RECOVERY WITH THE HELP OF A NERVE STIMULATOR. ADDITIONAL DOSES OF NORCURON® OR ANY OTHER NEUROMUSCULAR BLOCKING AGENT SHOULD NOT BE GIVEN BEFORE THERE IS A DEFINITE RESPONSE TO T_1 OR TO THE FIRST TWITCH. IF NO RESPONSE IS ELICITED, INFUSION ADMINISTRATION SHOULD BE DISCONTINUED UNTIL A RESPONSE RETURNS.

Severe Obesity or Neuromuscular Disease: Patients with severe obesity or neuromuscular disease may pose airway and/or ventilatory problems requiring special care before, during and after the use of neuromuscular blocking agents such as Norcuron®.

Malignant Hyperthermia: Many drugs used in anesthetic practice are suspected of being capable of triggering a potentially fatal hypermetabolism of skeletal muscle known as malignant hyperthermia. There are insufficient data derived from screening in susceptible animals (swine) to establish whether or not Norcuron® is capable of triggering malignant hyperthermia.

C.N.S.: Norcuron® has no known effect on consciousness, the pain threshold or cerebration. Administration must be accompanied by adequate anesthesia or sedation.

Drug Interactions: Prior administration of succinylcholine may enhance the neuromuscular blocking effect of Norcuron® (vecuronium bromide) for injection and its duration of action. If succinylcholine is used before Norcuron®, the administration of Norcuron® should be delayed until the succinylcholine effect shows signs of wearing off. With succinylcholine as the intubating agent, initial doses of 0.04-0.06 mg/kg of Norcuron® may be administered to produce complete neuromuscular block with clinical duration of action of 25-30 minutes. The use of Norcuron® before succinylcholine, in order to attenuate some of the side effects of succinylcholine, has not been sufficiently studied.

Other nondepolarizing neuromuscular blocking agents (pancuronium, d-tubocurarine, metocurine, and gallamine) act in the same fashion as does Norcuron®, therefore these drugs and Norcuron® may manifest an additive effect when used together. There are insufficient data to support concomitant use of Norcuron® and other competitive muscle relaxants in the same patient.

Inhalational Anesthetics: Use of volatile inhalational anesthetics such as enflurane, isoflurane, and halothane with Norcuron® will enhance neuromuscular blockade. Potentiation is most prominent with use of enflurane and isoflurane. With the above agents the initial dose of Norcuron® may be the same as with balanced anesthesia unless the inhalational anesthetic has been administered for a sufficient time at a sufficient dose to have reached clinical equilibrium.

Antibiotics: Parenteral/intraperitoneal administration of high doses of certain antibiotics may intensify or produce neuromuscular block on their own. The following antibiotics have been associated with various degrees of paralysis: aminoglycosides (such as neomycin, streptomycin, kanamycin, gentamicin, and dihydrostreptomycin); tetracyclines; bacitracin; polymyxin B; colistin; and sodium colistimethate. If these or other newly introduced antibiotics are used in conjunction with Norcuron®, unexpected prolongation of neuromuscular block should be considered a possibility.

Other: Experience concerning injection of quinidine during recovery from use of other muscle relaxants suggest that recurrent paralysis may occur. This possibility must also be considered for Norcuron®. Norcuron® induced neuromuscular blockade has been counteracted by alkalosis and enhanced by acidosis in experimental animals (cat). Electrolyte imbalance and diseases which lead to electrolyte imbalance, such as adrenal cortical insufficiency, have been shown to alter neuromuscular blockade. Depending on the nature of the imbalance, either enhancement or inhibition may be expected. Magnesium salts, administered for the management of toxemia of pregnancy, may enhance the neuromuscular blockade.

Drug/laboratory test interactions: None known.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term studies in animals have not been performed to evaluate carcinogenic or mutagenic potential or impairment of fertility.

Pregnancy: Pregnancy Category C: Animal reproduction studies have not been conducted with Norcuron®. It is also not known whether Norcuron® can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Norcuron® should be given to a pregnant woman only if clearly needed.

Pediatric Use: Infants under 1 year of age but older than 7 weeks, also tested under halothane anesthesia, are moderately more sensitive to Norcuron® on a mg/kg basis than adults and take about 1½ times as long to recover. Information presently available does not permit recommendations for usage in neonates.

ADVERSE REACTIONS: The most frequent adverse reaction to nondepolarizing blocking agents as a class consists of an extension of the drug's pharmacological action beyond the time period needed. This may vary from skeletal muscle weakness to profound and prolonged skeletal muscle paralysis resulting in respiration insufficiency or apnea.

Inadequate reversal of the neuromuscular blockade is possible with Norcuron® as with all curariform drugs. These adverse reactions are managed by manual or mechanical ventilation until recovery is judged adequate. Little or no increase in intensity of blockade or duration of action of Norcuron® is noted from the use of thiobarbiturates, narcotic analgesics, nitrous oxide, or droperidol. See OVERDOSAGE for discussion of other drugs used in anesthetic practice which also cause respiratory depression.

Prolonged to profound extensions of paralysis and/or muscle weakness as well as muscle atrophy have been reported after long-term use to support mechanical ventilation in the intensive care unit (see PRECAUTIONS).

The administration of Norcuron® has been associated with rare instances of hypersensitivity reactions (bronchospasm, hypotension and/or tachycardia, sometimes associated with acute urticaria or erythema).

OVERDOSAGE: The possibility of iatrogenic overdosage can be minimized by carefully monitoring muscle twitch response to peripheral nerve stimulation.

Excessive doses of Norcuron® produce enhanced pharmacological effects. Residual neuromuscular blockage beyond the time period needed may occur with Norcuron® as with other neuromuscular blockers. This may be manifested by skeletal muscle weakness, decreased respiratory reserve, low tidal volume, or apnea. A peripheral nerve stimulator may be used to assess the degree of residual neuromuscular blockade from other causes of decreased respiratory reserve.

Respiratory depression may be due either wholly or in part to other drugs used during the conduct of general anesthesia such as narcotics, thiobarbiturates and other central nervous system depressants. Under such circumstances, the primary treatment is maintenance of a patent airway and manual or mechanical ventilation until complete recovery of normal respiration is assured. Regonol® (pyridostigmine bromide) injection, neostigmine, or edrophonium, in conjunction with atropine or glycopyrrolate will usually antagonize the skeletal muscle relaxant action of Norcuron®. Satisfactory reversal can be judged by adequacy of skeletal muscle tone and by adequacy of respiration. A peripheral nerve stimulator may also be used to monitor restoration of twitch height. Failure of prompt reversal (within 30 minutes) may occur in the presence of extreme debilitation, carcinomatosis, and with concomitant use of certain broad spectrum antibiotics, or anesthetic agents and other drugs which enhance neuromuscular blockade or cause respiratory depression of their own. Under such circumstances the management is the same as that of prolonged neuromuscular blockade. Ventilation must be supported by artificial means until the patient has resumed control

DOSAGE AND ADMINISTRATION: Before prescribing, please consult complete product information. Norcuron® (vecuronium bromide) for injection is for intravenous use only. This drug should be administered by or under the supervision of experienced clinicians familiar with the use of neuromuscular blocking agents. Dosage must be individualized in each case. The dosage information which follows is derived from studies based upon units of drug per unit of body weight and is intended to serve as a guide only, especially regarding enhancement of neuromuscular blockade of Norcuron® by volatile anesthetics and by prior use of succinylcholine (see PRECAUTIONS/Drug Interactions). Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration whenever solution and container permit.

To obtain maximum clinical benefits of Norcuron® and to minimize the possibility of overdosage, the monitoring of muscle twitch response to peripheral nerve stimulation is advised.

The recommended initial dose of Norcuron® is 0.08 to 0.10 mg/kg (1.4 to 1.75 times the ED_{90}) given as an intravenous bolus injection. This dose can be expected to produce good or excellent non-emergency intubation conditions in 2.5 to 3 minutes after injection. Under balanced anesthesia, clinically required neuromuscular blockade lasts approximately 25-30 minutes, with recovery to 25% of control achieved approximately 25 to 40 minutes after injection and recovery to 95% of control achieved approximately 45-65 minutes after injection. In the presence of potent inhalation anesthetics, the neuromuscular blocking effect of Norcuron® is enhanced. If Norcuron® is first administered more than 5 minutes after the start of inhalation agent or when steady state has been achieved, the initial Norcuron® dose may be reduced by approximately 15%, i.e., 0.060 to 0.085 mg/kg.

Prior administration of succinylcholine may enhance the neuromuscular blocking effect and duration of action of Norcuron®. If intubation is performed using succinylcholine, a reduction of initial dose of Norcuron® to 0.04-0.06 mg/kg with inhalation anesthesia and 0.05-0.06 mg/kg with balanced anesthesia may be required.

During prolonged surgical procedures, maintenance doses of 0.010 to 0.015 mg/kg of Norcuron® are recommended; after the initial Norcuron® injection, the first maintenance dose will generally be required within 25 to 40 minutes. However, clinical criteria should be used to determine the need for maintenance doses. Since Norcuron® lacks clinically important cumulative effects, subsequent maintenance doses, if required, may be administered at relatively regular intervals for each patient, ranging approximately from 12 to 15 minutes under balanced anesthesia, slightly longer under inhalation agents. (If less frequent administration is desired, higher maintenance doses may be administered.)

Should there be reason for the selection of larger doses in individual patients, initial doses ranging from 0.15 mg/kg up to 0.28 mg/kg have been administered during surgery under halothane anesthesia without ill effects to the cardiovascular system being noted as long as ventilation is properly maintained.

Use by Continuous Infusion: After an intubating dose of 80-100 µg/kg, a continuous infusion of 1 µg/kg/min can be initiated approximately 20-40 min later. Infusion of Norcuron® should be initiated only after early evidence of spontaneous recovery from the bolus dose. Long-term intravenous infusion to support mechanical ventilation in the intensive care unit has not been studied sufficiently to support dosage recommendations (see PRECAUTIONS).

The infusion of Norcuron® should be individualized for each patient. The rate of administration should be adjusted according to the patient's twitch response as determined by peripheral nerve stimulation. An initial rate of 1 µg/kg/min is recommended, with the rate of the infusion adjusted thereafter to maintain a 90% suppression of twitch response. Average infusion rates may range from 0.8 to 1.2 µg/kg/min.

Inhalation anesthetics, particularly enflurane and isoflurane may enhance the neuromuscular blocking action of non-depolarizing muscle relaxants. In the presence of steady-state concentrations of enflurane or isoflurane, it may be necessary to reduce the rate of infusion 25-60 percent, 45-60 min after the intubating dose. Under halothane anesthesia it may not be necessary to reduce the rate of infusion.

Spontaneous recovery and reversal of neuromuscular blockade following discontinuation of Norcuron® infusion may be expected to proceed at rates comparable to that following a single bolus dose.

Infusion solutions of Norcuron® can be prepared by mixing Norcuron® with an appropriate infusion solution such as 5% glucose in water, 0.9% NaCl, 5% glucose in saline, or Lactated Ringers. Unused portions of infusion solutions should be discarded.

Infusion rates of Norcuron® can be individualized for each patient using the following table:

Drug Delivery Rate (µg/kg/min)	Infusion Delivery Rate (mL/kg/min)	
	0.1 mg/mL*	0.2 mg/mL†
0.7	0.007	0.0035
0.8	0.008	0.0040
0.9	0.009	0.0045
1.0	0.010	0.0050
1.1	0.011	0.0055
1.2	0.012	0.0060
1.3	0.013	0.0065

*10 mg of Norcuron® in 100 mL solution †20 mg of Norcuron® in 100 mL solution

The following table is a guideline for mL/min delivery for a solution of 0.1 mg/mL (10 mg in 100 mL) with an infusion pump.

NORCURON® INFUSION RATE – mL/MIN

Amount of Drug µg/kg/min	Patient Weight – kg						
	40	50	60	70	80	90	100
0.7	0.28	0.35	0.42	0.49	0.56	0.63	0.70
0.8	0.32	0.40	0.48	0.56	0.64	0.72	0.80
0.9	0.36	0.45	0.54	0.63	0.72	0.81	0.90
1.0	0.40	0.50	0.60	0.70	0.80	0.90	1.00
1.1	0.44	0.55	0.66	0.77	0.88	0.99	1.10
1.2	0.48	0.60	0.72	0.84	0.96	1.08	1.20
1.3	0.52	0.65	0.78	0.91	1.04	1.17	1.30

NOTE: If a concentration of 0.2 mg/mL is used (20 mg in 100 mL), the rate should be decreased by one-half.

Dosage in Children: Older children (10 to 17 years of age) have approximately the same dosage requirements (mg/kg) as adults and may be managed the same way. Younger children (1 to 10 years of age) may require a slightly higher initial dose and may also require supplementation slightly more often than adults. Infants under one year of age but older than 7 weeks are moderately more sensitive to Norcuron® on a mg/kg basis than adults and take about 1½ times as long to recover. See also subsection of PRECAUTIONS titled Pediatric Use. Information presently available does not permit recommendation on usage in neonates (see PRECAUTIONS). There are insufficient data concerning continuous infusion of vecuronium in children, therefore, no dosing recommendation can be made.

COMPATIBILITY: Norcuron® is compatible in solution with:

0.9% NaCl solution   Sterile water for injection   Lactated Ringers
5% glucose in water   5% glucose in saline

Use within 24 hours of mixing with the above solutions.

Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration whenever solution and container permit.

HOW SUPPLIED:

10 mL vials (10 mg vecuronium bromide) and 10 mL prefilled syringes of diluent (bacteriostatic water for injection, USP).
22 g 1¼" needle.   Boxes of 10   NDC No. 0052-0441-60
10 mL vials (10 mg vecuronium bromide) and 10 mL vials of diluent (bacteriostatic water for injection, USP).
Boxes of 10   NDC No. 0052-0441-17
10 mL vials (10 mg vecuronium bromide) only; DILUENT NOT SUPPLIED.   Boxes of 10   NDC No. 0052-0441-15
20 mL vials (20 mg vecuronium bromide) only; DILUENT NOT SUPPLIED.   Boxes of 10   NDC No. 0052-0442-46

STORAGE: 15°-30°C (59°-86°F). Protect from light.

AFTER RECONSTITUTION:

- When reconstituted with supplied bacteriostatic water for injection: CONTAINS BENZYL ALCHOHOL, WHICH IS NOT INTENDED FOR USE IN NEWBORNS. Use within 5 days. May be stored at room temperature or refrigerated.
- When reconstituted with sterile water for injection or other compatible I.V. solutions: Refrigerate vial. Use within 24 hours. Single use only. Discard unused portion.

Caution: Federal law prohibits dispensing without prescription.

International Trauma Anesthesia and Critical Care Society

1993

RESEARCH AWARDS

AREAS OF ELIGIBILITY

Within the general field of perioperative trauma anesthesia and critical care, including basic science or clinical research, clinical management, education, or administration.

- Prehospital/EMS/Field
- In Hospital
  - —Pre-Op Stabilization/Resuscitation
  - —Anesthetic Preparation/Induction
  - —Intraoperative Anesthesia
  - —Post-Op Critical Care: PACU/ICU
  - —Pain Management: Pre-Op/Post-Op/Field
- Administration/Organization of Trauma Anesthesia Services

CATEGORIES OF AWARD

- **Prospective Project Award** (up to $US 5,000.00)
  - —Official application must be used
  - —Applications must be received no later than **15, February 1993**
  - —Where relevant, applications must include institutional approval of human studies and/or animal research
  - —Applications must be accompanied by a budget list, copies of previously published material in the area, and any supporting documents to assess project viability
  - —Applications are invited from the international community. Applicants must be members of *ITACCS*
- **Retrospective Awards**
  - —Best Scientific Free Paper ($US 2,000.00)
  - —Best Scientific Poster ($US 2,000.00)
  - —Same rules apply as for Prospective Project, except non-ITACCS members are also eligible

Final judgements will be made during the "Sixth Annual Trauma Anesthesia and Critical Care Symposium," to be held in Baltimore, Maryland, USA, 20–22 May, 1993. For details on the symposium contact the Office of International Development, 410 W. Lombard St., Suite 416, Baltimore, MD, 21201, USA, Telephone 410-328-2399 FAX 410-328-0501

For application forms, detailed guidelines and other information on Research Awards, contact:

ITACCS
ATTN: Enrico M. Camporesi, M.D.
Chairman, ITACCS Research Committee
P.O. Box 4826
Baltimore, MD, USA 21211

Technical Report

Real time nitrogen monitoring: a unique parameter in patient care.

Summary.

Real time nitrogen monitoring provides unique clinical information. It allows differentiation and diagnosis of significant events - events which otherwise would be difficult to confirm. Overall, knowledge of circuit nitrogen concentrations can greatly enhance patient safety.

Detecting Venous Air Emboli.

Venous air emboli (VAE) occur when air enters the circulation through a lacerated vein in which venous pressure is below atmospheric pressure.[1]

Embolic events have been described in spinal fusions,[2] neuro procedures, organ transplantation[3] and orthopedic surgery.[4]

Air embolism involves air passing through the right heart and traversing the alveolar-capillary membrane. It can be measured as an increase in end-tidal nitrogen (EtN_2). Catastrophic VAE occur when large amounts of air enter the right heart creating an air lock.

Monitoring EtN_2 is a superior method for confirming the diagnosis of VAE.[5] Blood loss or sudden reductions in cardiac output can decrease $EtCO_2$ in the absence of VAE. VAE remain the only cause for sudden EtN_2 increase.[6]

Verifying Adequate Denitrogenation.

Preoxygenation prior to general anesthesia is used to prevent hypoxemia. The time required to preoxygenate a patient adequately can vary widely - it can be up to 10 minutes.

This is a special concern for babies and infants due to their increased metabolic rate; for patients with lung disease;[7] and for the obese, who may have less reserve due to reduced lung capacity.

The ability to assess adequacy of denitrogenation is paramount to patient safety. Rather than watching for increasing SpO_2, the key is observing wash-out of N_2 from the lungs.

Monitoring is the only way to be sure.

Monitoring Anesthesia Circuit Integrity.

Room air can be entrained into the anesthesia circuit. Entrained air contaminates the gas mixture with N_2 and can therefore be detected. Entrained air dilutes the mixture the patient is receiving, compromises the readings of monitoring devices and can thereby mask significant physiological changes.

Monitoring N_2 is the fastest and most reliable way to detect leaks.[8]

Detecting Nitrogen Accumulation.

In spite of high initial gas flows and denitrogenation procedures, excreted N_2 builds up during both closed circuit and low-flow anesthesia. N_2 levels as high as 15% have been reported during closed circuit anesthesia.[9]

N_2 accumulation decreases O_2 and N_2O concentrations and affects the depth of anesthesia. Thus, N_2 monitoring rather than simple maintenance of circuit volume is an important criterion for closed circuit anesthesia.[10]

More Information.

Please contact your Ohmeda representative if you would like more background on the advantages of nitrogen monitoring.

IARS MEMBERSHIP

FOR YOUR IN-TRAINING AND CONTINUING MEDICAL EDUCATION

The International Anesthesia Research Society is a nonprofit, scientific and educational corporation of the State of Ohio, founded in 1922 "to foster progress and research in anesthesia." To this end, the IARS

Publishes the oldest journal in the specialty, *Anesthesia & Analgesia*
Sponsors an annual scientific meeting (Congress) which is held in March
Funds projects in anesthesia-related research, clinical care, education, and administration through the B.B. Sankey Anesthesia Advancement Award, and the Ben Covino Research Award

Membership in the IARS is voluntary; it is also separate and distinct from membership in any other local, state, or national anesthesia organization. Membership is open to individuals who qualify in the various categories shown below. All memberships include a monthly subscription to *Anesthesia & Analgesia* which includes the abstract supplement and the Review Course Lectures Book. Members and Associate Members are entitled to a reduced registration fee at the IARS annual Congress, Educational Members pay no registration fee. Only IARS members may apply for the B.B. Sankey Anesthesia Advancement Award.

MEMBERSHIP CATEGORIES

MEMBERSHIP: Open to individuals with doctorate degrees who are licensed to practice in the medical, osteopathic, dental, or veterinary medicine fields (i.e., MD, MB, DO, DDS, DVM); and to individuals with doctorate degrees (PhD) in any scientific discipline who are engaged in academic, private, or commercial research.

ASSOCIATE MEMBERSHIP: Open to individuals in the allied health professions who are certified by their professional accrediting organization as nurse anesthetists (CRNA), respiratory therapists or technicians (RRT or CRTT), physician assistants (PA, MMS), and other allied health professionals in anesthesia-related practice.

Beginning with the January 1993 issue of *Anesthesia & Analgesia*, International Members will receive the Journal by Surface Air Lift (First Class to Canada) **at no additional charge**.

Annual (1992 Calendar Year) Dues for Members and Associate Members: $95 ($120 Int'l).

Annual (1993 Calendar Year) Dues for Members and Associate Members: $100.

EDUCATIONAL MEMBERSHIP: Open (with certification by program director) to doctors (interns/residents) enrolled in anesthesiology training programs; nurses enrolled in nurse anesthesia schools; students enrolled in programs leading to certification as physician assistants, respiratory therapists, or technicians.

Annual Dues for Educational Members:

2 Years beginning July 1992—$108 ($120 Int'l)	2 Years beginning January 1993—$110	NO POSTAGE SURCHARGE BEGINNING IN 1993
3 Years beginning July 1992—$163 ($175 Int'l)	3 Years beginning January 1993—$165	
4 Years beginning July 1992—$218 ($230 Int'l)	4 Years beginning January 1993—$220	

International Anesthesia Research Society

ANESTHESIA
&
ANALGESIA
Journal of the International Anesthesia Research Society

The **International Anesthesia Research Society** is a nonprofit, scientific, and educational corporation in the state of Ohio. Members of the Board of Trustees of the Society are: David R. Bevan, MA, MB, BChir, Michael K. Cahalan, MD, Douglas B. Craig, MD, FRCPC, Bruce F. Cullen, MD, Noel W. Lawson, MD, Edward D. Miller, Jr, MD, Dean H. Morrow, MD, J. G. Reves, MD, Robert K. Stoelting, MD, Stephen J. Thomas, MD, John L. Waller, MD, and K. C. Wong, MD, PhD. Emeritus Trustees are: E. Paul Didier, MD, Paul R. Dumke, MD, John T. Martin, MD, Emerson A. Moffitt, MD, Morris J. Nicholson, MD, and B. B. Sankey, MD.

Anesthesia & Analgesia (ISSN 0003-2999) is issued monthly for the IARS in two indexed volumes per year by Elsevier Science Publishing Co., Inc., 655 Avenue of the Americas, New York, NY 10010. Printed in USA. © 1992 by the International Anesthesia Research Society. Second class postage paid at New York, NY and at additional mailing offices.

Subscription information for 1992 applying to IARS members: USA and possessions, $95.00 per year; in all other countries, $120.00. Membership is available to individuals with doctorate degrees in medicine, osteopathy, dentistry, veterinary medicine, or other disciplines who are engaged in active clinical practice of or research in anesthesiology. Associate Membership is available to individuals certified, licensed, or accredited by anesthesia-related professions (CRNA, CRTT, RRT, Physician Assistant). Educational Membership (at a reduced price) is available to interns, residents, and students in nurse anesthesia and related training programs, for a 2-, 3-, or 4-year period upon completion of application including certification by applicant's program director.

All membership payments and correspondence regarding IARS member subscriptions should be sent to: International Anesthesia Research Society, Suite 140, 2 Summit Park Drive, Cleveland, OH 44131-2553.

Subscription information for 1992 applying to non-IARS members: Institutions, $150.00; nonmember individuals, $110.00. Outside the USA and possessions, please add $35.00 for surface postage and handling. For airmail, add $80.00 in USA, Canada, and Mexico; $70.00 for surface airlift to Europe; $85.00 for surface airlift to Japan; and $160.00 for airmail to the rest of the world. Postmaster: Send address changes to: *Anesthesia & Analgesia*, Elsevier Science Publishing Co., Inc., 655 Avenue of the Americas, New York, NY 10010.

Orders and inquiries regarding institutional and nonmember individual subscriptions should be directed to: Journals Fulfillment, Elsevier Science Publishing Co., Inc., 655 Avenue of the Americas, New York, NY 10010.

Single issues: Single copy information is available from Elsevier Science Publishing Co., Inc., upon request. Back volume (all issues prior to 1983) information is available from the IARS.

Advertising inquiries should be addressed to: Pharmaceutical Media, Inc., 440 Park Avenue South, 14th Floor, New York, NY 10016. This journal is printed on acid-free paper.

WAKE UP CALL

Why awaken patients from benzodiazepine sedation?

MAZICON® (flumazenil/Roche) antagonizes the sedative effects of benzodiazepines following general anesthesia, conscious sedation or in cases of benzodiazepine overdose.

In the clinical practice of anesthesia, there are excellent reasons to awaken patients with MAZICON. Intravenous administration of 0.2 mg/min (up to a total of 1 mg) of MAZICON:

- Provides a prompt, controlled awakening from benzodiazepine sedation
- Enhances your control over the depth and duration of sedation
- Facilitates postanesthesia patient assessment
- Patients emerge from sedation sooner — which is reassuring to the patient, the family and your staff
- Specific to benzodiazepines—does not antagonize narcotics or other CNS agents

When to accelerate awakening

MAZICON provides a controlled, smooth emergence within minutes of an effective dose, which may be particularly appropriate:

- After ambulatory procedures, such as biopsy, dilatation and curettage, hernia repair, arthroscopic surgery, plastic surgery or ophthalmic surgery—in these situations, restoring alertness with MAZICON allows the patient to cooperate, so that patient management can be facilitated
- When postprocedural sedation is unwanted, especially after short surgical or diagnostic procedures
- When postprocedural sedation may be undesirable in higher-risk patients

Adverse effects

The most common side effects in clinical trials were nausea and vomiting (11%), dizziness (10%), agitation (3% to 9%) and injection-site pain (3% to 9%).

MAZICON is associated with seizures, most often in patients on benzodiazepines for long-term sedation or patients showing signs of serious cyclic antidepressant overdose. Practitioners should individualize the dosage and be prepared to manage seizures.

Important safety information

Patients should be monitored for resedation, respiratory depression or other residual effects of benzodiazepines.

The availability of MAZICON does not diminish the need for prompt detection of hypoventilation and the need to be prepared to effectively intervene by establishing an airway and assisting ventilation. MAZICON has not been established as an effective treatment for benzodiazepine-induced hypoventilation.

Contraindicated in hypersensitivity to benzodiazepines or MAZICON; in patients taking benzodiazepines for control of potentially life-threatening conditions; and in patients showing signs of serious cyclic antidepressant overdose. In patients who are dependent on benzodiazepines, MAZICON may precipitate withdrawal syndromes.

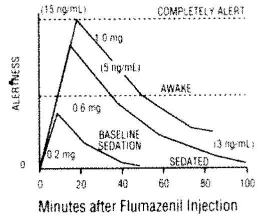
Please see following pages for complete product information.

MAZICON™
(flumazenil/Roche)
INJECTION

DESCRIPTION: MAZICON™ (flumazenil/Roche) is a benzodiazepine receptor antagonist. Chemically, flumazenil is ethyl 8-fluoro-5,6-dihydro-5-methyl-6-oxo-4H-imidazo[1,5-a](1,4) benzodiazepine-3-carboxylate. Flumazenil has an imidazobenzodiazepine structure, a calculated molecular weight of 303.3.
Flumazenil is a white to off-white crystalline compound with an octanol:buffer partition coefficient of 14 to 1 at pH 7.4. It is insoluble in water but slightly soluble in acidic aqueous solutions. MAZICON is available as a sterile parenteral dosage form for intravenous administration. Each mL contains 0.1 mg of flumazenil compounded with 1.8 mg of methylparaben, 0.2 mg of propylparaben, 0.9% sodium chloride, 0.01% edetate disodium, and 0.01% acetic acid; the pH is adjusted to approximately 4 with hydrochloric acid and/or, if necessary, sodium hydroxide.

CLINICAL PHARMACOLOGY: Flumazenil, an imidazobenzodiazepine derivative, antagonizes the actions of benzodiazepines on the central nervous system. Flumazenil competitively inhibits the activity at the benzodiazepine recognition site on the GABA/benzodiazepine receptor complex. Flumazenil is a weak partial agonist in some animal models of activity, but has little or no agonist activity in man.
Flumazenil does not antagonize the central nervous system effects of drugs affecting GABA-ergic neurons by means other than the benzodiazepine receptor (including ethanol, barbiturates, or general anesthetics) and does not reverse the effects of opioids.
PHARMACODYNAMICS: Intravenous MAZICON has been shown to antagonize sedation, impairment of recall and psychomotor impairment produced by benzodiazepines in healthy human volunteers.
The duration and degree of reversal of benzodiazepine effects are related to the dose and plasma concentrations of flumazenil as shown in the following data from a study in normal volunteers.

Magnitude and Duration of Reversal of Sedation as a Function of Flumazenil Dose*
Flumazenil doses of 0.2, 0.6 & 1.0 mg
(blood level in ng/mL)



*Sedation produced by midazolam infusion at a rate of 0.06 - 0.20 mg/kg/hr in healthy volunteers

Generally, doses of approximately 0.1 to 0.2 mg (corresponding to peak plasma levels of 3 to 6 ng/mL) produce partial antagonism, whereas higher doses of 0.4 to 1.0 mg (peak plasma levels of 12 to 28 ng/mL) usually produce complete antagonism in patients who have received the usual sedating doses of benzodiazepines. The onset of reversal is usually evident within 1 to 2 minutes after the injection is completed. Eighty percent response will be reached within 3 minutes, with the peak effect occurring at 6 to 10 minutes. The duration and degree of reversal are related to the plasma concentration of the sedating benzodiazepine as well as the dose of MAZICON given.
In healthy volunteers, MAZICON did not alter intraocular pressure when given alone and reversed the decrease in intraocular pressure seen after administration of midazolam.
PHARMACOKINETICS: After IV administration, plasma concentrations of flumazenil follow a two compartment open pharmacokinetic model with an initial distribution half-life of 7 to 15 minutes and a terminal half-life of 41 to 79 minutes. Peak concentrations of flumazenil are proportional to dose, with an apparent initial volume of distribution of 0.5 L/kg. After redistribution the apparent volume of distribution (V_{SS}) ranges from 0.77 to 1.60 L/kg. Protein binding is approximately 50% and the drug shows no preferential partitioning into red blood cells. Flumazenil is a highly extracted drug. Clearance of flumazenil occurs primarily by hepatic metabolism and is dependent on hepatic blood flow. In pharmacokinetic studies of normal volunteers, total clearance ranges from 0.7 to 1.3 L/hr/kg, with less than 1% of the administered dose eliminated unchanged in the urine. The major metabolites of flumazenil identified in urine are the de-ethylated free acid and its glucuronide conjugate. In preclinical studies there was no evidence of pharmacologic activity exhibited by the de-ethylated free acid. Elimination of radiolabelled drug is essentially complete within 72 hours, with 90% to 95% of the radioactivity appearing in urine and 5% to 10% in the feces.

Pharmacokinetic Parameters Following a 5-minute infusion of a total of 1.0 mg of MAZICON Mean (Coefficient of variation, Range)

C_{max} (ng/mL)	24 (38%, 11-43)
AUC (ng•hr/mL)	15 (22%, 10-22)
V_{ss} (L/kg)	1 (24%, 0.8-1.6)
Cl (L/hr/kg)	1 (20%, 0.7-1.4)
Half-life (min)	54 (21%, 41-79)

The pharmacokinetics of flumazenil are not significantly affected by gender, age, renal failure (creatinine clearance <10 mL/min), or hemodialysis beginning 1 hour after drug administration. Mean total clearance is decreased to 40% to 60% of normal in patients with moderate liver dysfunction and to 25% of normal in patients with severe liver dysfunction compared with age-matched healthy subjects. This results in a prolongation of the half-life from 0.8 hours in healthy subjects to 1.3 hours in patients with moderate hepatic impairment and 2.4 hours in severely impaired patients. Ingestion of food during an intravenous infusion of the drug results in a 50% increase in clearance, most likely due to the increased hepatic blood flow that accompanies a meal. The pharmacokinetic profile of flumazenil is unaltered in the presence of benzodiazepine agonists and the kinetic profiles of those benzodiazepines are unaltered by flumazenil.

CLINICAL TRIALS: MAZICON has been administered to reverse the effects of benzodiazepines in conscious sedation, general anesthesia, and the management of suspected benzodiazepine overdose.
CONSCIOUS SEDATION: MAZICON was studied in four trials in 970 patients who received an average of 30 mg diazepam or 10 mg midazolam for sedation (with or without a narcotic) in conjunction with both inpatient and outpatient diagnostic or surgical procedures. MAZICON was effective in reversing the sedating and psychomotor effects of the benzodiazepine, however, amnesia was less completely and less consistently reversed. In these studies, MAZICON was administered as an initial dose of 0.4 mg I.V. (two doses of 0.2 mg) with additional 0.2 mg doses as needed to achieve complete awakening, up to a maximum total dose of 1.0 mg. Seventy-eight percent of patients receiving flumazenil responded by becoming completely alert. Of those patients, approximately half responded to doses of 0.4 to 0.6 mg, while the other half responded to doses of 0.8 to 1.0 mg. Adverse effects were infrequent in patients who received 1 mg of MAZICON or less, although injection site pain, agitation and anxiety did occur. Reversal of sedation was not associated with any increase in the frequency of inadequate analgesia or increase in narcotic demand in these studies. While most patients remained alert throughout the 3 hour post-procedure observation period, resedation was observed to occur in 3% to 9% of the patients, and was most common in patients who had received high doses of benzodiazepine. (See PRECAUTIONS.)
GENERAL ANESTHESIA: MAZICON was studied in four trials in 644 patients who received midazolam as an induction and/or maintenance agent in both balanced and inhalational anesthesia. Midazolam was generally administered in doses ranging from 5 to 80 mg, alone and/or in conjunction with muscle relaxants, nitrous oxide, regional or local anesthetics, narcotics and/or inhalational anesthetics. Flumazenil was given as an initial dose of 0.2 mg IV, with additional 0.2 mg doses as needed to reach a complete response, up to a maximum total dose of 1.0 mg. These doses were effective in reversing sedation and restoring psychomotor function, but did not completely restore memory as tested by picture recall. MAZICON was not as effective in the reversal of sedation in patients who had received multiple anesthetic agents in addition to benzodiazepines.
Eighty-one percent of patients sedated with midazolam responded to flumazenil by becoming completely alert or just slightly drowsy. Of those patients, 36% responded to doses of 0.4 to 0.6 mg, while 64% responded to doses of 0.8 to 1.0 mg.
Resedation in patients who responded to MAZICON occurred in 10% to 15% of patients studied and was more common with larger doses of midazolam (>20 mg), long procedures (>60 minutes) and use of neuromuscular blocking agents. (See PRECAUTIONS.)
MANAGEMENT OF SUSPECTED BENZODIAZEPINE OVERDOSE: MAZICON was studied in two trials in 497 patients who were presumed to have taken an overdose of a benzodiazepine, either alone or in combination with a variety of other agents. In these trials, 299 patients were proven to have taken a benzodiazepine as part of the overdose, and 80% of the 148 who received MAZICON responded by an improvement in level of consciousness. Of the patients who responded to flumazenil, 75% responded to a total dose of 1.0 to 3.0 mg. Reversal of sedation was associated with an increased frequency of symptoms of CNS excitation. Of the

patients treated with flumazenil, 1% to 3% were treated for agitation or anxiety. Serious side effects were uncommon, but six seizures were observed in 446 patients treated with flumazenil in these studies. Four of these 6 patients had ingested a large dose of cyclic antidepressants, which increased the risk of seizures. (See WARNINGS.)

INDIVIDUALIZATION OF DOSAGE: GENERAL PRINCIPLES: The serious adverse effects of MAZICON are related to the reversal of benzodiazepine effects. Using more than the minimally effective dose of MAZICON is tolerated by most patients but may complicate the management of patients who are physically dependent on benzodiazepines or patients who are depending on benzodiazepines for therapeutic effect (such as suppression of seizures in cyclic antidepressant overdose).
In high-risk patients, it is important to administer the smallest amount of MAZICON that is effective. The 1-minute wait between individual doses in the dose-titration recommended for general clinical populations may be too short for high risk patients. This is because it takes 6 to 10 minutes for any single dose of flumazenil to reach full effects. Practitioners should slow the rate of administration of MAZICON administered to high risk patients as recommended below.
ANESTHESIA AND CONSCIOUS SEDATION: MAZICON is well tolerated at the recommended doses in individuals who have no tolerance to (or dependence on) benzodiazepines. The recommended dosages and titration rates in anesthesia and conscious sedation (0.2 to 1.0 mg given at 0.2 mg/min) are well tolerated in patients receiving the drug for reversal of a single benzodiazepine exposure in most clinical settings (see Adverse Events). The major risk will be resedation because the duration of effect of a long-acting (or large dose of a short-acting) benzodiazepine may exceed that of MAZICON. Resedation may be treated by giving a repeat dose at no less than 20-minute intervals. For repeat treatment, no more than 1.0 mg (at 0.2 mg/min doses) should be given at any one time and no more than 3.0 mg should be given in any one hour.
OVERDOSE PATIENTS: The risk of confusion, agitation, emotional lability and perceptual distortion with the doses recommended in patients with benzodiazepine overdose (3 to 5 mg administered as 0.5 mg/min) may be greater than that expected with lower doses and slower administration. The recommended doses represent a compromise between a desirable slow awakening and the need for prompt response and a persistent effect in the overdose situation. If circumstances permit, the physician may elect to use the 0.2 mg/minute titration rate to slowly awaken the patient over 5 to 10 minutes, which may help to reduce signs and symptoms on emergence.
MAZICON has no effect in cases where benzodiazepines are not responsible for sedation. Once doses of 3 to 5 mg have been reached without clinical response, additional MAZICON is likely to have no effect.
PATIENTS TOLERANT TO BENZODIAZEPINES: MAZICON may cause benzodiazepine withdrawal symptoms in individuals who have been taking benzodiazepines long enough to have some degree of tolerance. Patients who had been taking benzodiazepines prior to entry into the MAZICON trials who were given flumazenil in doses over 1 mg experienced withdrawal-like events 2 to 5 times more frequently than patients who received less than 1 mg.
In patients who may have tolerance to benzodiazepines, as indicated by clinical history or by the need for larger than usual doses of benzodiazepine, slower titration rates of 0.1 mg/min and lower total doses may help reduce the frequency of emergent confusion and agitation. In such cases special care must be taken to monitor the patients for resedation because of the lower doses of MAZICON used.
PATIENTS PHYSICALLY DEPENDENT ON BENZODIAZEPINES: MAZICON is known to precipitate withdrawal seizures in patients who are physically dependent on benzodiazepines, even if such dependence was established in a relatively few days of high dose sedation in Intensive Care Unit environments. The risk of either seizures or resedation in such cases is high and patients have experienced seizures before regaining consciousness. MAZICON should be used in such settings with extreme caution, since the use of flumazenil in this situation has not been studied and no information as to dose and rate of titration is available. MAZICON should be used in such patients only if the potential benefits of using the drug outweigh the risks of precipitated seizures. Physicians are directed to the scientific literature for the most current information in this area.

INDICATIONS AND USAGE: MAZICON is indicated for the complete or partial reversal of the sedative effects of benzodiazepines in cases where general anesthesia has been induced and/or maintained with benzodiazepines, where sedation has been produced with benzodiazepines for diagnostic and therapeutic procedures, and for the management of benzodiazepine overdose.

CONTRAINDICATIONS: MAZICON is contraindicated:

- in patients with a known hypersensitivity to flumazenil or to benzodiazepines.
- in patients who have been given a benzodiazepine for control of a potentially life-threatening condition (*e.g.* control of intracranial pressure or status epilepticus).
- in patients who are showing signs of serious cyclic antidepressant overdose. (See WARNINGS.)

WARNINGS:

THE USE OF MAZICON HAS BEEN ASSOCIATED WITH THE OCCURRENCE OF SEIZURES.
THESE ARE MOST FREQUENT IN PATIENTS WHO HAVE BEEN ON BENZODIAZEPINES FOR LONG-TERM SEDATION OR IN OVERDOSE CASES WHERE PATIENTS ARE SHOWING SIGNS OF SERIOUS CYCLIC ANTIDEPRESSANT OVERDOSE.
PRACTITIONERS SHOULD INDIVIDUALIZE THE DOSAGE OF MAZICON AND BE PREPARED TO MANAGE SEIZURES.

Risk of Seizures: The reversal of benzodiazepine effects may be associated with the onset of seizures in certain high-risk populations. Possible risk factors for seizures include: concurrent major sedative-hypnotic drug withdrawal, recent therapy with repeated doses of parenteral benzodiazepines, myoclonic jerking or seizure activity prior to flumazenil administration in overdose cases, or concurrent cyclic antidepressant poisoning.
MAZICON is not recommended in cases of serious cyclic antidepressant poisoning, as manifested by motor abnormalities (twitching, rigidity, focal seizure), dysrhythmia (wide QRS, ventricular dysrhythmia, heart block), anticholinergic signs (mydriasis, dry mucosa, hypo-peristalsis), and cardiovascular collapse at presentation. In such cases MAZICON should be withheld and the patient should be allowed to remain sedated (with ventilatory and circulatory support as needed) until the signs of antidepressant toxicity have subsided. Treatment with MAZICON has no known benefit to the seriously ill mixed-overdose patient other than reversing sedation and should not be used in cases where seizures (from any cause) are likely.
Most convulsions associated with flumazenil administration require treatment and have been successfully managed with benzodiazepines, phenytoin or barbiturates. Because of the presence of flumazenil, higher than usual doses of benzodiazepines may be required.

HYPOVENTILATION: Patients who have received MAZICON for the reversal of benzodiazepine effects (after conscious sedation or general anesthesia) should be monitored for resedation, respiratory depression, or other residual benzodiazepine effects for an appropriate period (up to 120 minutes) based on the dose and duration of effect of the benzodiazepine employed.
This is because MAZICON has not been established as an effective treatment for hypoventilation due to benzodiazepine administration. The availability of flumazenil does not diminish the need for prompt detection of hypoventilation and the ability to effectively intervene by establishing an airway and assisting ventilation.
MAZICON may not fully reverse postoperative airway problems or ventilatory insufficiency induced by benzodiazepines. In addition, even if MAZICON is initially effective, such problems may recur because the effects of MAZICON wear off before the effects of many benzodiazepines.
Overdose cases should always be monitored for resedation until the patients are stable and resedation is unlikely.

PRECAUTIONS: RETURN OF SEDATION: MAZICON may be expected to improve the alertness of patients recovering from a procedure involving sedation or anesthesia with benzodiazepines, but should not be substituted for an adequate period of post-procedure monitoring. The availability of MAZICON does not reduce the risks associated with the use of large doses of benzodiazepines for sedation.
Patients should be monitored for resedation, respiratory depression (see WARNINGS), or other persistent or recurrent agonist effects for an adequate period of time after administration of MAZICON.
Resedation is least likely in cases where MAZICON is administered to reverse a low dose of a short-acting benzodiazepine (<10 mg midazolam). It is most likely in cases where a large single or cumulative dose of a benzodiazepine has been given in the course of a long procedure along with neuromuscular blocking agents and multiple anesthetic agents.
Profound resedation was observed in 1% to 3% of patients in the clinical studies. In clinical situations where resedation must be prevented, physicians may wish to repeat the initial dose (up to 1 mg of MAZICON given at 0.2 mg/min) at 30 minutes and possibly again at 60 minutes. This dosage schedule, although not studied in clinical trials, was effective in preventing resedation in a pharmacologic study in normal volunteers.
USE IN THE ICU: MAZICON should be used with caution in the Intensive Care Unit because of the increased risk of unrecognized benzodiazepine dependence in such settings. MAZICON may produce convulsions in patients physically dependent on benzodiazepines. (See INDIVIDUALIZATION OF DOSAGE AND WARNINGS.)
Administration of MAZICON to diagnose benzodiazepine-induced sedation in the Intensive Care Unit is not recommended due to the risk of adverse events as described above. In addition, the prognostic significance of a patient's failure to respond to flumazenil in cases confounded by metabolic disorder, traumatic injury, drugs other than benzodiazepines, or any other reasons not associated with benzodiazepine receptor occupancy is not known.

USE IN OVERDOSE: MAZICON is intended as an adjunct to, not as a substitute for, proper management of airway, assisted breathing, circulatory access and support, internal decontamination by lavage and charcoal, and adequate clinical evaluation.

Necessary measures should be instituted to secure airway, ventilation and intravenous access prior to administering flumazenil. Upon arousal patients may attempt to withdraw endotracheal tubes and/or intravenous lines as the result of confusion and agitation following awakening.

HEAD INJURY: MAZICON should be used with caution in patients with head injury as it may be capable of precipitating convulsions or altering cerebral blood flow in patients receiving benzodiazepines. It should be used only by practitioners prepared to manage such complications should they occur.

USE WITH NEUROMUSCULAR BLOCKING AGENTS: MAZICON should not be used until the effects of neuromuscular blockade have been fully reversed.

USE IN PSYCHIATRIC PATIENTS: MAZICON has been reported to provoke panic attacks in patients with a history of panic disorder.

PAIN ON INJECTION: To minimize the likelihood of pain or inflammation at the injection site, MAZICON should be administered through a freely flowing intravenous infusion into a large vein. Local irritation may occur following extravasation into perivascular tissues.

USE IN RESPIRATORY DISEASE: The primary treatment of patients with serious lung disease who experience serious respiratory depression due to benzodiazepines should be appropriate ventilatory support (See PRECAUTIONS) rather than the administration of MAZICON. Flumazenil is capable of partially reversing benzodiazepine-induced alterations in ventilatory drive in healthy volunteers, but has not been shown to be clinically effective.

USE IN CARDIOVASCULAR DISEASE: MAZICON did not increase the work of the heart when used to reverse benzodiazepines in cardiac patients when given at a rate of 0.1 mg/min in total doses of less than 0.5 mg in studies reported in the clinical literature. Flumazenil alone had no significant effects on cardiovascular parameters when administered to patients with stable ischemic heart disease.

USE IN LIVER DISEASE: The clearance of MAZICON is reduced to 40% to 60% of normal in patients with mild to moderate hepatic disease and to 25% of normal in patients with severe hepatic dysfunction. (See PHARMACOKINETICS.) While the dose of flumazenil used for initial reversal of benzodiazepine effects is not affected, repeat doses of the drug in liver disease should be reduced in size or frequency.

USE IN DRUG AND ALCOHOL DEPENDENT PATIENTS: MAZICON should be used with caution in patients with alcoholism and other drug dependencies due to the increased frequency of benzodiazepine tolerance and dependence observed in these patient populations.

MAZICON is not recommended either as a treatment for benzodiazepine dependence or for the management of protracted benzodiazepine abstinence syndromes, as such use has not been studied.

The administration of flumazenil can precipitate benzodiazepine withdrawal in animals and man. This has been seen in healthy volunteers treated with therapeutic doses of oral lorazepam for up to 2 weeks who exhibited effects such as hot flushes, agitation and tremor when treated with cumulative doses of up to 3 mg doses of flumazenil.

Similar adverse experiences suggestive of flumazenil precipitation of benzodiazepine withdrawal have occurred in some patients in clinical trials. Such patients had a short-lived syndrome characterized by dizziness, mild confusion, emotional lability, agitation (with signs and symptoms of anxiety), and mild sensory distortions. This response was dose-related, most common at doses above 1 mg, rarely required treatment other than reassurance and was usually short lived. When required (5 to 10 cases), these patients were successfully treated with usual doses of a barbiturate, a benzodiazepine, or other sedative drug.

Practitioners should assume that flumazenil administration may trigger dose-dependent withdrawal syndromes in patients with established physical dependence on benzodiazepines and may complicate the management of withdrawal syndromes for alcohol, barbiturates and cross-tolerant sedatives.

DRUG INTERACTIONS: Interaction with central nervous system depressants other than benzodiazepines has not been specifically studied; however, no deleterious interactions were seen when MAZICON was administered after narcotics, inhalational anesthetics, muscle relaxants and muscle relaxant antagonists administered in conjunction with sedation or anesthesia.

Particular caution is necessary when using MAZICON in cases of mixed drug overdosage since the toxic effects (such as convulsions and cardiac dysrhythmias) of other drugs taken in overdose (especially cyclic antidepressants) may emerge with the reversal of the benzodiazepine effect by flumazenil. (See WARNINGS.)

The pharmacokinetics of benzodiazepines are unaltered in the presence of flumazenil.

USE IN AMBULATORY PATIENTS: The effects of MAZICON may wear off before a long-acting benzodiazepine is completely cleared from the body. In general, if a patient shows no signs of sedation within 2 hours after a 1.0 mg dose of flumazenil, serious resedation at a later time is unlikely. An adequate period of observation must be provided for any patient in whom either long-acting benzodiazepines (such as diazepam) or large doses of short-acting benzodiazepines (such as >10 mg of midazolam) have been used. (See INDIVIDUALIZATION OF DOSAGE.)

Because of the increased risk of adverse reactions in patients who have been taking benzodiazepines on a regular basis, it is particularly important that physicians query carefully about benzodiazepine, alcohol and sedative use as part of the history prior to any procedure in which the use of MAZICON is planned. (See DRUG AND ALCOHOL DEPENDENT PATIENTS.)

INFORMATION FOR PATIENTS: MAZICON does not consistently reverse amnesia. Patients cannot be expected to remember information told to them in the post-procedure period and instructions given to patients should be reinforced in writing or given to a responsible family member. Physicians are advised to discuss with their patients, both before surgery and at discharge, that although the patient may feel alert at the time of discharge, the effects of the benzodiazepine may recur. As a result, the patient should be instructed, preferably in writing, that their memory and judgment may be impaired and specifically advised:

1. Not to engage in any activities requiring complete alertness, and not to operate hazardous machinery or a motor vehicle until at least 18 to 24 hours after discharge, and it is certain no residual sedative effects of the benzodiazepine remain.
2. Not to take any alcohol or non-prescription drugs for 18 to 24 hours after flumazenil administration or if the effects of the benzodiazepine persist.

LABORATORY TESTS: No specific laboratory tests are recommended to follow the patient's response or to identify possible adverse reactions.

DRUG/LABORATORY TEST INTERACTIONS: The possible interaction of flumazenil with commonly used laboratory tests has not been evaluated.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Carcinogenesis: No studies in animals to evaluate the carcinogenic potential of flumazenil have been conducted.

Mutagenesis: No evidence for mutagenicity was noted in the Ames test using five different tester strains. Assays for mutagenic potential in *S. cerevisiae* D7 and in Chinese hamster cells were considered to be negative as were blastogenesis assays *in vitro* in peripheral human lymphocytes and *in vivo* in a mouse micronucleus assay. Flumazenil caused a slight increase in unscheduled DNA synthesis in rat hepatocyte culture at concentrations which were also cytotoxic; no increase in DNA repair was observed in male mouse germ cells in an *in vivo* DNA repair assay.

Impairment of fertility: A reproduction study in male and female rats did not show any impairment of fertility at oral dosages of 125 mg/kg/day. From the available data on the area under the curve (AUC) in animals and man the dose represented 120 x the human exposure from a maximum recommended intravenous dose of 5 mg.

PREGNANCY: CATEGORY C. There are no adequate and well-controlled studies of the use of flumazenil in pregnant women. Flumazenil should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Teratogenic Effects: Flumazenil has been studied for teratogenicity in rats and rabbits following oral treatments of up to 150 mg/kg/day. The treatments during the major organogenesis were on days 6 to 15 of gestation in the rat and days 6 to 18 of gestation in the rabbit. No teratogenic effects were observed in rats or rabbits at 150 mg/kg; the dose, based on the available data on the area under the plasma concentration-time curve (AUC) represented 120 x to 600 x the human exposure from a maximum recommended intravenous dose of 5 mg in humans. In rabbits, embryocidal effects (as evidenced by increased pre-implantation and post-implantation losses) were observed at 50 mg/kg or 200 x the human exposure from a maximum recommended intravenous dose of 5 mg. The no-effect dose of 15 mg/kg in rabbits represents 60 x the human exposure.

Nonteratogenic Effects: An animal reproduction study was conducted in rats at oral dosages of 5, 25 and 125 mg/kg/day of flumazenil. Pup survival was decreased during the lactating period, pup liver weight at weaning was increased for the high-dose group (125 mg/kg/day) and incisor eruption and ear opening in the offspring were delayed; the delay in ear opening was associated with a delay in the appearance of the auditory startle response. No treatment-related adverse effects were noted for the other dose groups. Based on the available data from AUC, the effect level (125 mg/kg), represents 120 x the human exposure from 5 mg, the maximum recommended intravenous dose in humans. The no-effect level represents 24 x the human exposure from an intravenous dose of 5 mg.

LABOR AND DELIVERY: The use of MAZICON to reverse the effects of benzodiazepines used during labor and delivery is not recommended because the effects of the drug in the newborn are unknown.

NURSING MOTHERS: Caution should be exercised when deciding to administer MAZICON to a nursing woman because it is not known whether flumazenil is excreted in human milk.

PEDIATRIC USE: MAZICON is not recommended for use in children (either for the reversal of sedation, the management of overdose or the resuscitation of the newborn), as no clinical studies have been performed to determine the risks, benefits and dosages to be used.

GERIATRIC USE: The pharmacokinetics of flumazenil have been studied in the elderly and are not significantly different from younger patients. Several studies of MAZICON in patients over the age of 65 and one study in patients over the age of 80 suggest that while the doses of benzodiazepine used to induce sedation should be reduced, ordinary doses of MAZICON may be used for reversal.

ADVERSE REACTIONS: SERIOUS ADVERSE REACTIONS: Deaths have occurred in patients who received MAZICON in a variety of clinical settings. The majority of deaths occurred in patients with serious underlying disease or in patients who had ingested large amounts of non-benzodiazepine drugs, (usually cyclic antidepressants) as part of an overdose.

Serious adverse events have occurred in all clinical settings, and convulsions are the most common serious adverse event reported. MAZICON administration has been associated with the onset of convulsions in patients who are relying on benzodiazepine effects to control seizures, are physically dependent on benzodiazepines, or who have ingested large doses of other drugs. (See WARNINGS.)

Two of the 446 patients who received MAZICON in controlled clinical trials for the management of a benzodiazepine overdosage had cardiac dysrhythmias (1 ventricular tachycardia, 1 junctional tachycardia).

ADVERSE EVENTS IN CLINICAL STUDIES: The following adverse reactions were considered to be related to MAZICON administration (both alone and for the reversal of benzodiazepine effects) and were reported in studies involving 1875 individuals who received flumazenil in controlled trials. Adverse events most frequently associated with flumazenil alone were limited to dizziness, injection site pain, increased sweating, headache and abnormal or blurred vision (3% to 9%).

BODY AS A WHOLE: Fatigue (asthenia, malaise), Headache, Injection Site Pain*, Injection Site Reaction (thrombophlebitis, skin abnormality, rash)

CARDIOVASCULAR SYSTEM: Cutaneous vasodilation (sweating, flushing, hot flushes)

DIGESTIVE SYSTEM: Nausea and Vomiting (11%)

NERVOUS SYSTEM: Agitation (anxiety, nervousness, dry mouth, tremor, palpitations, insomnia, dyspnea, hyperventilation)*, Dizziness (vertigo, ataxia) (10%), Emotional lability (crying abnormal, depersonalization, euphoria, increased tears, depression, dysphoria, paranoia).

SPECIAL SENSES: Abnormal Vision (visual field defect, diplopia), Paresthesia (sensation abnormal, hypoesthesia)

All adverse reactions occurred in 1% to 3% of cases unless otherwise marked.

*indicates reaction in 3% to 9% of cases.

Observed percentage reported if greater than 9%.

The following adverse events were observed infrequently (less than 1%) in the clinical studies, but were judged as probably related to MAZICON administration and/or reversal of benzodiazepine effects:

NERVOUS SYSTEM: Confusion (difficulty concentrating, delirium), Convulsions (see WARNINGS), Somnolence (stupor).

SPECIAL SENSES: Abnormal Hearing (transient hearing impairment, hyperacusis, tinnitus).

The following adverse events occurred with frequencies less than 1% in the clinical trials. Their relationship to MAZICON administration is unknown, but they are included as alerting information for the physician.

BODY AS A WHOLE: Rigors, shivering.

CARDIOVASCULAR: Arrhythmia (atrial, nodal, ventricular extrasystoles), bradycardia, tachycardia, hypertension, chest pain.

DIGESTIVE SYSTEM: Hiccup.

NERVOUS SYSTEM: Speech disorder (dysphonia, thick tongue).

Not included in this list is operative site pain that occurred with the same frequency in patients receiving placebo as in patients receiving flumazenil for reversal of sedation following a surgical procedure.

DRUG ABUSE AND DEPENDENCE: MAZICON acts as a benzodiazepine antagonist, blocks the effects of benzodiazepines in animals and man, antagonizes benzodiazepine reinforcement in animal models, produces dysphoria in normal subjects, and has had no reported abuse in foreign marketing.

Although MAZICON has a benzodiazepine-like structure it does not act as a benzodiazepine agonist in man and is not a controlled substance.

OVERDOSAGE: Large intravenous doses of MAZICON, when administered to healthy normal volunteers in the absence of a benzodiazepine agonist, produced no serious adverse reactions, severe signs or symptoms, or clinically significant laboratory test abnormalities. In clinical studies, most adverse reactions to flumazenil were an extension of the pharmacologic effects of the drug in reversing benzodiazepine effects.

Reversal with an excessively high dose of MAZICON may produce anxiety, agitation, increased muscle tone, hyperesthesia and possibly convulsions. Convulsions have been treated with barbiturates, benzodiazepines and phenytoin, generally with prompt resolution of the seizures. (See WARNINGS.)

DOSE AND ADMINISTRATION: MAZICON is recommended for intravenous use only. It is compatible with 5% dextrose in water, lactated Ringer's and normal saline solutions. If MAZICON is drawn into a syringe or mixed with any of these solutions, it should be discarded after 24 hours. For optimum sterility, MAZICON should remain in the vial until just before use. As with all parenteral drug products, MAZICON should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

To minimize the likelihood of pain at the injection site, MAZICON should be administered through a freely running intravenous infusion into a large vein.

REVERSAL OF CONSCIOUS SEDATION OR IN GENERAL ANESTHESIA: For the reversal of the sedative effects of benzodiazepines administered for conscious sedation or general anesthesia, the recommended initial dose of MAZICON is 0.2 mg (2 mL) administered intravenously over 15 seconds. If the desired level of consciousness is not obtained after waiting an additional 45 seconds, a further dose of 0.2 mg (2 mL) can be injected and repeated at 60-second intervals where necessary (up to a maximum of 4 additional times) to a maximum total dose of 1 mg (10 mL). The dose should be individualized based on the patient's response, with most patients responding to doses of 0.6 to 1 mg. (See INDIVIDUALIZATION OF DOSAGE.)

In the event of resedation, repeated doses may be administered at 20 minute intervals as needed. For repeat treatment, no more than 1 mg (given as 0.2 mg/min) should be administered at any one time, and no more than 3 mg should be given in any one hour.

It is recommended that MAZICON be administered as the series of small injections described (not as a single bolus injection) to allow the practitioner to control the reversal of sedation to the approximate endpoint desired and to minimize the possibility of adverse effects. (See INDIVIDUALIZATION OF DOSAGE.)

MANAGEMENT OF SUSPECTED BENZODIAZEPINE OVERDOSE: For initial management of a known or suspected benzodiazepine overdose, the recommended initial dose of MAZICON is 0.2 mg (2 mL) administered intravenously over 30 seconds. If the desired level of consciousness is not obtained after waiting 30 seconds, a further dose of 0.3 mg (3 mL) can be administered over another 30 seconds. Further doses of 0.5 mg (5 mL) can be administered over 30 seconds at 1-minute intervals up to a cumulative dose of 3 mg.

Do not rush the administration of MAZICON. Patients should have a secure airway and intravenous access before administration of the drug and be awakened gradually. (See PRECAUTIONS.)

Most patients with benzodiazepine overdose will respond to a cumulative dose of 1-3 mg of MAZICON, and doses beyond 3 mg do not reliably produce additional effects. On rare occasions, patients with a partial response at 3 mg may require additional titration up to a total dose of 5 mg (administered slowly in the same manner).

If a patient has not responded 5 minutes after receiving a cumulative dose of 5 mg MAZICON, the major cause of sedation is likely not to be due to benzodiazepines, and additional MAZICON is likely to have no effect.

In the event of resedation, repeated doses may be given at 20-minute intervals if needed. For repeat treatment, no more than 1 mg (given as 0.5 mg/min) should be given at any one time and no more than 3 mg should be given in any one hour.

SAFETY AND HANDLING: MAZICON is supplied in sealed dosage forms and poses no known risk to the health care provider. Routine care should be taken to avoid aerosol generation when preparing syringes for injection, and spilled medication should be rinsed from the skin with cool water.

HOW SUPPLIED: 5 mL multiple-use vials containing 0.1 mg/mL flumazenil:
Boxes of 10 (NDC 0004-6904-14).
10 mL multiple-use vials containing 0.1 mg/mL flumazenil:
Boxes of 10 (NDC 0004-6905-14).
Store at 59° to 86° F (15° to 30° C).

Achieve the power of balance.

Now more than ever, the realities of anesthesia management require providing the highest standards of patient care while controlling costs.

Ohmeda can help you achieve this delicate balance: $O=(MC)^2$.

Ohmeda = Maximized Care

Ohmeda offers sophisticated anesthesia delivery and monitoring systems to assist you in managing your patient during the rigors of surgery. Information systems from Ohmeda then turn case data into a key tool for quality assessment and improvement.

Ohmeda = Minimized Cost

Ohmeda products also help you manage the financial aspects of your anesthesia practice for efficiency, savings and revenue generation.

Maximized care. Minimized cost. For a new brochure that discusses how Ohmeda helps you achieve the delicate balance in anesthesia management, call 1-800-345-2700 or contact your Ohmeda representative.

If your seeking excellence, you'll find it in Maine

Maine Medical Center offers everything you'd expect from a major teaching hospital—a multidisciplinary environment, advanced technology, and a staff that works together as a team to provide the best health care possible. But we offer something unique—Portland, Maine. Located on one of the country's most picturesque coastlines, this small New England city offers an exciting waterfront area, countless recreational activities and a wealth of cultural attractions. If you're seeking excellence, you'll find it at Maine Medical Center.

Certified Registered Nurse Anesthetist

We are seeking an experienced CRNA to join our 16 CRNA/18 anesthesiologist care team of professionals. A wide variety of cases is offered, including neuro, vascular, renal transplant, pediatrics, and some obstetrics; no open heart.

Maine Medical Center offers competitive salaries commensurate with experience. Interested candidates may send a resume to: Human Resources, Holly MacEwan, Maine Medical Center, 22 Bramhall Street, Portland, ME 04102, or call collect at (207) 871-2974. An equal opportunity employer.

INTERNATIONAL ANESTHESIA RESEARCH SOCIETY

THE B.B. SANKEY ANESTHESIA ADVANCEMENT AWARDS

1993 B.B. SANKEY ANESTHESIA ADVANCEMENT AWARDS

Applications for up to $25,000 are invited for the 1993 Awards, subject to the following basic conditions:

- Proposals must be within the general field of anesthesiology and may be for research, clinical care, education, or administration.
- Applicants must be members of the International Anesthesia Research Society.
- Applications must be received in the IARS Cleveland office no later than December 11, 1992. Where relevant, applications must include institutional approval of human studies and/or animal research.
- The official application for the Award must be used. This form, as well as the guidelines for applicants, is available on request to:

International Anesthesia Research Society
2 Summit Park Dr., #140
Cleveland, OH 44131
Telephone: (216) 642-1124

The 1993 Awards will be announced at the 67th Congress of the International Anesthesia Research Society to be held at the San Diego Marriott, March 19–23, 1993.

Package Inserts and Other Dosage Guidelines Are Especially Useful With New Analgesics and New Analgesic Delivery Systems

Peter L. Bailey, MD, and Theodore H. Stanley, MD
Department of Anesthesiology, University of Utah School of Medicine, Salt Lake City, Utah

The introduction of new pharmaceutical compounds and new drug delivery devices and techniques usually promises increased patient benefits from improved safety, bioavailability, effectiveness, utility or convenience, and, on occasion, decreased cost. In the first few years after new drugs and devices are released, interested clinicans often informally test them for uses that were not originally intended and in patients, situations, or approaches in which they were not formally evaluated before approval. This is not only appropriate, for it may result in new uses or advantages for the products (or new safety issues), but is also expected by companies that manufacture these substances and devices and by the federal agencies that monitor and regulate their sales. We believe that it is in this spirit that the case report of Steinberg et al. (1), published in this issue, is best viewed.

Before FDA approval, the fentanyl transdermal system (Duragesic patches) used in this patient was evaluated in 357 patients in postoperative and pharmacokinetic studies (usually a single 25-, 50-, 75-, or 100-μg/h patch for 1 day for postoperative pain) and in 153 patients with chronic cancer pain (one to multiple patches, 25–600 μg/h of fentanyl for 1–866 days) (2–4). Most of the patients receiving Duragesic for postoperative pain were opioid naive (not tolerant to opioids), and most of those receiving the patches for chronic pain were considered tolerant to opioids owing to chronic opioid therapy (2–4).

Duragesic caused hypoventilation, defined as a respiratory rate <8 breaths/min or a $Paco_2$ >55 mm Hg, in 13 (3.6%) of the opioid-naive patients. None of the patients with 25- or 50-μg/h patches experienced hypoventilation (2–4). However, 6 of the 177 patients (3.4%) given 75-μg/h and 7 of the 105 patients (6.6%) given 100-μg/h patches for postoperative pain experienced hypoventilation. Nine of the 13 patients (69%) experiencing hypoventilation and receiving Duragesic for postoperative pain were <63 kg, and 10 were women (2–4). Twenty-five patients received Duragesic (100 μg/h) after thoracic surgery, and four of these experienced respiratory depression (16%) (2–4). In contrast, 3 of 80 (4%) of the patients receiving the same dose of Duragesic after nonthoracic surgery sustained respiratory depression. Only 3 of the 153 opioid-tolerant patients (2%) receiving Duragesic for chronic cancer pain experienced hypoventilation (2–4).

Significant respiratory depression, defined as a 50% reduction in the ventilatory response to CO_2, has generally been found to begin with fentanyl plasma concentrations in the range of 2–3 ng/mL (5–6). In the pre-FDA approval studies, no patients exposed to Duragesic (25 μg/h) experienced a maximum plasma fentanyl concentration of 2 ng/mL or above, and only 3% of patients exposed to 50-μg/h patches had a plasma concentration of fentanyl >2 ng/mL (all between 2 and 3 ng/mL) (2). In contrast, 15% and 31% of patients exposed to the 75- and 100-μg/h patches, respectively, had maximum plasma fentanyl concentrations of 2–3 ng/mL, and 4% and 11%, respectively, had plasma fentanyl concentrations >3 ng/mL (2).

Of the 357 non-opioid-tolerant patients receiving Duragesic, 5 (1.4%) (1 after 75 μg/h and 4 after 100 μg/h) were reported to be confused after Duragesic, whereas 1 patient (<1%) was agitated, 1 experienced depersonalization, 1 hallucinations, and 1 hostility (3). Of the 153 patients receiving Duragesic for chronic cancer pain, 20 (13%) were reported to be confused, 5 (3%) reported hallucinations, 5 reported anxiety, 2 (1%) reported agitation, and 2 experienced a paranoid reaction (3).

We believe that the above data are important because as a result, the pharmaceutical companies that developed Duragestic (Janssen Pharmaceutica and Alza Corp.) and the FDA agreed that Duragesic should only be indicated in the management of

chronic pain in opioid-tolerant patients requiring opioid analgesia (4). They did not recommend Duragesic in the management of postoperative pain because it was believed that the product had not been adequately studied and resulted in an unacceptable incidence of hypoventilation in these patients (4). They concluded that it was not possible from the available data to identify factors that could be used to select a dose of Duragesic that would be safe and effective in individual postoperative patients.

The Duragesic package insert warns that Duragesic doses >25 μg/h are too large for initiation of therapy in non-opioid-tolerant patients and should not be used to begin Duragesic therapy in those patients (4). It further warns that there has been no systematic evaluation of Duragesic as an initial opioid analgesic in the management of chronic pain, because most patients in the clinical trials were converted to Duragesic from other narcotics. It suggests that patients be converted to Duragesic by:

1. Calculating the previous 24-h analgesic requirement
2. Converting this amount from an equianalgesic oral morphine dose using a conversion table supplied in the insert
3. Choosing a Duragesic dose based on an oral or intramuscular morphine equivalence dose schedule also published in the package insert
4. Initiating Duragesic treatment using the recommended dose and titrating patients upward (*no more frequently than every 3 days after the initial dose or every 6 days thereafter*) until analgesic efficacy is attained because it may take up to 6 days after increasing the dose of Duragesic for the patient to reach equilibrium on the new dose. *During the initial application of Duragesic, it is advised that patients should use short-acting analgesics* for the first 24 h, as needed, until analgesic efficacy with Duragesic is attained. Thereafter, some patients still may require periodic supplemental doses of other short-acting analgesics for "breakthrough" pain. Appropriate dosage increments should be based on the daily dose of supplementary opioids using the ratio of 90 mg/24 h of oral morphine to a 25-μg/h increase in Duragesic dose.

Finally, the package insert advises that initial doses of Duragesic should be reduced in elderly, cachectic, or debilitated patients because of poor fat stores, muscle wasting, or altered clearance (4). The insert also suggests reducing the Duragesic dose in patients receiving other central nervous system depressants (a dose reduction of 50% or more is suggested) because of potentiation of action.

The patient presented by Steinberg et al. (1) was cachectic, elderly (71 yr old), and azotemic. It is unclear whether she was opioid tolerant when treatment started, but she clearly was experiencing opioid effects on admission to the hospital and up until the 10th day of admission. These effects included confusion, agitation, hallucination, disorientation, restlessness, paranoia, and pinpoint pupils. These types of opioid effects have been described after the use of all μ-receptor agonists and most δ-, κ-, and σ-agonists as well (2–4,7). Therefore, it is not necessary to postulate the accumulation of the metabolite norfentanyl as the mechanism for the reported side effects. Although normeperidine toxicity (due to central nervous system stimulation) after meperidine is highly correlated to increases in plasma concentration of the metabolite (8), whether norfentanyl can also cause these problems is unknown, and as far as Janssen Pharmaceutica knows (per a telephone conversation with J. Heykants, PhD), it has never been tested in humans or any other animal. Norfentanyl is less potent than either fentanyl or meperidine in the isolated guinea pig ileum contraction test, a test of opioid agonist activity (9). Norfentanyl is also rapidly metabolized to despropionyl norfentanyl (10). This pathway is only disrupted in patients with hepatic failure. Thus, there is little reason that norfentanyl should have accumulated, even though the patient's renal function was abnormal.

An additional possible cause of the patient's confusion, as indicated by the authors, was hypoxemia. A metanalysis was accomplished by FDA reviewers during the Duragesic New Drug Application review using plasma fentanyl concentrations obtained from both opioid-tolerant and non-opioid-tolerant patients (11). This analysis predicted that if Duragesic (50 μg/h) was used in opioid-naive patients weighing 50–74 kg and Duragesic (75 μg/h) in patients weighing 75 kg or more, then 3% of the patients would be expected to have a plasma fentanyl concentration between 2 and 2.5 ng/mL and a 15% risk of hypoventilation. The analyses also indicated that 1.5% of the patients would experience a fentanyl plasma concentration of 2.5–3.0 ng/mL and a 25% risk of hypoventilation. As mentioned earlier, it is unclear whether the patient in question was opioid naive, at least at the beginning of her exposures to Duragesic. However, within 4 days of initiating Duragesic therapy, the patient's dose of fentanyl had been increased from 25 to 125 μg/h. The Duragesic package insert specifically warns against this type of rapid increase in dosage because, although peak plasma concentrations of fentanyl after a single-patch application usually occur by 18–24 h, new peaks can occur even later (4). Thus, the risk of producing higher than expected plasma concentrations of fentanyl and hypoventilation are increased with this approach. The package insert also suggests that short-acting analgesic supplements be used as needed during the slow upward titration of Duragesic dosage, rather than the sustained-release morphine used in this case. Finally, as mentioned earlier, the package insert indicates that, at least at the time of Duragesic approval, all studies with Duragesic in patients with chronic cancer pain had been accomplished in opioid-tolerant patients taking other narcotics who were then converted to Duragesic. It warns that no systematic evaluation of Duragesic as an initial opioid analgesic in this patient population had yet been accomplished.

By the fifth day after admission (the ninth day after beginning Duragesic), the patient reported by Steinberg et al. (1) was receiving 2 mg of lorazepam and two 60-mg sustained-release morphine tablets during the day plus 125 μg/h of Duragesic. The additional compounds were administered despite the package insert warnings suggesting that central nervous system depressants should be decreased, not increased, with initial Duragesic application because of the increased risk of hypoventilation and hypotension.

Physicians in America and most of western civilization are not bound to administer drugs or practice medicine according to package insert-suggested guidelines. Our freedom, in this regard, allows new discoveries (good and bad) to be made every day. However, we believe that it is prudent to consider package insert and other medical publication guidelines carefully, especially soon after a new drug or drug delivery device becomes available. We also believe that although it is unclear what caused this patient's adverse effects, greater awareness of the different dynamics of transdermal fentanyl delivery (versus more traditional fentanyl administration techniques) is one benefit that may result from her experience.

---

To demonstrate any age-related differences in propofol requirements for induction of anesthesia, 150 healthy children aged 3–5 yr ($n = 50$), 6–9 yr ($n = 50$), and 10–15 yr ($n = 50$) scheduled for outpatient surgery were randomly assigned to receive an induction dose of propofol of 1.5, 2.0, 2.5, 3.0, or 3.5 mg/kg. To limit pain during injection, alfentanil (5 μg/kg) was administered before the propofol. Patients were classified as asleep or not asleep 30 s after the propofol. Incidence of excitation, injection pain, and apnea during induction of anesthesia were noted; arterial blood pressure and heart rate were recorded for 5 min after induction. More than 95% of the children were asleep in the dose groups receiving ≥2.5 mg/kg. The number of patients falling asleep after receiving 1.5 mg/kg of propofol increased significantly with increasing age ($P < 0.05$); the difference between the oldest and the youngest age groups was the most significant ($P < 0.05$). Significant decreases in mean arterial blood pressure and heart rate occurred after induction in all dose and age groups without any systematic intergroup differences. Apnea occurred more frequently in older children ($P < 0.01$) and with larger doses ($P < 0.01$). The most frequent side effect was erythema near the site of injection, and its occurrence was dose dependent. The authors conclude that 2.5 mg/kg of propofol, if preceded by 5 μg/kg of alfentanil, is an appropriate induction dose for children aged 3–15 yr and that the sleep response to 1.5 mg/kg is more in older children.

(Anesth Analg 1992;75:876–9)

Propofol is a useful anesthetic for outpatient surgery because it offers rapid recovery and has few side effects. In children, however, uncertainty has existed concerning dose requirements. Morton et al. (1) found that doses generally used for adults are also effective in children. Others report that children need more propofol than adults (2–5), which concurs with the study of Jonmarker et al. (6) in relation to thiopental requirements for anesthesia. Comparison among different studies is difficult owing to the different premedication regimes used. In comparing thiopental with propofol, Meursing et al. (7) suggested that a dose >2.5 mg/kg of propofol might be required to suppress excitatory phenomena in younger children. The authors attempted to determine propofol requirements for induction of anesthesia in children of different age groups.

Methods

Approval of the Human Research Committee and informed parental consent were obtained. One hundred fifty children, ASA physical status I or II, scheduled for elective outpatient surgery were assigned to three age groups (50 children per group): 3–5, 6–9, and 10–15 yr. They were further randomly assigned to five dose groups: 1.5, 2.0, 2.5, 3.0, and 3.5 mg/kg of propofol by blind drawing of tickets.

Most children were accompanied by one parent during induction of anesthesia. Before induction, baseline measurements of arterial blood pressure, heart rate, and O_2 saturation (Biox 3700 pulse oximeter, Ohmeda, Louisville, Colo.) were made. Venous access was established in the dorsum of the hand with a 22- or 20-gauge cannula. Thus far, the children received no premedication.

To limit pain during injection of propofol, 5 μg/kg of intravenous alfentanil was administered, and 20–30 s later the allocated dose of propofol was

injected over 10–15 s. During induction of anesthesia, the patients were observed for pain during injection and for excitation by an anesthesiologist unaware of the experimental treatment. Withdrawal of the hand, verbal expression of pain, grimacing, and starting to cry were interpreted as pain during injection; other spontaneous movements were called excitation. Any local reactions and other side effects were also noted, particularly apnea requiring controlled ventilation. If apnea occurred after administration of propofol that lasted longer than 1 min or caused the O_2 saturation to decrease below 90%, ventilation was controlled until spontaneous ventilation was resumed. Thirty seconds after injection of propofol, an assessment was made as to whether the patient was asleep. The same assessor, who was unaware of the study treatment, classified the patient as asleep if the eyelash reflex was negative and there was no response (gross movement) to application of the face mask. If either of these criteria were not fulfilled, the patient was classified as not asleep; in that case, an additional dose of 1 mg/kg of propofol was administered and repeated as required until the patient was deemed asleep.

Once asleep, patients were allowed to spontaneously breathe 70% N_2O and 30% O_2. Arterial blood pressure, heart rate, and O_2 saturation measurements were made at 30, 60, 120, 180, and 300 s after the first propofol injection. At the same intervals, patients were again classified as asleep or not asleep. Any patients who, according to the criteria mentioned earlier, awoke during the 5-min observation period, were given an additional dose of 1 mg/kg of propofol.

After the 5-min observation period, anesthesia was continued as considered appropriate. Three to four hours postoperatively, the patients were assessed as either fully awake or drowsy. We also noted whether any nausea was felt (according to the patient or the parent's impression) and whether the child had vomited at least once; appetite was evaluated as good if the patient had already started eating solids without any problem or if he or she wanted to eat something. These postoperative assessments were not necessarily made by a blinded assessor. In addition, local skin reactions to the propofol and other side effects were recorded.

In statistical analysis of arterial blood pressure and heart rate observations, we included only those patients who did not need an additional dose of propofol to fall asleep so as to keep the groups comparable. Of the apneas requiring controlled ventilation, those occurring after an additional dose of propofol were not counted.

The principal categorical variables are presented in the form of contingency tables according to dose and age groups. Statistical analysis of differences between groups was carried out using χ^2-tests and two-sided Fisher's exact probability test as appropriate (8).

Table 1. Demographic Data of 150 Children Undergoing Elective Outpatient Surgery

	M/F	Age (yr)	Weight (kg)
Dose group (mg/kg)			
1.5	20/10	8.6 ± 3.4	31.8 ± 13.5
2.0	19/11	7.9 ± 2.8	28.9 ± 11.1
2.5	23/7	8.3 ± 3.2	30.8 ± 13.0
3.0	24/6	8.2 ± 3.6	31.0 ± 13.3
3.5	21/9	7.8 ± 3.4	29.5 ± 13.4
Age group (yr)

6–9	37/13		
10–15	35/15		
Total	107/43		

M, male; F, female.
Values for age and weight are mean ± SD.

Continuous variables are presented as mean ± SD. Mean percentage decreases of mean arterial blood pressure and heart rate between baseline and 300 s after injection of propofol were calculated according to age and dose groups. To these two variables a two-factor (age and dose) analysis of variance (GLM-procedure in Statistical Analysis System [SAS]) was applied (9), with linear contrasts in dose groups. A P value <0.05 was considered statistically significant.

Results

Owing to the predominance of male genital surgery, 107 boys and 43 girls participated in the study. Age, weight, and gender distribution were similar in the five dose groups (Table 1). Pain on injection of propofol was observed in 6 of 150 patients (4%). Excitation was noted in 25 of 150 patients (17%). There was no significant difference in the incidence of pain or excitation among age or dose groups.

The number of patients asleep 30 s after administration of each propofol dose is shown in Table 2. The dose groups receiving ≥ 2.5 mg/kg had $>95\%$ sleep response to the respective dose. When considering the age groups separately (Table 2), the 1.5-mg/kg dose group showed statistically significant differences ($P < 0.05$) among the age groups: the older the patients, the more fell asleep at this dose. The difference between the oldest and the youngest age groups was the most significant ($P < 0.05$). Within the other dose groups, differences among age groups were not statistically significant.

Apnea requiring controlled ventilation occurred in 21.6% of the patients. The percentages for the differ-

MAP, mean arterial blood pressure; HR, heart rate.
Values for decrease of MAP and decrease of HR are mean ± SD.
[a] $P < 0.01$.

ent age and dose groups are shown in Table 3. There was a significant relation to age and dose, in that controlled ventilation was required more often in older children ($P < 0.01$) and at larger doses ($P < 0.01$).

The mean percentage decreases in mean arterial blood pressure and heart rate from baseline to 300 s are shown in Table 3 for the five dose groups and the three age groups. There was no significant overall difference among dose or age groups. When using linear contrasts, some dose-group percentages showed differences ($P < 0.05$): 1.5 versus 2.0 mg/kg, 2.0 versus 2.5 mg/kg (heart rate decrease), and 1.5 versus 3.0 mg/kg (arterial blood pressure decrease).

Postoperative alertness assessment showed that 139 of 147 patients (95%) were fully awake and 8 of 147 (5%) were drowsy. In three patients, this assessment was erroneously omitted. Nausea occurred in 26% and vomiting in 19% of the patients. Incidence of vomiting was significantly less frequent ($P < 0.05$) in the 3–5-yr age group (6%) than in the 6–9- and 10–15-yr age groups (23% and 29%, respectively). Postoperatively, 53% of the patients had good appetite.

Erythema near the site of injection occurred in seven patients in the 3.0- and 3.5-mg/kg dose groups only; this dose dependency was significant ($P < 0.05$). Other minor side effects were skin rash on the chest (four patients) and hiccup, minor bronchospasm, and myoclonia (each in one patient). These side effects showed no significant relation to age or dose. None of the side effects needed intervention.

Discussion

The results indicate that a dose of 2.5 mg/kg of propofol is sufficient to induce sleep (according to the criteria set forth in Methods) in children aged 3–15 yr. Preadministration of alfentanil may account for this dose requirement being lower than that reported by Patel et al. (5) and Westrin (10). Hannallah et al. (11) reported the same dose requirements in children aged 3–12 yr as in this study but without pretreatment with alfentanil; they used the large antecubital vein and thus avoided pain on injection. Aun et al. (12) also found dose requirements for propofol induction comparable to ours.

Maturational changes during infancy and childhood may result in age-related differences in pharmacodynamic and pharmacokinetic properties of drugs. Thus, we postulate that maturational changes may produce different responses to propofol among children of different age groups. The results of this dose-response study, at least those of the 1.5-mg/kg dose group, indicate that the response is enhanced with increasing age. This is in accordance with the findings of Jonmarker et al. (6) who found a markedly greater dose requirement for thiopental induction in infants than in older children. Westrin (10) reported a less marked but still significant difference in dose requirements between the same two age groups as in the Jonmarker et al. (6) study, when propofol was used instead of thiopental. Recently, Aun et al. (12) demonstrated that young children need more propofol than older children. Possible explanations for this phenomenon may be age-related differences in cardiac output in relation to body weight, resulting in differences in the arterial peak concentration reaching the brain, and age-related differences in pharmacodynamics. However, Hannallah et al. (11) did not find any age-related differences in dose requirements. Arterial blood pressure and heart rate decreased in all patient groups but without clinical consequences. This is in accordance with some other studies in children (2,7,8,13). Other authors, however, report a stable heart rate (1,4,11). Although hemodynamic differences were demonstrable between some dose groups, there was no systematic relation with the dose. Our results correspond well with the findings of Short and Aun (13) who reported somewhat greater decreases of arterial blood pressure and heart rate, but their patients breathed halothane during the 5-min observation period; they, too, were unable to demonstrate any dose-related differences in hemodynamic changes.

Pain during injection is an established problem with propofol (7). Because alfentanil is effective in limiting this pain (14), we considered its omission unethical. The 4% incidence of pain with alfentanil recorded in this study compared with 20% without it in a previous study (7) confirms the efficacy of alfentanil.

The incidence of excitation is not age or dose related, which refutes our suggestion (7) that relatively high doses may be required to suppress excitation, especially in younger children. Apnea requiring controlled ventilation occurred in 21.6% of the patients, which is very similar to the results of Hannallah et al. (11) and Westrin (10), who found an incidence of apnea of 21% and 18%, respectively. Ventilatory changes were clearly related to both dose and age. The fact that older children had more apnea and showed a better sleep response to the 1.5-mg/kg dose suggests that other immediate effects of propofol could also be age dependent, but we failed to demonstrate this with respect to hemodynamic changes. Hannallah et al. (11) did not find any age-related differences at all, and the correlation that they found between dose and apnea incidence was not significant.

The data on postoperative assessment of alertness, nausea, and vomiting are difficult to evaluate realistically owing to a lack of standardized anesthetic technique and the varying duration of procedures (10 min–2 h). Nevertheless, 95% of the patients were fully awake 3 h postoperatively; this does not conflict with the general opinion that recovery from propofol is rapid.

All side effects observed in this study were minor. The most frequently occurring side effect was local redness, which occurred only with those doses higher than that needed to anesthetize most patients.

The authors conclude that in healthy children aged 3–15 yr, a dose of 2.5 mg/kg of propofol induces sleep in >95% of patients if preceded by alfentanil (5 μg/kg), which is effective in limiting pain on injection. A remarkable and statistically significant age-related difference was found both in sleep-inducing effects of 1.5 mg/kg of propofol and in the incidence of apnea, to the effect that younger children are more resistant. The most frequent side effect was local redness, which occurred only with doses >2.5 mg/kg. On the basis of these results, a clear age-related dose recommendation cannot be made, but 2.5 mg/kg would seem a reasonable guideline for the induction dose of propofol in children aged 3–15 yr.

We gratefully acknowledge the financial and scientific support provided by ICI and Inge Kraaijeveld. We also thank Jacqueline F. Aukes-Jager for her help with the preparation of the manuscript and our anesthesiology associates for their cooperation during the study.

Effectiveness of Preoperative Sedation With Rectal Midazolam, Ketamine, or Their Combination in Young Children

David S. Beebe, MD, Kumar G. Belani, MBBS, MS, Pi-Nian Chang, PhD,
Peggy S. Hesse, PhD, James S. Schuh, MD, Ji-Chia Liao, MD, PhD, and
Richard J. Palahniuk, MD

Departments of Anesthesiology and Pediatrics, University of Minnesota Hospitals and Clinics, Minneapolis, Minnesota

To determine which of three types of rectal sedation was most effective preoperatively in facilitating parental separation and intravenous cannulation in young children, 100 children 3.0 ± 1.7 (mean ± SD) yr of age were randomly assigned to four equal groups. One group (M-K-A) received rectal midazolam (0.5 mg/kg), ketamine (3 mg/kg), and atropine (0.02 mg/kg). The other sedation groups received the same doses of midazolam and atropine (M-A) or ketamine and atropine (K-A) alone, and the control group (A) received only rectal atropine. Most children in either the M-K-A (100%) or M-A (92%) groups separated easily from their parents without struggling or crying, significantly more than in the K-A (60%) or A (64%) groups. However, more children in the M-K-A group (44%) were asleep during separation than in the M-A group (8%; $P < 0.05$). Only 20% of the children in the M-A or M-K-A groups cried during intravenous catheter placement, significantly less than in the K-A (56%) or A (92%) groups. Intravenous catheter placement was also successful significantly more often in the M-A (80%) and M-K-A (84%) groups than in the K-A (48%) or A (40%) groups. Complications were similar among the groups, but there was evidence that midazolam prolonged recovery time in some patients. Rectal midazolam with or without ketamine is a useful technique when intravenous catheter placement before induction of anesthesia is desired.

(Anesth Analg 1992;75:880–4)

The presence of an intravenous (IV) catheter before induction of anesthesia in a young child gives the anesthesiologist the option of performing an IV induction of general anesthesia and provides a means of rapidly administering medications should complications during the induction occur. However, pain, anxiety, and fear of needles and of parental separation can make IV cannulation before induction of anesthesia difficult in infants and young children. In addition, painful, frightening venopunctures may cause long-term psychological complications in children and make subsequent contacts with health professionals more difficult, particularly in patients who require multiple anesthetics and procedures (1).

The use of midazolam administered rectally to facilitate IV catheterization in young children before induction of anesthesia was previously investigated by DeJong and Verburg (2). They found that the response of children to IV placement who were given midazolam (0.5 mg/kg) rectally before IV catheterization was similar to a group of children given midazolam (0.15 mg/kg) intramuscularly, but without the crying and pain associated with an intramuscular injection. They did not, however, have a control group with which to compare the effectiveness of either rectal or intramuscular midazolam, their observers were not blinded to the drugs administered, and their patients were not completely randomized.

We hypothesized that a combination of midazolam, ketamine, and atropine administered rectally would significantly diminish the pain, fright, and struggling often associated with IV catheter placement in young children and increase the probability of successful IV placement. Midazolam would provide sedation and might diminish recall of the IV catheter placement or other procedures associated with surgery or anesthesia (2–5). Ketamine would diminish the pain associated with IV cannulation as well as provide sedation (6). Atropine would counteract the hypersalivation often seen with the use of

0003-2999/92/$5.00

ketamine and has been found effective when combined with either ketamine (6) or midazolam (2) administered rectally.

In a preliminary, uncontrolled investigation, we found that a combination of midazolam (0.5 mg/kg), ketamine (3 mg/kg), and atropine (0.02 mg/kg) appeared to attenuate the response to IV cannulation without causing excessive sedation. The purpose of this randomized, single-blind study was to determine whether this combination of midazolam, ketamine, and atropine was superior to a combination of the same dose of midazolam and atropine alone, ketamine and atropine alone, or to a control group receiving only rectal atropine in providing sedation for separation and for preinduction IV cannulation in young children.

Methods

After University of Minnesota Human Subjects Committee approval and parental consent, 100 ASA physical status I, II, and III patients ranging in age from 8 mo to 7 yr scheduled to undergo a variety of elective surgical procedures were randomly assigned to four groups of 25 patients each. The control group (group A) received atropine (0.02 mg/kg). Group K-A received ketamine (3 mg/kg) and atropine (0.02 mg/kg). Group M-A received midazolam (0.5 mg/kg) and atropine (0.02 mg/kg). Group M-K-A received midazolam (0.5 mg/kg), ketamine (3 mg/kg), and atropine (0.02 mg/kg). All drugs were administered rectally with a 2.0-mm pediatric feeding tube (Pharmaseal) lubricated with sterile lubricant (Surgilube) and inserted 7–10 cm beyond the anal opening.

A child psychologist unaware of the drug(s) administered, observed the children preoperatively, at induction of anesthesia, on emergence, and postoperatively in the recovery room. The level of sedation was graded for each child (a) before administration of rectal medication; (b) during insertion of the rectal catheter; (c) immediately after administration, (d) 10 min after administration; and (e) at separation from the parents (15 min after administration). Patients were graded at each time interval as follows: 1 = asleep; 2 = calm but awake; 3 = restless; 4 = crying and upset. The pulse and respiratory rates were recorded before the administration of the sedative and 10 min after administration. Arterial oxygen saturation was recorded on arrival in the operating room before the administration of oxygen and then throughout the perioperative period.

In the operating room, an IV catheter was placed or attempted by the staff anesthesiologist responsible for the case. Ninety-seven patients had 1% lidocaine injected subcutaneously with a 28-gauge needle before placement of the IV catheter. Three patients, one each from the A, M-A, and M-K-A groups, had catheters placed or attempted without the local anesthetic. The response to the IV catheter placement was graded by the child psychologist at three times: (a) when the patient's hand or foot was held, and he was approached with a needle; (b) when the skin was infiltrated with lidocaine; and (c) when the IV catheter was placed. Children were graded at each point as 1 = asleep/obtunded—no response to approach with needle, lidocaine instillation, or IV placement; 2 = calm—awake but no crying or withdrawal when approached by needle, local infiltration, or catheter placement; 3 = withdraws but allows—pulls away with stimulus but no crying; or 4 = crying—uncooperative and struggling with stimulation. The success or failure of the IV catheter placement was also noted, and the number of attempts before the catheter was successfully placed was recorded. No child received more than two unsuccessful IV attempts before a mask induction of anesthesia was performed. The anesthesiologist's opinion as to the ease of the IV placement (satisfactory or unsatisfactory) was also recorded.

After successful IV placement, general anesthesia was induced with IV thiopental followed by a skeletal muscle relaxant. If the IV placement was unsuccessful, anesthesia was induced with nitrous oxide and halothane via face mask. The response to the application of a face mask if the IV catheter was unable to be placed was graded by the child psychologist as either 1 = calm—no restraint necessary, or 2 = restless/struggling—restraint required.

The complications of either IV or mask induction of anesthesia, including (a) laryngospasm, (b) arterial oxygen saturation <90%, (c) emesis, and (d) excessive salivation, were noted by the attending anesthesiologist and recorded by the child psychologist. Postoperative complications, including (a) laryngospasm, (b) arterial oxygen saturation <90%, (c) excessive salivation, (d) nausea and vomiting, and (e) postextubation croup, were also noted by the attending anesthesiologist and recorded by the child psychologist, as was the time to extubation. Intraoperative and postoperative narcotic usage was also recorded for each patient.

In the postanesthesia recovery room (PACU), the patients were assigned a numerical score using a modified Aldrete (7) scale by the PACU nurse every 30 min. The scale assigns a score between 0 and 2, 2 being normal in each of five categories: respiration, activity, alertness, blood pressure, and temperature. The children were discharged if the modified Aldrete score was >8, with a minimal score of 2 in the respiration, activity, and alertness categories, and after being examined by the attending anesthesiologist. The time from the end of surgery until the patients were discharged from the PACU was recorded and compared among the groups. A pro-

M-K-A, midazolam (0.5 mg/kg), ketamine (3 mg/kg), and atropine (0.02 mg/kg); M-A, midazolam (0.5 mg/kg) and atropine (0.02 mg/kg); K-A, ketamine (3 mg/kg) and atropine (0.02 mg/kg); A, atropine (0.02 mg/kg) (control).

Data presented are mean values ± SD (or No. of patients).

longed discharge time was defined as a discharge time of >30 min.

Results were reported as mean ± SD or percentage. Comparisons among groups were made using the χ^2 method with Yates' correction for continuity for categorical data and analysis of variance for continuous variables. Significance was defined as $P < 0.05$.

Results

The mean age (± SD) of the patients was 3.0 ± 1.7 yr, and the mean weight was 15.2 ± 5.1 kg. There were no significant differences among the four groups in age, weight, gender, ASA physical status, and length or type of operation (Table 1).

Rectal administration of drugs caused transient distress in some patients, but by 10 min most patients were calm. Although most patients who received midazolam and atropine alone separated calmly from their parents, significantly more patients who received all three drugs were asleep at separation than those who received midazolam and atropine alone, ketamine and atropine alone, or the control solution (Figure 1).

The response to IV catheterization and success rate of IV catheterization were improved in both groups that received midazolam. However, similiar to the response to parental separation, significantly more children who received all three drugs were asleep when approached by the anesthesiologist and a needle (Figure 2). Eighty-four percent of intravenous catheters in the M-A group and 80% in the M-K-A group were successfully placed, both significantly greater ($P < 0.05$) than the success rate for the patients who received ketamine and atropine (48%) or rectal atropine alone (40%). The anesthesiologists also thought that the child's response to cannulation was satisfactory more often in the M-A (84%) and M-K-A (76%) groups than the K-A (48%) and A (28%) groups (M-A vs K-A or A, $P < 0.05$; M-K-A vs K-A or A, $P < 0.05$).

Of the four patients in the M-A and five patients in the M-K-A groups in which IV catheterization failed, two in the M-K-A (40%) and two in the M-A (50%) groups, respectively, required restraint for the application of a face mask for the inhalation induction of anesthesia. In contrast, 9 of the 11 patients in the K-A group (82%) and 14 of the 15 (93%) patients in the A group in whom IV cannulation failed required restraint for the mask induction of anesthesia, significantly greater than the groups receiving midazolam (M-A plus M-K-A vs K-A plus A; $P < 0.05$).

There was no difference in the percentage of patients who had laryngospasm (A, 4%; K-A, 4%; M-A, 0%; M-K-A, 4%), excessive salivation (A, 4%; M-A, 0%; K-A, 0%; M-K-A, 0%), emesis (A, 4%; M-A, 0%; K-A, 0%; M-K-A, 0%), or oxygen saturation to <90% (A, 4%; K-A, 0%; M-A, 0%; M-K-A, 0%) on induction of anesthesia among the four groups. There was no change in the heart or respiratory rates during the preoperative study period in any of the four groups. The mean room air arterial oxygen saturation before induction of anesthesia but after administration of the rectal solutions was similar in the A (99% ± 1%), K-A (98% ± 2%), M-A (100% ± 1%), and M-K-A (99% ± 2%) groups.

The percentage of patients who received narcotics intraoperatively was similar in the M-K-A (75%), M-A (56%), K-A (76%), and A (60%) groups, as was the percentage of patients requiring narcotics in the recovery room: M-K-A (24%), M-A (32%), K-A (40%), and A (32%).

There also was no difference in the percentage of patients among each group who on emergence from anesthesia had laryngospasm (A, 12%; K-A, 4%; M-A, 4%; M-K-A, 8%), oxygen saturation <90% (A, 8%; K-A, 8%; M-A, 0%; M-K-A, 8%), excessive sali-

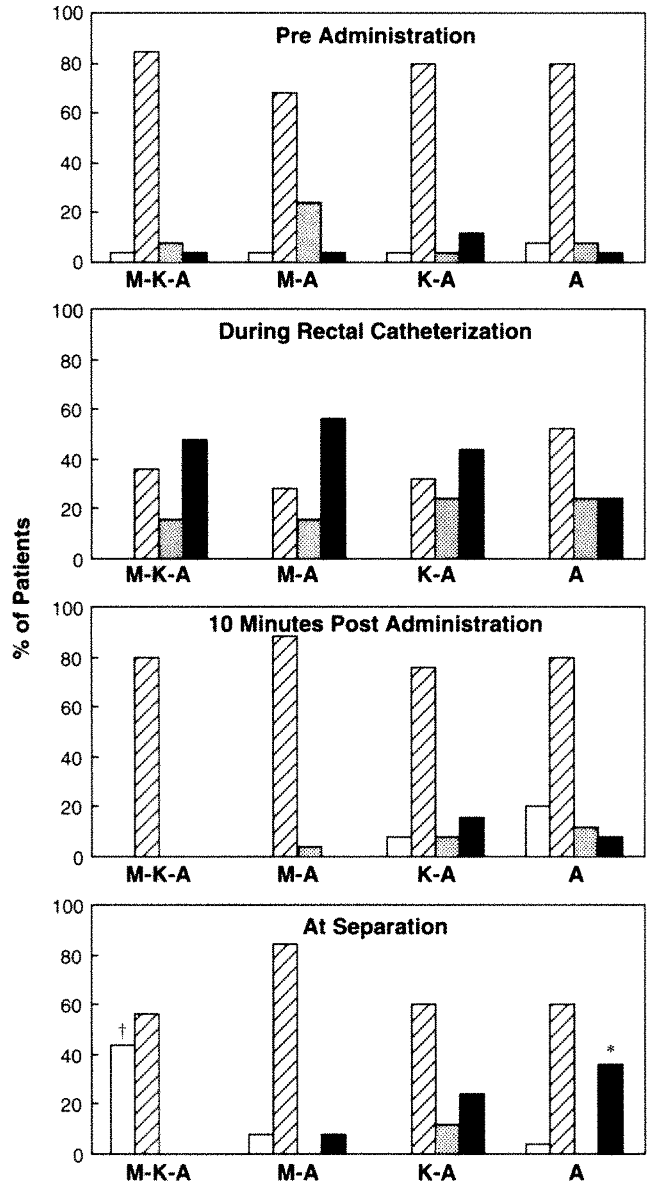

Figure 1. Percentage of patients in each sedation category before administration, during rectal catheterization, 10 min after administration, and at separation. M-K-A, midazolam (0.5 mg/kg), ketamine (3 mg/kg), and atropine (0.02 mg/kg); M-A, midazolam (0.5 mg/kg) and atropine (0.02 mg/kg); K-A, ketamine (3 mg/kg) and atropine (0.02 mg/kg); A, atropine (0.02 mg/kg). *Open bar,* asleep; *hatched bar,* calm; *stippled bar,* restless; *solid bar,* crying. *$P < 0.05$; A vs M-A or M-K-A. †$P < 0.01$; M-K-A vs M-A, K-A, or A.

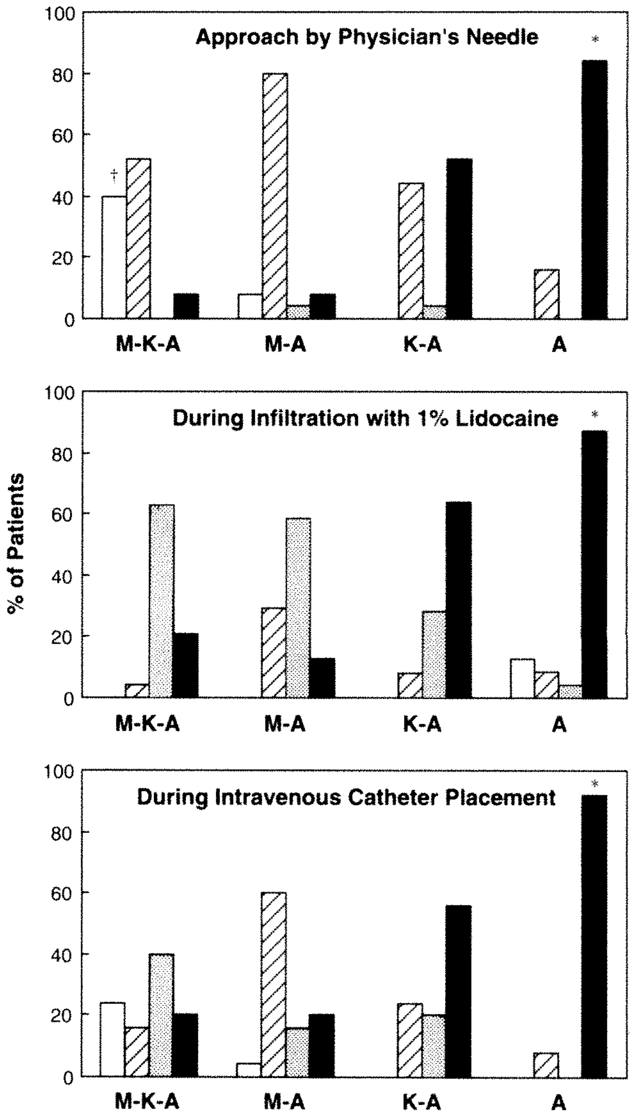

Figure 2. Percentage of patients in each response category on approach with a physician's needle, during local anesthetic infiltration, and during intravenous catheterization. Abbreviations as in Figure 1. *Open bar,* asleep; *hatched bar,* calm; *stippled bar,* withdraws but allows; *solid bar,* crying. *$P < 0.05$, A vs K-A; $P < 0.001$, A vs M-A or M-K-A. †$P < 0.05$; M-K-A vs M-A, K-A, or A.

vation (A, 0%; K-A, 8%; M-A, 0%; M-K-A, 4%), postextubation croup (A, 0%; K-A, 0%; M-A, 4%; M-K-A, 4%), or nausea and vomiting (A, 8%; K-A, 0%; M-A, 0%; M-K-A, 0%).

Eighty percent of the patients in the M-K-A group, 84% in the M-A group, 88% in the K-A group, and 80% in the A group underwent extubation in the operating room. The remainder of the patients in the M-K-A group and K-A groups underwent extubation within the first 15 min after surgery. However, in two patients in the M-A group and in one in the A group, the tracheas remained intubated beyond 30 min in the recovery room until recovery from anesthesia occurred. In addition, the trachea of one patient in the A group remained intubated overnight electively because of extensive surgery in the pharynx and concern that the airway would be compromised by early tracheal extubation.

Discharge time was prolonged in more children in the M-A group (48%) than in those who received the control solution (21%; $P < 0.05$). More children had delayed discharge in the M-K-A (40%) and K-A (24%)

groups as well, but the differences from the children who received the control solution were not statistically significant (M-K-A vs A: $0.05 < P < 0.10$; K-A vs A: P = NS). All of the children with prolonged discharge times in the M-A and M-K-A groups and 50% in the K-A and 80% in the A groups had an intravenous induction with thiopental. The mean times to discharge were also longer in the M-A (59 ± 43 min), M-K-A (51 ± 33 min), and K-A (47 ± 39 min) groups than in the children who received the control solution (40 ± 21 min), but the differences among the groups were not statistically significant.

Discussion

This study clearly demonstrated that rectally administered midazolam, with or without ketamine, facilitated IV cannulation in young children. Both the response to IV cannulation and the success rate of IV catheterization were improved in children who received midazolam or midazolam plus ketamine. In addition, this study confirmed the results of other studies of rectal sedation and showed that rectal midazolam facilitated parental separation (2,5).

Most children who received midazolam and atropine alone remained awake both during parental separation and IV cannulation. This finding was consistent with the results of a study by Spear et al. (5), which showed that doses of midazolam up to 3 mg/kg administered rectally did not produce unconsciousness in young children. In contrast, the addition of ketamine (3 mg/kg) to midazolam and atropine caused 44% of the children in our study to be asleep when separating from their parents. This may be due to an interaction of midazolam with ketamine rather than a simple additive effect, because none of the children who received ketamine and atropine alone and only 8% of those who received midazolam and atropine alone were asleep at separation.

The anesthesiologist may desire the child to be asleep during the time of parental separation, and this can be achieved with the addition of ketamine to midazolam and atropine. There also was no evidence of arterial oxygen desaturation during this period. However, when sedating an infant or young child, the anesthesiologist must have the equipment and monitoring available to manage an unconscious patient. In situations where it is desirable to have the patient awake but cooperative before the induction of general anesthesia, midazolam should be used without ketamine.

We were not, however, able to demonstrate any benefit of adding ketamine to midazolam and atropine in improving IV placement. Because most children who did not receive midazolam were crying before the lidocaine was instilled or the IV catheter was placed, anxiolysis, provided by midazolam, not analgesia, may be the important factor in aiding IV catheterization in young children.

The incidence of perioperative complications in the children who received each of the three types of rectal sedation was similar to that of the children who received the control solution. There was, however, evidence that rectal midazolam prolonged recovery time in some patients. This differed from the study by Spear et al. (5), where rectal midazolam at doses up to 1.0 mg/kg was found not to prolong recovery time in young children. However, all of the children in their study received an inhaled induction of general anesthesia with halothane and nitrous oxide rather than the IV induction with thiopental received by all of the patients in our study given rectal midazolam whose recovery times were prolonged. This suggests that rectal midazolam may interact with IV thiopental to prolong discharge time. The possibility of an interaction of midazolam with IV induction drugs or other IV agents to prolong recovery time should be considered by anesthesiologists when using rectal sedation with midazolam.

In summary, midazolam and atropine with or without ketamine aided IV catheter placement and facilitated parental separation in young children. The addition of ketamine to midazolam and atropine caused more children to be asleep. Although the rectal route of administration may cause transient distress, rectally administered midazolam and atropine with or without ketamine can be a useful combination for cooperative separation of children from their parents and for IV catheter placement before induction of general anesthesia.

Plasma Lidocaine Concentrations During Epidural Blockade With Isoflurane or Halothane Anesthesia

Toshiaki Nishikawa, MD, Shinichi Inomata, MD, Minako Igarashi, MD, Toru Goyagi, MD, and Hiroshi Naito, MD

Department of Anesthesiology, Institute of Clinical Medicine, University of Tsukuba, Tsukuba City, Japan

Because isoflurane maintains hepatic blood flow at higher flows than halothane, we proposed that the elimination of lidocaine would be different between these two volatile anesthetics. The plasma lidocaine concentrations were determined in 14 female patients undergoing epidural blockade plus isoflurane anesthesia and compared with those obtained during halothane anesthesia for lower abdominal surgery. General anesthesia was maintained with isoflurane (0.46% ± 0.04% [mean ± SE] inspired, $n = 7$) or halothane (0.48% ± 0.05% inspired, $n = 7$) and 67% nitrous oxide in oxygen. All patients received 2% lidocaine solution, 10 mL as a bolus dose and continuous administration at a rate of 10 mL/h, through the epidural catheter. The plasma lidocaine concentrations over 180 min after the epidural injection in patients receiving isoflurane were similar to those in patients receiving halothane. The results suggest that low inspired concentrations of isoflurane do not reduce plasma lidocaine concentrations in patients during epidural blockade, compared with halothane.

(Anesth Analg 1992;75:885–8)

Seventy percent of lidocaine is removed from the blood in one circulation through the liver; therefore high plasma concentrations of lidocaine are achieved in patients with a low hepatic blood flow (1). Scott et al. (2) reported that hepatic blood flow is extremely important with regard to the rate at which elimination occurs because the liver is responsible for the destruction of lidocaine.

According to several reports, isoflurane maintains hepatic blood flow and hepatic oxygen supply at higher levels than halothane (3–8), although isoflurane produces a moderate decrease in hepatic blood flow (9). A more recent clinical study demonstrated in humans anesthetized with fentanyl that hepatic blood flow increased significantly during 1.0 MAC of isoflurane but not during 1.0 MAC of halothane (10). The current clinical study was designed to compare the plasma lidocaine concentrations during epidural blockade in surgical patients anesthetized with isoflurane or halothane.

Methods

Fourteen adult female patients, ASA physical status I, ranging in age from 25 to 51 yr, scheduled to undergo epidural blockade plus general anesthesia for surgical procedures of the lower abdomen, were selected for this study. The study protocol was approved by our Institutional Human Studies Committee, and written informed consent was obtained from each patient. No patient had any hepatic, cardiopulmonary, or neurologic disorders. All patients were premedicated with oral diazepam (10 mg) and famotidine (20 mg) 90 min before arrival in the operating room. A 16-gauge intravenous catheter was placed after local infiltration of 1% mepivacaine for infusion of lactated Ringer's solution at an approximate rate of 10 $mL \cdot kg^{-1} \cdot h^{-1}$ throughout the study.

After patients were placed in the lateral ducubitus position, the skin of the lumbar region was washed with antiseptic solutions and draped, and local infiltration was performed using 1% mepivacaine (5 mL) intradermally and subcutaneously at L2-3 or L3-4 intervertebral space. A 16-gauge Tuohy needle was then introduced into the epidural space using the balloon technique. After identification of the epidural space, an epidural catheter was advanced cephalad approximately 4–5 cm into the epidural space for continuous blockade. The patient was then placed in the supine position.

All patients were anesthetized with thiamylal (4–5 mg/kg IV), and tracheal intubation was facilitated with administration of vecuronium (~0.2 mg/kg IV). Then, general anesthesia was maintained with isoflurane or halothane (~0.5% inspired) and 67% nitrous oxide in oxygen. The inspired concentration of volatile anesthetic was adjusted to maintain small and centrally fixed pupils. The lungs were mechanically ventilated to maintain $Paco_2$ between 30 and 42 mm Hg with monitoring of end-tidal CO_2. A radial arterial cannula was placed for continuous monitoring of arterial pressure and blood sampling for measurements of plasma lidocaine concentration and arterial blood gas analyses.

Epidural anesthesia was produced by injection through the epidural catheter of 2% plain lidocaine solution (10 mL). A test dose was not used. Immediately after the initial injection, 2% plain lidocaine solution was continuously infused into the epidural space at a rate of 10 mL/h for 3 h (11,12).

Arterial blood samples for measurement of plasma lidocaine concentrations were withdrawn at 5, 10, 15, and 20 min and then at 20-min intervals after the first injection of lidocaine for 180 min. Blood samples were collected into glass tubes, centrifuged at 3000 rpm, and stored at −25°C until analyzed. The plasma lidocaine concentration was measured by homogeneous enzyme immunoassay (model aca discrete clinical analyzer, Du-Pont Company, Wilmington, Del.) (13). The coefficient for variability in this method was <6%, and the assay range was 1.0–12.0 μg/mL. This technique for lidocaine assay has been proved to be accurate, with a high degree of specificity and precision (14,15). The area under the plasma lidocaine concentration versus time curve to 180 min after epidural injection ($[AUC]_0^{180}$) for each patient was calculated using the trapezoidal rule (16).

Arterial blood gases were measured before and at 1-h intervals after the initial epidural administration of lidocaine. Electrocardiogram, radial arterial pressure, rectal temperature, and urinary volume were monitored in all patients throughout the study. Blood loss was replaced as necessary. Hypotension was defined as a decrease in systolic arterial pressure >30% of the preanesthetic value or a systolic arterial pressure of <90 mm Hg. Hypotension was treated with ephedrine (5–10 mg IV).

Values are presented as mean ±SE. Comparison of plasma lidocaine concentrations between the two groups was performed using two-way analysis of variance and Student's *t*-test; *P* values <0.05 were considered statistically significant.

Table 1. Summary of General Anesthetics, Upper Analgesic Level of Epidural Blockade, Ephedrine, Blood Loss, Urinary Output, Crystalloid Infusion, and Blood Transfusion in the Two Study Groups

	Isoflurane group (n = 7)	Halothane group (n = 7)
Inspired concentration of volatile anesthetics (%)	0.46 ± 0.04	0.48 ± 0.05
Thiamylal (mg/kg)	4.9 ± 0.1	4.7 ± 0.1
Vecuronium (mg/kg)	0.20 ± 0.01	0.21 ± 0.01
Upper analgesic level of epidural blockade (Th)	7.7 ± 0.5	7.7 ± 0.4
No. of ephedrine injections	1.5 ± 0.5	1.1 ± 0.4
Ephedrine (mg)	7.9 ± 2.9	6.4 ± 2.6
Blood loss (mL)	445 ± 145	545 ± 229
Urinary output (mL)	215 ± 40	203 ± 45
Lactated Ringer's solution ($mL \cdot kg^{-1} \cdot h^{-1}$)	11.2 ± 0.8	11.3 ± 0.8
Blood transfusion (mL)	214 ± 128	228 ± 119

Th, thoracic dermatome.

Values are mean ± SE. There are no significant differences between the two groups.

Results

There were no significant differences between the isoflurane and halothane groups in age (38 ± 3 vs 38 ± 4 yr), body weight (48 ± 3 vs 56 ± 4 kg), and height (157 ± 2 vs 157 ± 2 cm), respectively. The mean inspired concentrations of isoflurane and halothane were 0.46% ± 0.04% and 0.48% ± 0.05%, respectively (Table 1). In addition, there were no significant differences between both groups with respect to doses of general anesthetics, upper analgesic level of epidural blockade, number of ephedrine injections, dose of ephedrine, blood loss, urinary output, infusion rate of crystalloid solution, amount of transfused blood, and arterial blood gas values during the study (Tables 1 and 2).

Arterial plasma concentration of lidocaine in the isoflurane group was not different at any period up to 180 min after epidural injection of lidocaine, compared with the halothane group (Figure 1). Therefore, there was no statistically significant difference between the two groups in $[AUC]_0^{180}$ (780 ± 51 and 701 ± 41 $\mu g \cdot min \cdot mL^{-1}$, respectively, in the isoflurane and halothane groups).

No patient showed clinical signs or symptoms associated with systemic toxicity of the local anesthetics during emergence from general anesthesia. In all patients, an adequate cutaneous analgesia (thoracic dermatome >10) was confirmed by one of the authors at the end of the operation (Table 1).

Discussion

The current clinical study demonstrated that low inspired concentrations of isoflurane do not reduce plasma lidocaine concentrations during epidural an-

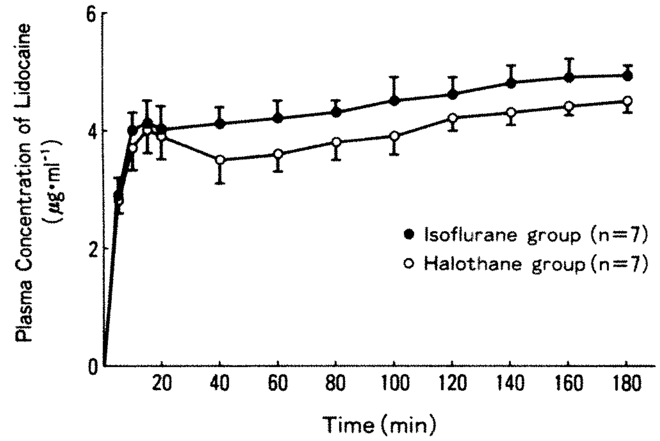

Figure 1. Plasma concentration of lidocaine after epidural injection of 2% plain lidocaine solution, 10 mL as a bolus dose, followed by a continuous infusion at 10 mL/h in patients anesthetized with isoflurane or halothane and nitrous oxide in oxygen.

esthesia in humans compared with halothane. This finding could be attributed to similar effects of low concentrations of isoflurane and halothane on hepatic blood flow in patients undergoing lower abdominal surgery under epidural plus general anesthesia.

Hepatic clearance of lidocaine is one of the major determinants of plasma concentration, because lidocaine is a drug with a high intrinsic clearance and extraction ratio; approximately 70% of lidocaine is removed from the blood reaching the liver in one circulation (1). Therefore, because its hepatic clearance is more influenced by hepatic blood flow than by hepatic enzyme activity (17,18), reductions in hepatic blood flow associated with low cardiac output have been reported to result in higher plasma lidocaine concentrations in patients with heart failure (19,20) or in animals with hypovolemia (21).

Hepatic blood flow could be disturbed primarily by the pharmacologic properties of anesthetics, their associated hemodynamic alterations, and surgical procedures during anesthesia (22). Among volatile anesthetics, isoflurane seems to have minimal deleterious effects on hepatic circulation, evidenced by previous animal and human investigations (3–8,10). Indeed, equal degrees of arterial hypotension have been demonstrated to be accompanied by pronounced reduction in hepatic blood flow during halothane anesthesia but not during isoflurane anesthesia (3–8). However, there are few data concerning the effects of low concentrations of volatile anesthetics (<1.0 MAC) on hepatic blood flow.

Gelman (23) and Bohrer et al. (24) described the importance of surgical stress-induced derangements in hepatic blood flow. According to their extensive works on hepatic circulation, surgical stress should have a profound influence on the hepatic blood supply. Laparotomy as a surgical stress is indeed associated with mesenteric vasoconstriction and the release of vasoactive substances that could disturb the hepatic circulation (25–27). More important, these derangements are reported to persist for several hours. However, epidural blockade could have alleviated these surgical stress responses to a great extent in the present study.

Therefore, no difference in plasma lidocaine concentrations over 180 min between the isoflurane and halothane anesthesia groups in the present study (Figure 1) could be attributed to comparable effects of low concentrations of both volatile anesthetics on hepatic circulation. Because hypotension was treated immediately with ephedrine, and numbers of hypotensive episodes and the mean total administered doses of ephedrine were comparable between the two groups (Table 1), it appears that anesthesia-induced systemic hemodynamic alterations were clinically similar between the isoflurane and halothane anesthesia groups. Likewise, the effects of isoflurane and halothane at the low concentrations used during the current study may also not produce differences in hepatic circulation between the two groups, because Gelman et al. (3) emphasized that anesthetics may only modulate the hemodynamic alterations in the liver induced by surgical stress. Furthermore, because isoflurane has a more potent vasodilating action than halothane in humans (28,29), no difference in plasma lidocaine concentrations may be due to the fact that increased absorption of lidocaine through the epidural vessels would have masked the accelerated hepatic uptake of lidocaine during isoflurane anesthesia.

In conclusion, low concentrations of isoflurane do not reduce plasma lidocaine concentrations during epidural anesthesia in patients undergoing lower abdominal surgery compared with halothane. This finding may be due to similar effects of low concentrations of volatile anesthetics on hepatic blood flow during epidural blockade.

We thank Mrs. Y. Isaka for her help in the measurement of plasma lidocaine concentrations.

---

The purpose of this study was to develop a reliable model to independently quantify motor and sensory block produced by local anesthetics. The sciatic nerve was blocked in 52 rats by injecting 0.2 mL of 0.125%, 0.25%, 0.5%, or 0.75% bupivacaine (n = 13 for each concentration). Accurate needle placement was achieved using a nerve stimulator at 0.2 mA and 1 Hz. Ten control rats received 0.9% saline (n = 5) or sham nerve stimulation (n = 5). Motor block was assessed by measuring hindpaw grip strength with a dynamometer. Sensory block was determined by measuring hindpaw withdrawal latency from radiant heat. The intensity of both motor and sensory block measured at 30-min intervals was plotted against time until full recovery to obtain the area under the curve. Intergroup comparisons using analysis of variance showed increasing area under the curve with increasing concentrations of bupivacaine for motor blocks ($P < 0.05$ for all intergroup comparisons except 0.5% vs 0.75%) and sensory blocks ($P < 0.05$ for all intergroup comparisons). Normal saline or sham nerve stimulation did not result in any motor or sensory block.

(Anesth Analg 1992;75:889–94)

Several investigators have used in vivo animal models to evaluate local anesthetic-induced conduction block. The sciatic nerve block has been used in the guinea pig (1–4) and rat (5–12); spinal block in sheep (13), monkey (14), dog (10,15–18), rabbit (2,3,7,19–22), rat (23–26), mouse (25,27), and marmoset (23); and epidural block in the dog (10,28), cat (29), rat (30), and marmoset (23). Although some of these studies reported motor as well as sensory effects of local anesthetics, none quantified both variables objectively. All studies used visual observation to grade motor block. The presence of sensory anesthesia was tested by eliciting vocalization, withdrawal, or respiratory response to pinprick, heat, or pressure stimulus. In addition, all reported sciatic nerve block models used blind percutaneous injections, except one in which a silicone sheath was surgically implanted around the sciatic nerve (12).

We present a model of percutaneous sciatic nerve block in the rat using a nerve stimulator to locate the sciatic nerve accurately. Modification of a technique to measure grip strength (31) enabled us to quantify intensity and duration of unilateral grip strength objectively. We measured paw withdrawal latency from radiant heat stimulation (5,32,33) to quantify the intensity and duration of unilateral sensory anesthesia.

Methods

All experiments were approved by the Institutional Animal Care and Use Committee and conducted in accordance with their guidelines.

Percutaneous Rat Sciatic Nerve Model

Male Sprague-Dawley rats (Taconic Farms, Pa.) (365 ± 26 g [mean ± SD], range 345–410) were housed five per cage in a room with controlled environmental temperature, humidity, and artificial lighting (7 AM–8 PM). The animals had free access to food and water and were not tested for at least 10 days after their arrival from the supplier.

All animals were anesthetized by placing them in a chamber flushed with 5% halothane in oxygen at a rate of 2 L/min for 5 min. The animals were then removed from the chamber and allowed to breathe room air. After being placed on their left side, the groove between the greater trochanter of the right

femur and the ischial tuberosity was identified by palpation. A 24-gauge 45° beveled Teflon-shielded needle (Stimuplex, B. Braun, Melsungen, Germany) attached to a nerve stimulator (DigiStim II, Neuro-Technology, Houston, Tex.) was advanced into the groove while being stimulated at 1 Hz. A pilot study of 15 rats showed the minimal effective current required to produce twitch with the needle tip directly on the surgically exposed sciatic nerve to be 0.2 mA. It has been shown that direct current stimulation of the rat sciatic nerve using 0.5 mA does not cause neuropathologic changes (34). Close proximity of the needle tip to the sciatic nerve during percutaneous blocks was confirmed by a noticeable twitch of the hindpaw at a stimulus intensity ≤0.2 mA. While the operator held the needle steady, an assistant activated a Harvard infusion pump to inject 0.2 mL of the test solution at a constant rate of 1.2 mL/min through a catheter attached to the needle. All animals were returned to their cages to recover from anesthesia after the injection was completed.

Assessment of Motor Block

We modified an apparatus described for measuring bilateral grip strength (31) to measure unilateral hindpaw grip strength after the sciatic nerve block. The modified device consists of a horizontally mounted, 6-mm mesh stainless steel screen attached to an electronic force-gauge dynamometer (model DFGHS2, Chatillon, Greensboro, N.C.) that samples at a rate of 4500/s and updates the digital display 15 times per second. Rats were positioned on a plexiglass bench adjacent to the screen so that the two forelimbs and the normal hindlimb rested on the bench and the blocked hindlimb rested on the screen.

For each test, the rat's tail was pulled backward in a smooth but firm manner until the rat's grip on the screen was broken. The dynamometer registered peak grip strength in grams. The strongest response of three consecutive attempts was used for statistical analysis. Baseline grip strength was measured by a blinded operator before the sciatic nerve block and again every 30 min after the block until return to baseline grip strength.

Assessment of Sensory Block

Sensory anesthesia of the plantar surface of the paw was determined using unilateral hindpaw withdrawal latency (PWL) to radiant heat stimulation (32,33,35). Rats were placed in bottomless, clear plexiglass rectangular chambers (12 × 16 × 30 cm high) on a glass shelf (2 mm thick) and allowed to acclimate to their surroundings for 5 min. The surface temperature of the shelf was measured with a thermistor monitor (Mon-a-therm, model 4070, Mallinckrodt, St. Louis, Mo.). The surface of the glass shelf was maintained at a constant temperature between 27.5 and 28.5°C using a warm-air blower situated below. A movable radiant heat source (tungsten halogen projector lamp, 150 W, 100 V, GTE, Winchester, Ky.) powered by a constant current supply was focused on the glass from below through a 4-mm-diameter aperture. A single switch activated both the radiant heat source and an electronic timer capable of measuring 0.1-s intervals. In a series of experiments, the distance from lamp to glass and initial temperature of the glass shelf were adjusted by trial and error to yield a mean PWL of 5.2 ± 0.6 s.

After the animal settled in place on the glass shelf, the heat source was positioned under the plantar surface of the desired hindpaw, assuring that the plantar skin was in contact with the glass. The heat source was turned on until the hindlimb was briskly withdrawn from the glass shelf. Average baseline PWL was determined in triplicate for the entire study group. For PWL testing, a cutoff time of 10 s was used to avoid thermal injury (erythema, edema, or blistering). However, in pilot studies, repeated PWL testing (more than eight times) to cutoff time (10 s) in paralyzed paws sometimes resulted in thermal injury. Additionally, in pilot studies, we found that every animal with complete motor block as evidenced by a clubbed paw had maximal PWL. Thus, we decided to assess PWL only when complete motor paralysis was not present.

Experimental Design

Sixty-two rats were divided into six groups. Rats in groups I–IV ($n = 13$ per group) were injected with 0.2 mL of 0.125% bupivacaine (group I), 0.25% bupivacaine (group II), 0.5% bupivacaine (group III), or 0.75% bupivacaine (group IV) (Marcaine HCl, Winthrop Pharmaceuticals, New York, N.Y.). The pH of the commercially prepared solutions was 5.9, 5.8, and 5.5 for 0.25%, 0.5%, and 0.75% solutions, respectively. The 0.125% solution was prepared by diluting 0.25% bupivacaine with 0.9% saline and adjusting the final pH to 5.9 using 1 M NaOH. Group V ($n = 5$) was injected with 0.2 mL of 0.9% saline (pH 5.4), and group VI ($n = 5$) had nerve stimulation alone, without any solution injected.

After injection (or nerve stimulation alone), motor block was measured by a blinded observer every 30 min. Nerve block was deemed successful if complete motor block was present at 30 min. Failure to grip the screen and complete clubbing of the hindpaw was indicative of complete motor block. Animals in groups I–IV that did not develop complete clubbing were not included for statistical analysis (10).

Grip-strength testing was performed at 30-min intervals after the block, and once the rat regained the ability to grip the screen, PWL testing was also performed at 30-min intervals. Both grip strength and PWL testing were continued every 30 min until return to baseline. Hindpaws were visually inspected for erythema, edema, or blistering at the end of each experiment.

Data Analysis and Statistics

Intensity of motor block was determined at each time interval for each rat by computing percent of preinjection grip strength. Intensity of sensory block was calculated for each rat at each time interval by determining percent maximal possible effect (% MPE), according to the following formula:

$$\% \text{ MPE} = \frac{\text{Postinjection latency} - \text{Preinjection latency}}{\text{Cutoff time (10 s)} - \text{Preinjection latency}} \times 100.$$

The percent motor block and percent MPE were plotted against time to determine the area under the curve (AUC) using the linear trapezoidal method (36,37). Results were expressed as mean ± SD. Differences in motor or sensory block produced by each bupivacaine concentration were compared using their respective AUCs. For statistical comparison, analysis of variance was used. If a significant F value ($P < 0.05$) was seen with analysis of variance, a protected least-significant difference test was used to make intergroup comparisons (38) using Complete Statistical Systems software (StatSoft, Tulsa, Okla.).

Results

At 30 min, 12 of 13 (92%) of the rats in groups I, II, and IV had complete clubbed paw; thus, 1 rat from each of these groups was eliminated from the study. All rats in group III had complete clubbed paw. No group V or VI rat had clubbing at any time. No intergroup differences existed for frequency of blocks among groups I–IV, all of which differed significantly from groups V and VI.

Mean baseline hindpaw grip strength was 649 ± 89 g. In groups I–IV, the intensity and duration of motor block increased with increasing bupivacaine concentration (Figure 1); 0.5% bupivacaine produced a greater AUC than 0.125% or 0.25% ($P < 0.05$) but an AUC similar to that produced by 0.75% bupivacaine (Figure 2). No group V or VI animal had a decrease in grip strength from baseline. Both groups were significantly different from groups I–IV but not from one another.

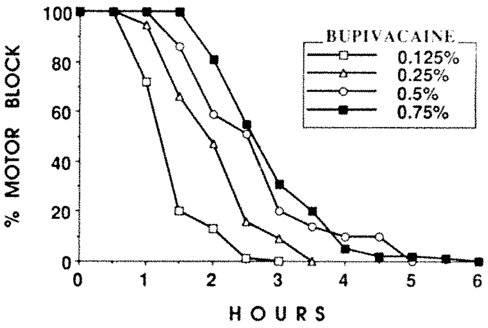

Figure 1. Mean duration of motor block for various concentrations of bupivacaine, as measured by grip strength. Percent motor block was calculated as 1 − (postblock grip strength/preblock grip strength) × 100. Time 0 represents the first testing interval. For clarity, standard deviations are not shown.

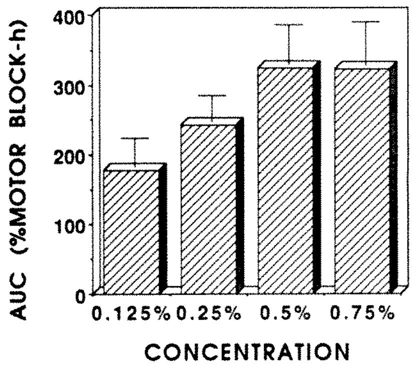

Figure 2. Total area under the curve (AUC) for motor block produced by various concentrations of bupivacaine. All intergroup comparisons significantly different, except 0.5% versus 0.75%.

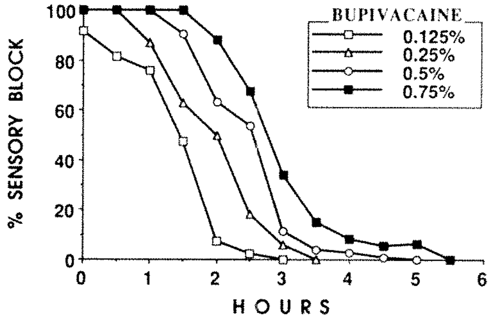

Figure 3. Mean duration of sensory block for various concentrations of bupivacaine, as measured by paw withdrawal latency. Percent maximal possible effect was calculated as explained in text. Time 0 represents the first testing interval. For clarity, standard deviations are not shown.

The mean preblock PWL was 5.0 ± 0.5 s. The mean PWL for all rats fell within 2 SD of the mean for the entire group. The intensity and duration of sensory block increased with increasing concentration of bupivacaine (Figure 3). Increasing concentration of bupivacaine produced increasing AUC ($P < 0.05$) for all intergroup comparisons (Figure 4). No animal in groups V or VI had sensory block. No rat had erythema, edema, or blistering of the hindpaw.

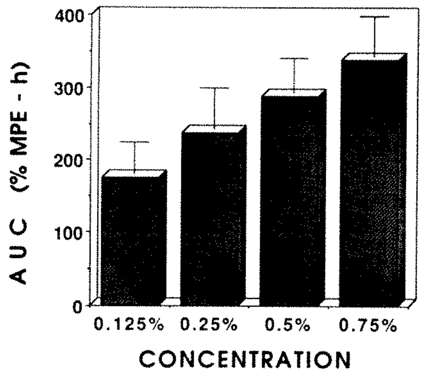

Figure 4. Total area under the curve (AUC) for sensory block produced by various concentrations of bupivacaine. All intergroup comparisons significantly different. % MPE, percent maximal effect.

Discussion

We describe here a percutaneous rat sciatic nerve block model that allowed us to independently quantify motor and sensory block produced by various concentrations of bupivacaine.

Sciatic Nerve Model

The sciatic nerve block model for evaluation of local anesthetic action was first described in the guinea pig in 1935 (1) and later used by others (2–4). A rat sciatic nerve model was described in 1958 (5). We found no subsequent reports using the guinea pig model, perhaps because the rat's natural posture makes motor block easier to evaluate (5). The original rat sciatic nerve block used a tuberculin syringe fitted with a 26-gauge needle to inject the popliteal space (5). Although other reports use more proximal injection sites (6–9,11,12), a recent study used the popliteal approach to inject 0.1 mL of local anesthetic in 450–600-g rats (10). The others used 0.2–0.25 mL of local anesthetic in 130–250-g rats (6–9,11). A conventional needle-syringe arrangement was utilized in all of these studies. Recently, a silicone sheath was surgically implanted around the sciatic nerve to permit multiple local anesthetic injections through a subcutaneous port to study neurotoxic effects (12).

We believe that the method we describe is superior to previously described models. The uncertainties of blind injection are avoided by using nerve stimulation to locate the nerve precisely. Although this is not a new technique for ensuring proper needle placement (39), we can find no use of it reported for these purposes. The block can usually be performed in <2 min by using the greater femoral trochanter and the ischial tuberosity as landmarks. The injected volume of 0.2 mL is consistent with the volume used in previous reports (6–9,11), although our rats were larger. The immobile needle technique (40) maximizes injection accuracy. Nerve stimulation-guided needle placement in conjunction with an automated infusion pump ensures a standard rate of injection and consistently results in a high success rate (94%).

Evaluation of Motor Block

Evaluation of sciatic motor block in the rat induced by injected local anesthetic has previously been based on semiquantitative observations of such variables as ability of the rat to negotiate an inclined wire mesh or on observation of the rats' posture and degree of apposition of the hindpaw digits (5–12,26,30). One investigator did attempt to quantify hindpaw motor function after injury of sciatic nerves (41). Rats were allowed to walk over photographic paper after the hindpaws were painted with photographic developer. The hindpaw imprints were then analyzed, and an index of motor function was derived.

We measured unilateral hindpaw grip strength based on a device recently described using a screen attached to an electronic dynamometer to assess bilateral hindpaw grip strength in the rat (31). We modified this device to allow testing of unilateral hindpaw grip strength by extending the forepaw platform rest to include the unblocked hindpaw as well. This left only the blocked hindpaw in contact with the screen.

Testing at 30-min intervals allowed measurement of duration and intensity of motor block. By then plotting the percent of baseline block for each time interval for every rat, we were able to calculate the AUC for each rat and to make intergroup comparisons of total AUC using analysis of variance.

We believe that the simplicity, reliability, and precision of this method makes it clearly superior to previously reported methods to measure intensity and duration of motor block.

Evaluation of Sensory Block

Some in vivo animal studies of local anesthetic conduction block have assessed sensory loss using nonquantitative methods (3,4,19,23). We have found no study reporting assessment of sensory anesthesia after rat sciatic nerve block. We used a radiant heat source to evaluate sensory anesthesia, applying recently described technology for measuring cutaneous hindpaw anesthesia in the rat (5,32,33).

Analgesia tests in the rat using thermal stimulation (tail flick, hot plate) have been used for 50 yr (42,43). These tests are useful for evaluation of systemic or neuraxial analgesics but have limited application for local anesthetics, because they cannot clearly differentiate between motor and sensory block. Also, utility of the tail-flick test to predict clinical action of local anesthetics is unclear, because intrathecal or epidural injections in the rat and mouse have been reported to result in a hyperreflexive tail-flick response (24, 25,30). Hot-plate testing to evaluate effects of local anesthetics has also been reported (27,30); however, like the tail-flick test, it cannot be used for unilateral testing.

An advantage of the thermal stimulation system described here is that a unilateral hindpaw can be tested. This allows the animal's unblocked other paw to serve as a control. Another significant advantage of this model is that it permits independent motor and sensory testing. A rat with complete motor block but incomplete sensory block still can withdraw its paw, because the hip muscles not innervated by the sciatic nerve allow withdrawal from the heated glass. It may be important to assess differential anesthetic effects on motor and sensory block, especially because injection of neurotoxic substances may cause prolonged motor block with little or no sensory loss or hyperesthesia.

In preliminary studies, we, like other investigators (33,44), found that baseline PWL was inversely related to the initial temperature of the glass shelf surface. This was nullified by controlling the shelf surface to a measured temperature of 27.5–28.5°C by heating with a hot-air blower beneath the shelf or cooling its surface with a damp sponge. Baseline PWL values were very consistent so long as temperature was controlled. This consistency in PWL also allowed us to use a 10-s cutoff time to calculate percent MPE and AUC.

To avoid the possibility of heat stimulation beyond the desired paw surface area, we used an aperture diameter of 4 mm and took particular care to stimulate only hindpaw skin in direct contact with the glass surface (33,45,46). Tissue injury is a potential pitfall of any thermal testing system. We did not begin to measure PWL until motor block regressed enough to permit paw motion. This avoided unnecessary hindpaw heating for the maximal (cutoff) time of 10 s.

Conclusion

The percutaneous rat sciatic model we describe here allowed us to independently assess motor and sensory block produced by various concentrations of bupivacaine. The nerve stimulator enabled us to perform the blocks easily without surgery and to achieve a high rate of success. The grip strength and PWL tests allowed us to accurately quantify degree of block. The sensitivity of these tests allowed detection of even small degrees of block and discriminated among different concentrations of local anesthetic. This method may be useful for evaluation of local anesthetics.

Lumbar Subarachnoid Ethylenediaminetetraacetate Induces Hindlimb Tetanic Contractions in Rats: Prevention by $CaCl_2$ Pretreatment; Observation of Spinal Nerve Root Degeneration

B. C. Wang, MD, D. Li, MA, MB, J. M. Hiller, PhD, E. J. Simon, PhD, G. Budzilovich, MD, and D. E. Hillman, PhD

Departments of Anesthesiology, Psychiatry, Pharmacology, Neuropathology, Physiology, and Biophysics, New York University School of Medicine, New York, New York

Disodium ethylenediaminetetraacetate (Na_2EDTA) has replaced sodium bisulfite as the antioxidant in 2-chloroprocaine, Nesacaine CE. This study was undertaken to determine whether this new formulation has neurotoxic effects when administered in the subarachnoid space. Sprague-Dawley rats receiving subarachnoid injections of 1.5 mM or higher concentrations of Na_2EDTA immediately initiated a circling behavior that was followed by the development of tetanic contractions of the hindlimbs lasting for 15–20 min. The tetanic contractions were followed by a brief period of hindlimb paralysis. Pretreatment of rats by subarachnoid injections of 1 mM $CaCl_2$ prevented the development of tetanic contractions and paralysis of the hindlimb. Histologic examination of animals receiving Na_2EDTA revealed moderate to severe focal degenerative changes in spinal nerve roots. Control rats receiving subarachnoid injections of normal saline solution did not develop tetanic contraction nor pathological changes on light microscopy. These results suggest that the preservative used in Nesacaine-MPF may be neurotoxic.

(Anesth Analg 1992;75:895–9)

Sodium bisulfite, an antioxidant contained in 2-chloroprocaine, Nesacaine CE, has recently been replaced by a chelator, disodium ethylenediaminetetraacetate (EDTA) dihydrate. A number of adverse effects have been reported after enteral and parenteral administration of EDTA. These include teratogenicity (1); collagen fibril depletion (2); intestinal villi shortening (3); neural crest tumor formation and cell death in rats and mice (4); hepatic necrosis in calves (5); and contact allergy (6), vasculitis, cardiac tamponade, hemolytic anemia, and renal damage in humans (7). Moreover, systemic hypocalcemia and increased parathyroid hormone have been reported in humans after radiography with contrast media containing EDTA (8). Use of this type of contrast for coronary angiography has also caused ventricular fibrillation and repolarization changes (9). Ethylenediaminetetraacetate containing 2-chloroprocaine-MPF has been used widely as an epidural anesthetic and may enter the subarachnoid space through accidental dural puncture. The effects of EDTA in the subarachnoid space are unknown. A rat model was used to test the effects of EDTA in the subarachnoid space.

Methods

With approval of our Animal Care and Research Committee, Sprague-Dawley rats weighing 500–600 g were anesthetized with 0.5 mL/kg intramuscular injection of an anesthetic mixture that contained ketamine (42.85 mg/mL), xylazine (8.57 mg/mL), and acepromazine (1.42 mg/mL). After lumbar laminectomy, with aseptic technique, PE10 subarachnoid space (SAS) catheters (Becton Dickinson, Parsippany, N.J.) were implanted under direct vision with a technique recently reported (10). One week after surgery, correct position of the SAS catheter was verified by observing temporary hindlimb paralysis after induction of spinal block with 0.05 mL of 1.5% lidocaine. One or more days after this test, the animals were divided into five groups receiving SAS injections at 1-h intervals, as follows: group 1 (control

1	NE	NE	NE	NE
2	NE	NE	3rd	2nd
3	NE	NE	2nd	1st
4	NE	NE	NE	1st
5	NE	NE	NE	1st
6	NE	NE	1st	1st

EDTA, ethylenediaminetetraacetate; NE, no effect (no tetanic contraction); 1st, 2nd, 3rd, injection number when tetanic contractions were observed.

animals, $n = 6$) received three SAS injections (at 1-h intervals) of normal saline solution (NS) (50 μL [0.05 mL], pH 5). Group 2 (EDTA only, $n = 6$) received (at 1-h intervals) three to four SAS injections of 0.05 mL of Na_2EDTA (molecular weight 336.21, pH 4.5–4.8) of varied concentrations on different days, including 0.01% (0.3 mM), 0.025% (0.75 mM), 0.05% (1.5 mM), and 0.1% (3 mM). Group 3 ($CaCl_2$ + Na_2EDTA, $n = 7$), at 1-h intervals, received three SAS injections of 148 μL of 1 mM (0.01%) $CaCl_2$ (molecular weight 110.99, pH 5–5.7), which was immediately followed by 148 μL of 3 mM (0.1%) Na_2EDTA. Additionally, at 1-h intervals, two other rats received the $CaCl_2$ + EDTA combination six times. Group 4 (histologic study, $n = 3$ [not counting the rat from group 2]) received eight injections of 0.05 mL of 0.1% Na_2EDTA at 1-h intervals and were killed 3 days later for pathological examination of the spinal cords. Group 5 (additional histologic study of saline solution control animals, $n = 6$) received 0.05 mL of NS at 1-h intervals for 8 h and were killed 5 days later for pathological examination.

Results

There was no demonstrable motor abnormality after SAS injection of NS and 0.01% and 0.025% Na_2EDTA. One minute after 0.1% Na_2EDTA injection, five of six rats in group 2 circled around continuously and then developed tetanic contractions of the hindlimbs at a frequency of 100+/min. Four animals manifested this behavior after the first injection and one after the second injection. Three rats developed tetanic contractions of hindlimbs after 0.05% Na_2EDTA injection: one after the first, one after the second, and one after the third injection. Hindlimb paralysis lasting 10–15 min usually followed the tetanic contractions. Table 1 summarizes the results in group 2. Tetanic contractions and other motor abnormalities were not seen in group 3 rats when SAS Na_2EDTA injections were preceded by $CaCl_2$. Tetanic contractions developed in all of the group 4 animals between the fourth and eighth injections.

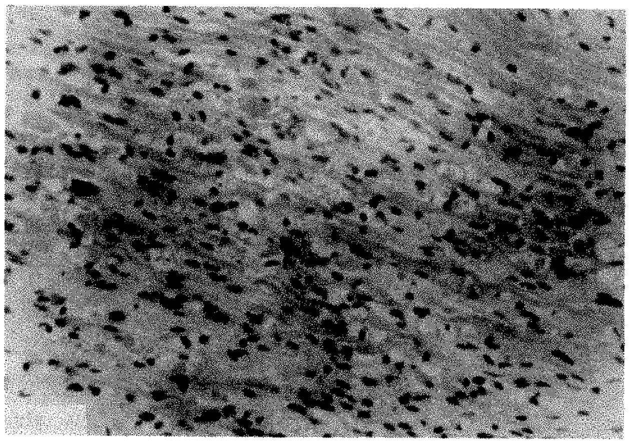

Figure 1. Low-power magnification (×25) of hematoxylin-eosin-stained section of rat spinal nerve root 6 days after receiving subarachnoid injection of Na_2EDTA. Approximately one-third of the fibers show acute vacuolar and granular degeneration. A relatively intact portion of the root is shown in the *right upper corner.*

Pathological examinations were performed in 10 animals: one from group 2, three from group 4, and six from group 5. The animal from group 2 was killed for histologic examination 6 days after receiving SAS Na_2EDTA injection every hour for 3 h. This rat had tetanic contractions after receiving the second and third SAS injections containing 0.1% and 0.05% Na_2EDTA, respectively. Before autopsy, this rat had already recovered from hindlimb paralysis and showed no sign of motor abnormality. Histologic examination revealed focal lesions characterized by destruction of axons and their myelin sheaths, resulting in cystic degeneration of nerve roots. Prominent macrophage activity was evident (Figures 1 and 2). The spinal cords of two of the three animals in group 4 revealed Wallerian degeneration of spinal nerve roots (Figures 3 and 4). In the histologic sections examined, the remaining rat in group 4 did not show degenerative changes. The spinal cord and spinal roots of group 5 rats did not show pathological changes after SAS injection of NS. There were no tetanic contractions in group 5.

Discussion

Before the formulation change, Chloroprocaine CE, Nesacaine CE contained 0.2% sodium bisulfite, which was shown to be neurotoxic in rabbits (11–13) and rats (14). Subsequently, the manufacturer reduced the antioxidant content to 0.07% and eventu-

ally eliminated it altogether, replacing it with EDTA. Recent reports of severe back pain after epidural chloroprocaine (Nesacaine-MPF) prompted the authors to examine the effects of EDTA in the SAS to determine if the new formulation of chloroprocaine is appropriate. We did not pinpoint the etiology of the back pain but were led to believe that EDTA is the possible cause by the following findings: (a) SAS administration of EDTA induced tetanic contractions, probably as a result of hypocalcemia; (b) $CaCl_2$ pretreatment prevented the development of tetanic contractions; (c) microscopic evidence of spinal nerve root degeneration was observed, a condition that may be associated with nerve root irritation causing pain. These three findings are discussed next.

Tetanic Contractions

The fact that low concentrations (0.01% and 0.025%) of Na_2EDTA did not cause tetanic contractions indicates a concentration-dependent effect. As shown in Table 1, four rats developed tetanic contractions after the first injection of 0.1% EDTA, whereas with 0.05% EDTA, only one developed tetanic contractions after the first injection, one after the second, and one after the third. This would suggest that cumulative dosage and duration of contact may influence the result.

Because the SAS of the rat is very small, the volume of the injectate has to be limited. For this reason, we had to use concentrations of EDTA higher than the 0.011% contained in the commercial solution of chloroprocaine-MPF; however, in terms of total milligrams, the dose that we used was still only approximately 1/40 of the amount of EDTA contained in a single epidural dose of chloroprocaine-MPF in humans. In general, based on body weight, drug dosage for rats is usually much larger than that for humans.

Ethylenediaminetetraacetate chelates calcium, which plays an important role in neuromuscular function, including repolarization of the myocardium (9). Hypocalcemia causes tetany; however, the exact mechanism for the production of tetanic contraction after SAS EDTA administration remains unresolved.

In a previous study (15), tetanic contractions were also produced by EDTA administered in the epidural space. As expected, the latency period before the development of tetanic contractions after epidural EDTA was longer than that after SAS injection, because it takes time to pass through the dura.

Calcium Chloride Pretreatment

The fact that pretreatment with $CaCl_2$ prevented the development of tetanic contractions in group 3 suggests that hypocalcemia secondary to chelation could be the responsible factor. The preventive role of $CaCl_2$ was further supported by the fact that the two additional rats in group 3 did not develop tetanic contractions even after receiving, at 1-h intervals, eight injections of the combination of $CaCl_2$ + EDTA. The report of successful treatment of severe back pain after epidural Nesacaine-MPF with $CaCl_2$ (16) reinforced this support.

Patients with parathyroid hormone deficiency, impaired calcitriol synthesis, hypomagnesemia and hypermagnesemia, and diseases of the kidneys and liver are especially at risk for hypocalcemia (17). Vitamin D is synthesized in the skin or absorbed by the gut, 25-hydroxylated in the liver, and then 1-hydroxylated in the kidneys to its most active form, calcitriol. Therefore, diseases of the kidneys or liver could impair calcium homeostasis, and in patients with such ailments even a low concentration of EDTA may be unsafe.

Myoclonic seizures, probably secondary to increased serotonergic activity in the spinal cord, have been reported in rats after a tenfold analgesic dose of intrathecal morphine. This effect was reduced by pretreatment with parachlorophenylalanine in doses that reduced spinal 5-hydroxytryptamine (serotonin) by approximately 60% (18). Speculatively, if EDTA produces tetanic contractions by acting on the serotonergic pathway in the spinal cord, it would be inadvisable to add EDTA to intrathecal morphine preparations.

Opioid receptors may be affected by EDTA through calcium modulation. The binding of opioid receptors is affected by the valence of the cation (i.e., monovalent or divalent) and the site of binding (i.e., μ, δ, κ). In membrane suspensions from guinea pig brain or cerebellum, Paterson et al. (19) found that $CaCl_2$ inhibited equilibrium binding at μ and κ sites but potentiated binding at δ sites. Kappa receptors have been linked to direct blockade of the calcium channel (19). The κ-ligand dynorphin A decreases basal free intracellular calcium in rat cortical synaptosomes.

Through calcium modulation, EDTA may affect the calcium channel (20), the secondary messenger, the muscarinic receptor (21), and the acetylcholine and norepinephrine neurotransmitter release (22,23). There is evidence suggesting that leucine enkephalin and acetylcholine are cotransmitters stored in and released from the same nerve terminals in the parasympathetic ganglia of the bladder (24).

Degeneration of the Spinal Nerve Roots

Our preliminary observation that spinal nerve roots had degenerated lends support to similar results from previous investigations of epidural and SAS administration of EDTA (15,25). This would suggest that the reported severe back pain after epidural chloroprocaine-MPF (16,26–30) could be due to spinal nerve root irritation caused by EDTA contained in the anesthetic solution. Unfortunately, we did not perform pathological studies on all of our animals. Further research, including studies of Nesacaine-MPF, are warranted.

Recently, on the basis of autopsy findings in 15 patients, without substantiating evidence, Sjoberg et al. (31) have tried to exonerate low-concentration sodium metabisulfite and EDTA from causing neurotoxicity. We commend their efforts in the study but disagree with their interpretation of results. Their table of "Pathoanatomic findings" listed several patients with neurilemoma, loss of axon, demyelination of spinal nerve roots, 10 patients with "puzzling" mononuclear infiltration ("five had radiotherapy of the spinal column and three had potentially neurotoxic cytostatic treatment"), one patient with degeneration of the dorsal column and dorsal horns with focal subpial vacuolization and demyelination at the level of a neurilemoma, and one patient with arterial thrombosis and medullary infarction of the spinal cord. One patient developed paraplegia and urinary retention 158 days after the start of the intrathecal treatment, and the authors called this "an expected consequence of large daily dose (7–10 mg/h) of intrathecal bupivacaine given to cope with severe neurogenic pains." They claim that "the incidence and extent of the microscopic nerve root lesion were not related to the concentrations and cumulative doses of morphine (and its preservatives) or bupivacaine, the osmolarity and pH of the analgesic mixture, or the duration of treatment." It appears that they attribute the pathological lesions to tumor invasion, radiation therapy, and treatment with potential neurotoxic agents. Without a control study for substantiation, it would be inappropriate to make such claims that might lead medical professionals to disregard the potential toxicity of bisulfite and EDTA. We have observed nearly all these focal pathological findings in our animal models with use of EDTA (15,25) in the absence of tumor invasion, irradiation, or treatment with neurotoxic agents (Figures 1–4). Irreversible hindlimb paralysis has also been reported after intrathecal bisulfite administration in rabbits (11).

We do not assume that preservatives are responsible for all of the lesions described by Sjoberg et al. (31), but we cannot rule out EDTA and bisulfite as the cause of pathology in some of the patients. Accidental dural puncture, although rare, can be a nuisance in epidural anesthesia. Drugs intended for epidural administration could inadvertently enter the SAS. Therefore, incorporating EDTA in epidural anesthetics may be unwise before its safety is proved. Moreover, the fact that the cases of severe back pain were reported after epidural anesthesia with chloroprocaine containing EDTA suggests that complications can occur even without dural puncture.

We thank Dr. Herman Turndorf, Professor and Chairman of the Department of Anesthesiology of New York University, for his continued support and encouragement. We also thank Dr. Sanford Miller for reading the manuscript.

Prolongation of Epidural Anesthesia Using a Lipid Drug Carrier With Procaine, Lidocaine, and Tetracaine

Lev Langerman, MD, Gilbert J. Grant, MD, Mark Zakowski, MD, Eliahu Golomb, MD, PhD, Sivam Ramanathan, MD, and Herman Turndorf, MD

Department of Anesthesiology, New York University Medical Center, New York, New York

---

This study evaluated the effect of a lipid drug carrier (iophendylate) on epidural anesthesia. The intensity and duration of motor blockade produced by aqueous and lipid preparations of local anesthetics were assessed in rabbits with long-term indwelling catheters in the epidural space. Motor blockades produced by procaine (1%, 2%, and 4%), lidocaine (1%, 2%, and 4%), and tetracaine (0.5%, 1%, and 2%) in normal saline solution were compared with the effects produced by equimolar amounts of the drug solutions in iophendylate. Procaine (4%) in aqueous solution produced motor blockade lasting 30 ± 3.54 min (mean ± SD) versus 84 ± 4.18 min in lipid solution. Lidocaine (2% and 4%) in aqueous solution produced motor blockade lasting 41 ± 4.18 and 65 ± 6.12 min versus 39 ± 4.18 and 118 ± 10.1 min, respectively, in lipid solution. Aqueous tetracaine (0.5%, 1%, and 2%) produced motor blockade of 106 ± 9.62, 189 ± 6.52, and 273 ± 26.8 min versus 284 ± 14.7, 335 ± 15.8, and 365 ± 26.9 min, respectively, in their lipid counterparts. A control group of animals that received normal saline solution or iophendylate alone did not exhibit motor blockade. These results may be attributed to sustained release of local anesthetics from the lipid vehicle. Hence, lipid drug carriers may be effective in prolonging epidural anesthesia.

(Anesth Analg 1992;75:900–5)

Epidural administration of local anesthetic is considered a relatively safe and reliable method for providing anesthesia, postoperative analgesia, and treatment of chronic pain. Local anesthetic may be administered as a single injection, continuously, or in repeated doses. The action of the drug administered as a single injection is time limited, restricted to procedures lasting <2–3 h. Continuous or repeated administration of the drug requires catheterization of the epidural space. A remarkable increase in the popularity of epidural anesthesia during the past two decades was accompanied by reports of complications related to continuous catheterization. These complications included accidental catheterization of the epidural veins (1–3), migration of the catheter subdurally (4–7) or into the paravertebral space (8,9), knotting (10), and breaking (11) during withdrawal. Prolongation of anesthetic action of a single dose may help to avoid epidural catheterization in some cases, thereby preventing the associated complications. The combination of local anesthetics with a vasoconstrictor has been proposed for such prolongation of epidural anesthesia. Epinephrine was found effective in prolonging the anesthetic action of lidocaine (12–14). However, it was found less effective in combination with long-acting local anesthetics, such as bupivacaine (15,16) or etidocaine (14,17). With the implementation of slow-release systems by the pharmaceutical industry, there were few attempts to introduce them for the prolongation of epidural anesthesia. Slow-release pharmacokinetic profiles (18) and prolongation of nerve blocking effect (19) in dogs, using local anesthetics in liposomal formulations, were reported. In previous studies in rabbits, we showed that the pharmacologic effect was prolonged by intrathecally injecting a lipid solution of 1% tetracaine (20) and 5% meperidine (21). On the basis of this approach, the current study was designed to evaluate the effectiveness of different concentrations of procaine, lidocaine, and tetracaine in prolonging epidural anesthesia using drug preparations incorporated in a lipid vehicle.

Methods

The following experiments were performed in accordance with established laws and guidelines and approved by the Institutional Committee of Laboratory Animal Care. Adult male rabbits of Dutch Belt strain

(Millbrook Farms, Amherst, Mass.) weighing 2–2.5 kg were used in this study. The animals were housed individually in standard cages, given free access to food and tap water, and kept on a 12-h light/dark cycle.

Long-term catheterization of the epidural space in rabbits was performed using a modification of the procedure previously used for cannulation of the spinal space that we described elsewhere (22). Briefly, operations were performed under aseptic and antiseptic conditions. Polyethylene tubing PE-10 (Clay Adams, Parsippany, N.J.) 300 mm long, 0.61 mm outer diameter, 0.28 mm inner diameter, was used for catheterization. A ring from the tip of a Luer-type plastic syringe, cut 3 mm from the end, was sealed around the catheter 20 mm from the tip. A nylon monofilament suture 6-0 was tied around the catheter 30 mm from the proximal end and fixed with epoxy glue. Disinfection of the catheters was provided by 70% alcohol. Before implantation, catheters were irrigated with distilled water and proximal tips closed with stainless steel plugs. Animals were premedicated with droperidol (1 mg/kg), atropine (0.1 mg/kg), and ketamine (50 mg/kg) subcutaneously. The surgical fields in the dorsal cervical and lumbar areas were shaved and cleaned with iodine/alcohol solution, and 2% lidocaine (3 mL) was injected subcutaneously over the seventh lumbar spinal process. The skin and fasciae were opened between the sixth lumbar and first sacral processes by midline incision, and muscles were separated by blunt dissection. The seventh spinal process was removed and the ligamentum flavum exposed. The slit in the ligamentum flavum was made, and the distal end of the catheter was inserted caudad. The external portion of the catheter was passed subcutaneously, exteriorized via an incision at the dorsal neck, and tied to a buttonlike polyethylene disk implanted subcutaneously. The internal portion of the catheter was fixed to the periosteum of the posterior lamina. Postoperatively, animals were allowed a recovery period of 24 h and then examined.

Three local anesthetics—tetracaine, lidocaine, and procaine—were purchased from Sigma (St. Louis, Mo.) in hydrochloride and free-base forms. Iophendylate (Pantopaque) was purchased from Alcon Laboratories (Humacaol, Puerto Rico) and normal saline solution from Travenol (Baxter Laboratories, Toronto, Canada). All drug solutions were prepared on the day of experiment, and no preservatives were used. Drugs were administered using 0.25-mL Hamilton syringes (Reno, Nev.) and 30-gauge needles using the infusion pump (Harvard Apparatus, South Natick, Mass.). The injection rate was adjusted to 0.25 mL/min. Solutions were injected in volumes of 100 μL/kg. The dead space of the catheter was irrigated by 40 μL of 0.9% sodium hydrochloride. The dead space of the catheters was evaluated previously and found to range from 15 to 18 μL. Equimolar solutions of hydrochloride and free-base drug forms were adjusted on a molecular weight basis.

Because it was not possible to evaluate sensory blockade accurately in the current model, the anesthetic action was assessed by estimating the intensity and duration of motor blockade. This method was used previously in animal models (23–25) and in humans (26,27) as well. Assessment of the local anesthetic action was performed by observing animal movements using criteria suggested by Feldman and Covino (24) for dogs. Motor blockade was graded according to the scale proposed by Bromage (26) for humans, which we modified for the rabbit model as follows: 0 = free movement of hindlimbs without limitation; 1 = limited or asymmetric movement of the hindlimbs to support the body and walk; 2 = inability to support the back of the body on hindlimbs, with detectable ability to move the limbs and respond to pain stimulus; and 3 = total paralysis of the hindlimbs. To evaluate motor blockade, the animals were removed from the restraining hammocks and placed on the floor at 10-min intervals. The intensity of the motor blockade over time was assessed according to the scale just described and displayed on a graph, as proposed by Van Zundert et al. (27).

In a pilot study, we obtained a reproducible motor blockade produced by repeated epidural injections of local anesthetics 24, 48, and 72 h after the operation. We also found that 4–5 days after cannulation, the effect may be reduced owing to the formation of adhesions around the catheter tip. Because each animal served as its own control, our experiments were conducted within the first 72 h after the operation. A separate group of animals was treated by epidural injection of normal saline solution and then by iophendylate to assess the possible influence of the vehicle or the injection procedure on motor blockade.

Postoperatively, animals were randomly assigned to 10 equal groups (five animals in each group). Randomization was performed before anesthetic administration using a blind combination of two groups of cards. Set 1 contained one card for each rabbit, each of which was assigned a number. Set 2 included nine groups labeled with the name of the drug (lidocaine, procaine, or tetracaine) and a code (A, B, or C) and one group labeled normal saline solution. For the selection of dosage, an "up-and-down" adjustment method was used. If a third-degree block was produced by the initial dose, the next administered dose was decreased twofold. If the initial dose produced only a first- or second-degree block, the subsequent injected dose was doubled. The duration and intensity of the motor block were assessed. Twenty-four hours after injection of the aqueous solution, an equivalent amount of the drug in lipid solution was administered, and motor blockade was again evaluated. The investigator who evaluated the motor blockade was unaware of the identity of the injected solutions. The order of injections (aqueous solutions before lipid solutions) was used because iophendylate remains in the epidural space for a long time. The presence of lipid substance close to the site of injection affects redistribution of the injected drug. Therefore, animals that receive lipid solutions cannot be used for additional experiments.

Concentrations that produced effect in both drug forms were selected for comparison. Finally, three concentrations of each drug were assessed.

Duration, maximal intensity, and onset period of maximal blockade were analyzed by nonparametric tests (Mann-Whitney or the Kruskal-Wallis test, followed by nonparametric Tukey-type multiple-comparisons tests, when appropriate). Differences among variables obtained from lipid versus aqueous solutions within the same animal group were analyzed using the Friedman test. A P value <0.05 was considered the limit for significance.

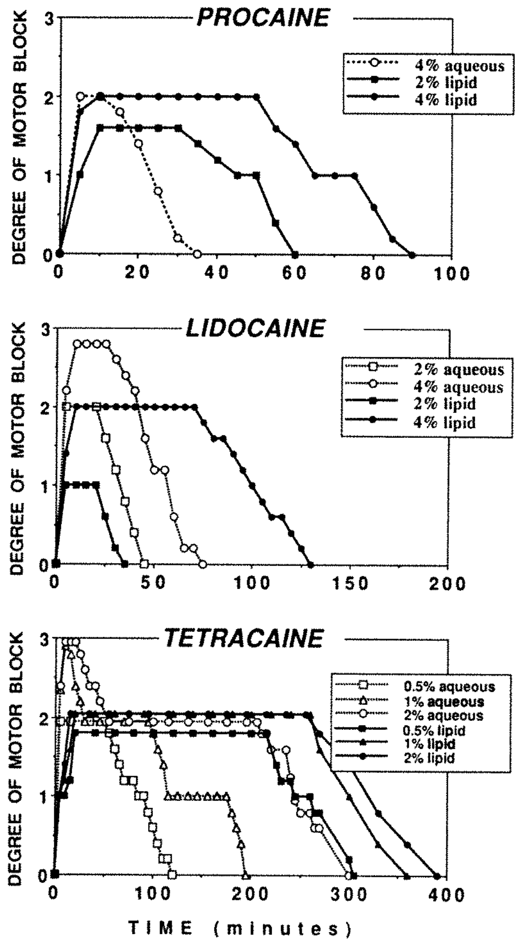

Figure 1. Time-course of motor blockade in response to epidural injections of lipid (iophendylate) versus aqueous (normal saline) solutions of procaine, lidocaine, and tetracaine.

Results

All animals awoke and moved actively using all four limbs within 1 h after the operation. None of the animals developed neurologic deficit or inflammation in the area of the surgery postoperatively. The injections of drugs in the doses assessed during the experiments were easily tolerated by all animals and did not cause noticeable discomfort. However, animals became agitated at attempts to inject the anesthetics in concentrations >4%. Pain was probably caused by the high osmolarity of the administered solutions. The maximal concentration of the injectate was therefore limited to 4%. Finally, the following solutions were assessed: 1%, 2%, and 4% of procaine; 1%, 2%, and 4% of lidocaine; and 0.5%, 1%, and 2% of tetracaine. The duration and intensity of the motor blockade produced by epidural injection of the drugs are expressed graphically in Figure 1.

Administration of 2% procaine in normal saline solution and 1% procaine or lidocaine in both (lipid or aqueous) solvents did not produce motor blockade in any of the treated animals.

The intensity of motor blockade produced by epidurally injected local anesthetics in the same solvent increased as a function of drug dosage. A significant increase in the intensity of the motor blockade, as a result of increasing the drug concentration, was found among lipid solutions of 2% and 4% lidocaine, aqueous solutions of 2% and 4% lidocaine, and aqueous solutions of 0.5% and 1% or 2% tetracaine. Differences among the maximal effects produced by other solutions did not reach significant levels.

The onset of maximal motor blockade produced by aqueous and lipid solutions of the drugs ranged from 5 to 10 and 5 to 20 min after the injection, respectively. No significant differences were found between these onset periods among different concentrations of drugs in the same preparation form. Duration of motor blockade significantly increased with the increase of the injected dose among all of the anesthetics tested (Figure 1).

A comparison between the effects produced by equal concentrations of anesthetics in aqueous versus lipid solution revealed the following results: (a) aqueous and lipid solutions of 4% procaine produced a similar intensity of motor blockade; (b) aqueous solution of 2% procaine did not produce motor blockade in contrast to the lipid preparation, which produced motor blockade in all treated animals; and (c) aqueous solutions of lidocaine and tetracaine produced significantly higher degrees of motor blockade than equivalent concentrations of lipid preparations, except for 0.5% tetracaine, which produced similar degrees of motor blockade in both preparations.

Motor blockade produced by aqueous and lipid solutions of procaine and lidocaine reached maximal effect between 5 and 10 min and did not show significant differences between the two preparation forms. Motor blockade produced by aqueous and lipid solutions of tetracaine reached maximal values within 5–10 and 10–20 min, respectively. The differences between the two formulations were significant in all three concentrations tested. A comparison between the durations of motor blockade produced by equivalent drug concentrations in different solvents showed a significant prolongation of motor blockade in animals treated by lipid solutions, except for 2% lidocaine (Figure 2). Durations of motor blockade produced by assessed solutions and ratios between equivalent anesthetic concentrations in the lipid versus aqueous preparation are presented in Figure 2.

Animals treated by epidural administration of normal saline solution or iophendylate did not show any degree of motor blockade.

Discussion

Our study examined the possibility of prolonging epidural anesthesia by using a lipid drug carrier. The mechanism for prolonging the local anesthetic action in this study was based on the different solubilities of two drug forms (salt and free base) in aqueous and lipid solvents. The water-soluble salt form of the drug was dissolved in normal saline solution. The lipid-soluble free-base form of the drug was dissolved in iophendylate, which was synthesized as iodized fatty acids. (The base form of most local anesthetics is lipid soluble and nearly insoluble in water [28].) Clinical use of iophendylate in humans is controversial because of the possibility of aseptic arachnoiditis. We used iophendylate in our study as a model of a lipid drug carrier. Other lipids or lipid-based vehicles (e.g., liposomes, emulsions) may be suggested and developed in the future. In each case, pharmacologic and toxicologic studies will be required before final implementation of any new formulation in clinical practice.

Local anesthetics injected into the epidural space in aqueous solutions easily diffuse into the interstitial fluid and are then absorbed by epidural fat and neural roots. Local anesthetics injected epidurally in lipid solution to reach the neuraxis need to diffuse from the lipid medium into the interstitial fluid. The base form of the anesthetics is insoluble in aqueous medium and therefore should pass preliminary ionization. Because the process of ionization is limited to the surface between the lipid and aqueous milieu, only a small amount of the drug is available to pass it and diffuse from the solvent toward the neuraxis at any given time. Hence, the lipid solvent serves as a drug depot, and the injected solution acts as a sustained-release formulation.

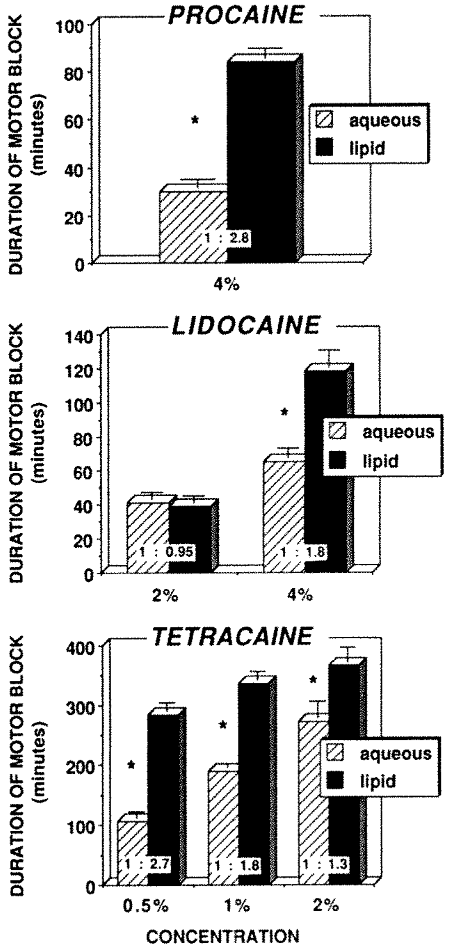

Figure 2. Duration of motor blockade produced by epidural injection of procaine, lidocaine, and tetracaine. *Hatched* and *solid bars*, mean responses to injections produced by equivalent concentrations of anesthetic in aqueous versus lipid solution, respectively; *numbers in boxes*, aqueous/lipid ratio of duration; *error bars*, SEM. *Significant differences between durations produced by the aqueous and lipid solutions.

We injected various concentrations of procaine, lidocaine, and tetracaine epidurally in aqueous and lipid solutions and assessed their anesthetic action by evaluating the intensity and duration of the motor blockade. We believe that it would have been preferable to use sensory in addition to motor blockade to evaluate anesthetic action in the present study, but for technical reasons, the current model did not permit us to evaluate sensory blockade for longer than 2 h. We acknowledge that some discrepancy may exist between motor and sensory blockade. However, the pattern of their action is similar, and their molecular mechanism is the same. Therefore, motor blockade has previously been used as a marker of local anesthetic action (23–27), and we used it to compare the effects produced by aqueous and lipid solutions of local anesthetics in the current study.

A comparison between the effects produced by two different treatments can be designed in two distinct ways: using two different groups of patients or using each patient as his or her own control. The latter design is optimal if the order of treatment is randomized. In our study, a constant order of injections (aqueous solutions always before lipid solutions) did not permit randomization of the aqueous and lipid injections. However, we believe that by randomizing the injections of the aqueous solutions, using different investigators to inject the drug and to evaluate the effect, and not informing the latter investigator of the identity of the injected solution, we avoided the influence of bias on the results.

Our study showed that epidural injection of local anesthetics in lipid solutions produced a longer effect than the injection of aqueous drug solutions. This prolongation of anesthetic action may be attributed to the limited rate of drug release from the lipid solvent. Our data suggest that a lipid drug carrier can be used as a vehicle in a slow-delivery system for prolongation of local anesthetic action.

A comparison between the effects produced by two formulations of 2% lidocaine, which was the lowest effective concentration in the present study, showed a decrease of the motor blockade duration produced by the lipid preparation. This might occur because the relatively small amount of anesthetic released from the lipid solution was insufficient for maintaining the drug concentration on the nerve tissue at an effective level. Evidently, when the concentration of the lidocaine was increased to 4%, the lipid solution of the anesthetic produced a significantly longer motor blockade than the aqueous solution.

Lipid solution of 2% procaine produced motor blockade of second degree in all treated animals, but an equivalent amount of the drug in aqueous solution did not produce any effect. Most likely, because of the poor lipid solubility of procaine (29), its uptake from the aqueous solution into nerve membranes or epidural fat is relatively low. Therefore it is possible that a considerable portion of the drug undergoes vascular absorption by bulk flow before reaching the neuraxis. Lipid solution of procaine was absorbed very slowly and remained in the epidural space for a longer period of time. Evidently, the rate of the procaine release from the lipid solution was sufficient to maintain an effective concentration on the nerve tissue. As a result, lipid solution of 2% procaine produced motor blockade, and the equivalent concentration of aqueous solution did not produce any effect.

Finally, among local anesthetics tested in this study, only tetracaine was effective in producing considerably prolonged motor blockade. This is most likely due to its exclusively slow release from the iophendylate. This may be explained by the strong affinity of tetracaine to a lipid vehicle (30) owing to its high partition coefficient (29), compared with those of lidocaine or procaine. The duration of effect produced by different concentrations of lipid formulations of tetracaine lasted from 5 to 7 h. This finding clearly indicates that appropriate lipid formulations of local anesthetics may considerably prolong epidural anesthesia. Hence, the development of lipid or lipid-containing vehicles for local anesthetics may, in particular cases, be helpful in avoiding the continuous catheterization of the epidural space and in replacing it with single injection of drug.

Subblocking Concentrations of Local Anesthetics: Effects on Impulse Generation and Conduction in Single Myelinated Sciatic Nerve Axons in Frog

Stephen A. Raymond, PhD

Anesthesia Research Laboratories, Brigham and Women's Hospital and Harvard Medical School, Boston, Massachusetts

Phenomena seen in axons exposed to subblocking doses serve as the basis for interpreting clinical and behavioral observations during onset and recovery of peripheral nerve block. To delineate the changes in excitability and in impulse conduction caused by subblocking concentrations of local anesthetics (LAs) in myelinated peripheral nerve fibers, LAs were applied to excised frog sciatic nerves while impulse conduction was monitored in single axons. For concentrations ranging from 0.01 to 1.2 times the LA concentration needed to block impulse conduction, three measures of susceptibility to LA were made to quantify the action of the drugs on "resting" fibers (firing rates ≤0.5 Hz): the increase in the threshold for electrical activation of impulses, the increase in conduction latency reflecting the slowing of impulse conduction in the region exposed to LA, and the "critical blocking concentration" of LA just sufficient to prevent impulse conduction in the recorded fiber. Wide interfiber variation in these variables was observed (e.g., for lidocaine, latency increases at block ranged from 66% to 257% of control, blocking concentrations ranged from 0.29 to 1.40 mM), which was not correlated with fiber diameter (as indicated by resting conduction velocity). Mathematical modeling of impulse conduction in fibers exposed to LA demonstrated that the interfiber variation in susceptibility to LA block could result from interfiber differences in the density of sodium and potassium channels. The effects of LA were also studied in active fibers (firing rates >0.5 Hz). Local anesthetics reversibly inhibited two normally occurring afteroscillations in membrane threshold related to afterpotentials following an impulse. These were "superexcitability," a transient lowering of threshold lasting as long as 1 s, and "depression," a phase of raised threshold peaking within 2–4 s after an impulse and recovering slowly over several minutes. Impulse activity also transiently increased the apparent potency of LAs. Such "use-dependent" increases in threshold and decreases in conduction velocity showed kinetics that were agent specific, lasting 1 s after a burst of impulses for lidocaine and lasting >10 s for bupivacaine. At low concentrations, within the range of nontoxic plasma concentrations after systemic administration, the predominant actions of LAs on conducting fibers were transient decreases in excitability and conduction velocity in combination with a reduction of intrinsic oscillatory aftereffects of impulse discharge. These effects may degrade decoding of information in discharge patterns without actually blocking conduction of infrequent impulses, suggesting how functional blockade of coordinated movement and perception may occur even without complete blockade of impulse conduction.

(Anesth Analg 1992;75:906–21)

During onset and regression of peripheral nerve blocks with local anesthetics (LAs), the nerve fibers are exposed to subblocking concentrations. Psychophysical studies of partially blocked nerves have shown a curious failure of function even under conditions where blockade of impulse conduction is incomplete, as in the case where the sensation of cooling the skin is prevented even though Aδ fibers can still conduct impulses in response to electrical stimulation (1). The intent of the experimental studies reported here has been to observe and describe the actions of LAs on the processes underlying impulse conduction. These processes also modulate membrane excitability and thereby influence impulse generation in fibers. By studying excitability and latency in conducting fibers subjected to patterns of impulse discharge ranging from isolated impulses to high-frequency trains, we hoped to derive an integrated picture of the interactions between LAs and impulse activity.

The basis for the anesthesia produced by LAs was first deduced from observations of compound action potentials, which decreased in amplitude as the im-

pulses in individual fibers were blocked. It is now established that the primary mechanism of this blocking action is the attenuation of depolarizing Na^+ current as documented by voltage-clamp studies of squid axon and of single nodes of Ranvier, and more recently by studies of small patches of membrane containing one or more ion channels (2). The effects of LA on propagated impulses in individually recorded conducting fibers were first reported by Franz and Perry (3). That study and subsequent work with single fibers of vagus nerve (4) provided important evidence *against* the size principle of susceptibility to LA, which has held that susceptibility of axons to conduction block by LA depends on axon diameter, being greater for smaller diameter axons (5). Given the doubt about the relevance of axon size determining differential susceptibility, it is important to learn what other factors may be important. Our work was done to characterize how sensitive particular axons are to LA and to investigate the extent and basis for interfiber variation.

We have studied actions of LAs on individually recorded myelinated fibers in a mixed nerve where 2–6 cm of the conduction path was exposed to LA, exceeding the exposure length over which decremental conduction will substantially raise the concentration of LA (abbreviated here as [LA]) needed to block impulse propagation (6). By tracking both the speed of impulse propagation (by measuring the conduction latency) and the level of stimulation needed to generate an impulse (by measuring the firing threshold), it is possible to observe effects of LAs at subblocking concentrations for impulse conduction. Because action potentials thus continue to conduct, it was also possible to study the interactive effects of impulse activity and LA, some of which are revealed in the intact fiber but have not been reported in studies of dissected nodes or isolated channels. These include afterpotentials and afteroscillations in membrane excitability, which are intrinsic to conducting fibers (7) and which may be important in impulse interval coding (8–10). Disruption of such codes may block the "message" of the fiber without preventing conduction of all of the impulses carrying the message (11).

Methods

Sciatic nerves were excised from large frogs, *Rana pipiens*, after pithing of brain and spinal cord by experienced personnel. The investigations were authorized in proposals approved by the Harvard Medical Area Standing Committee on Animals. This report is based on integrated observations from 170 nerves and >200 fibers.

Nerve Support

The nerves were placed in a Boyle-Conway saline-glucose solution bubbled with 3%–6% CO_2 in air, containing (in mM): NaCl 80.5, KCl 2.1, $CaCl_2$ 1.8, $MgSO_4$ 1.2, Na_2SO_4 0.66, $NaHCO_3$ 25.0, Na_2HPO_4 2.6, KH_2PO_4 0.5, and glucose 3.3. The Pco_2 was adjusted to hold pH at a constant value (±0.05 pH units) between 7.3 and 7.4. Temperature was regulated at 18 ± 0.5°C using a Peltier device. The nerve sheath was left intact except for the last 1 cm of the conduction path, where fibers were teased apart for recording with small-diameter plastic suction electrodes. Two pairs of stimulating electrodes were used, one to condition the fiber by evoking trains of conducted impulses and the other to test for threshold by applying stimuli just strong enough to activate the single fiber under study. Stimulating pulses were monophasic current pulses the intensity and duration of which were adjusted either to be well above threshold for conditioning or to be at threshold for testing the membrane excitability. Fibers could be studied for ≥2 days under these conditions, so most data are from one fiber per nerve.

Excitability Measurement and Determination of Blocking Concentration

Impulse conduction velocity (conduction distance divided by the latency) and the threshold for electrical activation of a conducted impulse (threshold [in coulombs], the product of pulse current intensity and pulse duration) are indications of the relative excitability of the membrane. Latency was measured for each conducted impulse using a latency meter that we constructed to produce a voltage proportional to the time interval between the rising edge of the stimulus and the arrival of an impulse at the recording electrode. The impulse was detected by a Schmitt trigger set to undergo a transition during the steepest section of the rising phase of the impulse, thus minimizing the temporal fluctuations resulting from recording noise. Threshold was "hunted" (7) by adjusting the stimulus strength automatically so as to maintain the probability of triggering a conducted action potential at 50%. This was achieved by a decremental decrease of the stimulus after a response and an incremental increase by the same small amount (0.25%–1% of either the duration or the amplitude of the stimulus pulse) after each failed stimulus. Local anesthetics (lidocaine, bupivacaine, and 2-chloroprocaine) supplied by ASTRA Pharmaceuticals (Westborough, Mass.) were dissolved in Boyle-Conway solution at concentrations such that adding 0.1 mL to the solution bathing the conduction path would raise the bath concentration of LA by

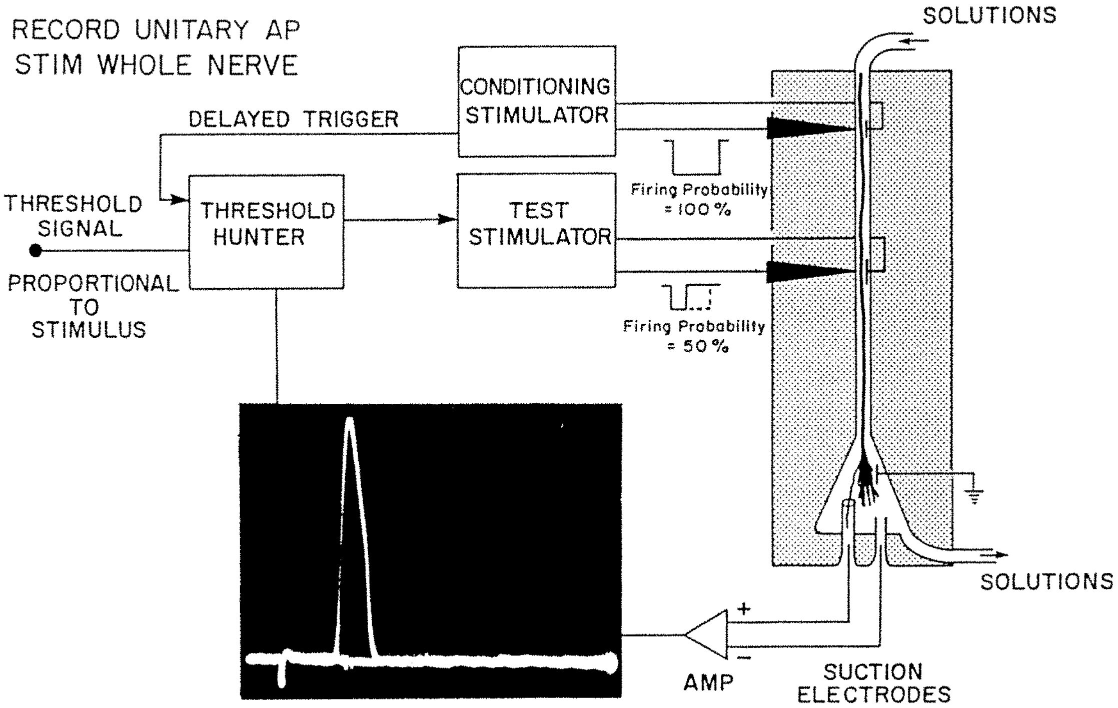

Figure 1. Diagram of preparation. The action potential (AP) *inset* is a photograph from the oscilloscope showing two overlapping sweeps. One was a flat trace after a failed stimulus at slightly below threshold intensity, and the other exhibited a unit potential recorded from a large fiber at the far end of the conduction path after a successful stimulus just above threshold intensity. Thus, traces were either flat (note the baseline under the potential) or unitary with an easily detected spike, and the entire conduction path including the recording site could be exposed to local anesthetic in the circulating solutions without obscuring the detection of impulses. The threshold hunter controlled both the amplitude and duration of stimuli. It lowered the next stimulus whenever an action potential occurred and raised it whenever the stimulus failed, thus converging on the 50% firing probability. Latency was measured for conduction from the test electrode (connected to the "test stimulator") to the tip of the recording electrode (5–6 cm).

0.1 mM (Figure 1). To measure the blocking concentration of LA, [LA] was increased in steps, each followed by an equilibration time. The critical blocking concentration (C_b) was determined by interpolation between the highest nonblocking dose and the next increment in [LA] that resulted in conduction failure during the equilibration time. The interpolation was based on exponentials fit to the latency increases measured in the fiber before blockade (Figure 2B). In all cases of blockade, the impulses were restored on washing with LA-free solution. For fiber 25 (Table 1) the C_b was replicated three times by repeated 0.05-mM supplements and dilutions at 1.35-mM concentration.

Tonic and Phasic Effects

A "tonic" action of LAs on excitability was determined by using infrequent test stimuli given at sufficiently long intervals (2 s for lidocaine and 2-chloroprocaine; 20 s for bupivacaine) that any "phasic" or transient effects of previous impulses had decayed. Conditioning impulses given at such long intervals are called "singlet" conditioning pulses (CPs). Effects of impulse activity in the presence of LAs were studied by stimulating the nerve with conditioning bursts of 1–64 CPs and then testing the threshold at various delays afterward. The transient afteroscillation in threshold was plotted by incrementing the delay of the test stimulus from the singlet CPs or from the last pulse of repeated conditioning bursts. The rate of repetition was determined empirically to be slow enough that no cumulative effect on tonic threshold was seen.

Means are reported ± the SD based on the number of degrees of freedom ($N - 1$). Correlation coefficients (r) were calculated by linear regression under Quattro Pro 3.0 (Borland, Scotts Valley, Calif.); Z scores were computed by multiplying r by the square root of the number of degrees of freedom, and r values were considered significant for $P < 0.01$.

Mathematical Models

Computer simulations of conducted action potentials were used to determine the degree of interfiber variation in susceptibility to LAs that would be expected on the basis of variations in densities of

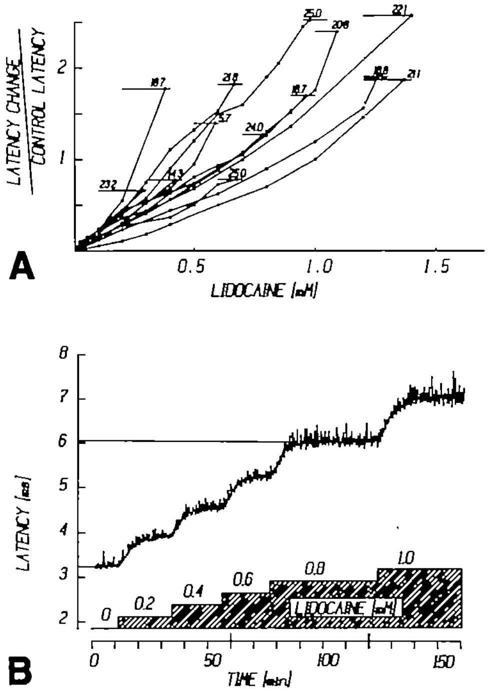

Figure 2. A. The fractional increase in latency (the increase in latency normalized by the resting latency) was measured (*circles*) after equilibration to increments of lidocaine concentration. The resting conduction velocity (m/s) for a particular fiber before application of lidocaine is shown above the *horizontal line* terminating each curve, which is drawn at the maximal latency attained before conduction block. The line spans the increment in lidocaine concentration between the last concentration at which equilibration was complete without block and the next increment in concentration that resulted in block at or before complete equilibration. Latency for each conducted impulse was plotted throughout the exposures (as shown in part B for example, Fiber 4 in Table 1; stimuli at 0.5 Hz). The steady-state latency reached after each increment was taken graphically by fitting a line by eye to the lower edge of the commonly occurring latencies (for example, the bottom of the "*solid*" part of the trace, as shown for the control latency and the latency after equilibration with 0.8 mM lidocaine). The occasionally longer latencies, appearing as spikes in the temporally compressed curve, occur because of delays in the generation of conducting impulses that can result when stimulation is near the threshold (9). During the equilibration to the highest concentration, the latency-versus-time plots were used to estimate whether equilibration had just begun or was nearly complete before the block in impulses occurred, and thus to interpolate a value for the critical blocking concentration (C_b). Slope sensitivities were measured at half the C_b.

voltage-gated ion channels. The mathematical model for the squid giant axon of Hodgkin and Huxley (12) was modified for myelinated frog fibers as follows. The ionic currents at nodes (i_{HH}) were given by Crank-Nicholson integration (13) of Equation (1) at 25-μs intervals for each of 31 sequential nodes connected by passive internodes:

$$i_{HH} = \bar{g}_{Na}m^3h(v - E_{Na}) + \bar{g}_K n^4(v - E_K) + g_l(v - E_l), \qquad (1)$$

where $\bar{g}_{Na}$ and $\bar{g}_K$ are the maximal specific conductances for Na^+ and K^+ and g_l is the voltage-independent "leak" conductance; E_{Na}, E_K, and E_l are the Nernst equilibrium potentials for Na^+, K^+, and leak-permeable ions; and m, h, and n range between 0 and 1, depending on membrane voltage and time according to equations of the type

$$dm/dt = \alpha_m - (\alpha_m + \beta_m)m, \qquad (2)$$

and similarly for dh/dt and dn/dt, where α and β are rate constants that depend only on membrane voltage and temperature and at 18.5°C, the temperature of the simulation, are given by

$$\alpha_m = 3.82[0.1(-V + 25)/e^{(-V+10)/10} - 1],$$

$$\beta_m = 3.82[4e^{-V/18}], \qquad (3)$$

$$\alpha_h = 3.82[0.07e^{-V/20}],$$

$$\beta_h = 3.82[1/(e^{(-V+30)/10}+1)], \qquad (4)$$

$$\alpha_n = 3.82[0.01(-V + 10)/(e^{(-V+10)/10} - 1)],$$

$$\beta_n = 3.82[0.125e^{-V/80}], \qquad (5)$$

where V is the membrane potential relative to a resting potential of -65 mV, and v in Equation (1) is the now conventional membrane potential inside relative to outside (i.e., v = -65 mV, when V = 0 mV). Values adopted for the fixed parameters were $\bar{g}_{Na}$ = 1.20 mho/cm^2 at nodes and 0.0 mho/cm^2 at internodes; $\bar{g}_K$ = 0.36 mho/cm^2 at nodes and 0.0 mho/cm^2 at internodes; g_l = 0.001 mho/cm^2 and capacitance = 1 μF/cm^2 for nodal, internodal, and Schwann cell membrane; E_{Na} = +50 mV, E_K = -77 mV, and E_l = 54.402 mV. The passive internodes were each represented by five separately computed segments of 10-μm diameter wrapped with 250 layers of myelin, which was modeled as decreasing the leakage conductance and the membrane capacitance in proportion to the reciprocal of the number of myelin layers (1/250).

Tonic blockade of Na^+ channels was modeled as a first-order process by reducing the density of available channels, $\bar{g}_{Na}$, by the factor $K_d/([LA] + K_d)$, where K_d is the equilibrium dissociation constant (in mM) for binding of LA to Na^+ channels, and [LA] is the concentration of LA (in mM). The tonic blockade of K^+ channels was also incorporated into this model by multiplying $\bar{g}_K$ by the analogous factor for binding of LA to K^+ channels. Use-dependent binding is an incremental effect mainly on Na^+ channels that occurs during the depolarization for each action potential. Use-dependent binding was modeled by multiplying a proportional rate constant for forward binding (0.5 ms^{-1}·mM^{-1}) by the [LA], by dt, and by the fractional increase in Na^+ conductance during the action potential, $g_{Na}(t)/\bar{g}_{Na}$, (14), where the depolarization exceeded 3% of the resting potential. The unbinding of LA from these phasically bound chan-

[a] Fibers 1–13 and 25 were exposed to lidocaine over the entire conduction path. Thresholds and latencies were measured throughout the exposure and wash. In fibers 14–24, the critical blocking concentrations (C_b) were measured with 2–3 cm of the conduction path exposed to lidocaine, and thresholds were not measured. Mean (± SD) C_b = 0.88 ± 0.35 mM.

[b] There was no significant correlation of the resting conduction velocity (CV) with measures related to conduction safety (i.e., with C_b, maximal change in threshold, or maximal change in latency).

[c] Slope sensitivity, expressed as percent change in latency per mM, did not predict the degree of maximal increase in latency ($r = 0.134$) but was weakly indicative of the blocking concentration ($r = 0.51$; $P < 0.045$ for latency slope sensitivity vs C_b).

[d] Fibers most resistant to block tended also to show the largest maximal latency ($r = 0.72$; $P < 0.009$ for maximal latency and C_b).

[e] Fibers showing a large increase in latency also showed a large increase in threshold ($r = 0.78$; $P < 0.005$ for maximal latency vs maximal threshold).

nels was modeled by multiplying a reverse proportional rate constant, 0.025 ms^{-1}, (14) by the proportion of phasically bound channels and by dt. I wrote the model as a FOCAL program in the CABLE environment (13) supplied by Dr. Michael Hines, and the simulation was run on an Everex Step 20 80386 microcomputer. Percentage changes in latencies for conduction of action potentials from the first to the 25th node in the model were exported to Generic Cadd (Generic Software, Bothell, Wash.) and plotted on an HP Laserjet III offset printer.

Results

Tonic Actions on Excitability and Blockade

Stepwise increases in [LA] result in progressive increases in the firing threshold (15) and in the latency of impulse conduction (Figure 2). After each step in [LA], the latency and threshold initially increased rapidly, arriving at a new stable level over the course of 7–25 min (sheath intact), reflecting equilibration of the LA with sites distributed along the axon in the exposed region of the nerve. The latency at steady state was longer at higher concentrations, and impulses were conducted at their slowest possible rate in these fibers at [LA] values just below those causing conduction failure. The increase in latency before block with lidocaine in the population of 13 A-fibers exposed over the entire conduction path to blocking concentrations ranged from 66% to 257% of the control latency, revealing significant interfiber variation (Figure 2). The tonic blocking concentrations were interpolated (see Methods) using records tracking the latency for each conducted impulse (such as in Figure 2B). Blocking concentration (C_b) is a traditional measure of susceptibility of an axon to LA, and the range of C_b values measured to within 0.05 mM in 25 fibers (0.29–1.40 mM) is a second indication of interfiber variation in susceptibility (Table 1).

Another measure of tonic susceptibility to LA that can be used to compare susceptibility to LA among different fibers at subblocking concentrations is the "slope sensitivity" of a fiber, referring to the degree of slowing (or of raised threshold) per unit increase in [LA]. Exposure to weak concentrations (e.g., <0.3 mM lidocaine in Figure 2A) was sufficient to differentiate axons according to this measure, and axons that showed a high slope sensitivity relative to the other fibers at low concentrations tended to preserve their relative susceptibility by this measure over higher concentrations (Figure 2A). However, high slope sensitivity to LA did not necessarily ensure that block would occur at low concentrations, because in some fibers the latency increase before block could be more than three times greater than in other fibers. The maximal change in threshold before block (Table 1) also was not strongly correlated with C_b ($r = 0.29$), although maximal latency change was larger for axons with higher C_b ($r = 0.72$; data from Table 1). Despite its weak correlation with C_b ($r = 0.51$), the latency slope sensitivity was not a reliable

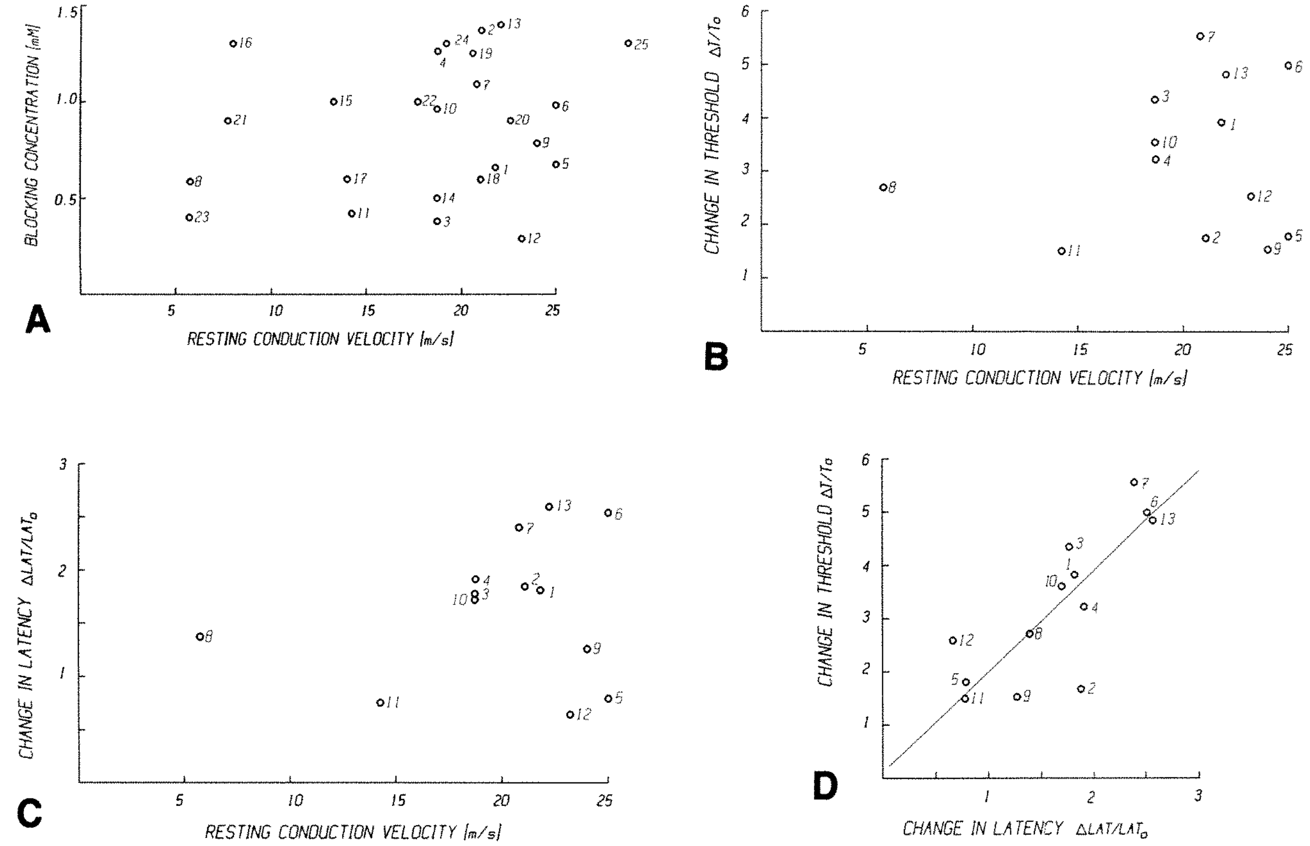

Figure 3. Susceptibility versus conduction velocity (CV). **A.** Tonic blocking local anesthetic concentration [LA] versus resting CV for 25 axons exposed over lengths >2 cm and for which the critical blocking concentration (C_b) is known within 0.1 mM (r = 0.23; $P < 0.15$). **B.** Maximal change in the tonic threshold as a factor of control threshold (difference in the product of stimulus current [mA] times stimulus pulse duration [μs] measured just before block of impulse conduction and that measured under control conditions before application of lidocaine divided by the control threshold) versus CV for 13 fibers (r = 0.17; $P < 0.29$). **C.** Maximal change in latency (ΔLAT) as a factor of the control latency (difference between latency measured just before block and control latency normalized by the control latency) versus CV for the same 13 fibers as in **B** (r = 0.16; $P < 0.29$). The fibers in **A** and **B** were exposed over the entire conduction path. *Data points* from each fiber are from Table 1. **D.** Significant correlation between the maximal change in threshold before block in a given fiber (**B**) and the maximal change in latency (ΔLAT) for the same fiber (**C**) (r = 0.78; $P < 0.005$).

predictor of blocking concentration. For example, the five fibers conducting at 14.3, 24.0, 18.7, 20.8, and 22.1 m/s in Figure 2A show nearly overlapping slope sensitivity for latency (138%–177%/mM determined at $C_b/2$), yet range in C_b from 0.42 to 1.4 mM. These two measures of susceptibility to LA (latency slope sensitivity and C_b) thus varied somewhat independently among fibers, indicating that multiple factors in the axon govern its sensitivity to LA.

None of the measures of blocking susceptibility to LA (C_b, the maximal threshold increase, or the maximal latency increase before block) were strongly related with resting conduction velocity (Figure 3A–C). Axons showing larger increases in threshold after a dose of LA also tended to show relatively larger increases in latency. The maximal changes in latency and threshold shown just before block (Table 1) reflect this correlation (r = 0.78; Figure 3D).

Simulations of Interfiber Variation

Mathematical models of impulses conducting in single frog axons have been used to test whether variation in the density of Na^+ and K^+ channels could account for interfiber variation in tonic susceptibility to LA. Structurally, the model fiber used for the data shown in Figure 4 was 10 μm in axon diameter, with nodes 1.3 mm apart and internodes wrapped by 250 layers of myelin (see Methods). Its resting conduction velocity was 22.8 m/s over a conduction distance of 3.25 cm with no LA present. Changing only the density of K^+ channels ($\bar{g}_K$) over a range of 40%–200% of the control density (Figure 4) changed the resting conduction velocity (CV) by <10% (24.2 m/s for 40% $\bar{g}_K$ and 20.5 m/s for 200% $\bar{g}_K$), but it altered slope sensitivity measured at half the C_b by >65% (72.4% per mM for 40% $\bar{g}_K$, 98.8% per mM for

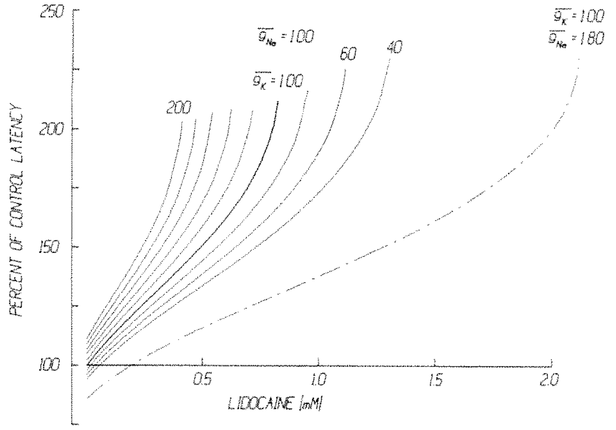

Figure 4. Change in latency during exposure to lidocaine as predicted from a computer model of conducting frog fibers (13,32). A family of curves relates the percentage increase in latency to lidocaine concentration in the same manner as the experimental results shown in Figure 2. Curves were calculated for a 10-μm-diameter fiber with 1.3-mm passive internodes at 18.5°C. Latency was measured for a propagated action potential stimulated at node 0 and recorded 25 nodes away when the membrane potential at that node crossed −30 mV. Block (defined when the membrane potential of the 25th node did not increase above −30 mV) was titrated to within 10 μM. Thus, the last plotted latency was measured for exposure of 25 identical nodes to a lidocaine concentration (K_d for g_{Na} = 0.2 mM; K_d for g_K = 0.6 mM) within 10 μM of that required to block propagation. The nodal density of Na^+ channels was taken as proportional to the Hodgkin and Huxley (12) variable $\bar{g}_{Na}$ (10 times $\bar{g}_{Na}$ for squid giant axon [32]). It was assumed that all 25 nodes were alike in $\bar{g}_{Na}$ and in $\bar{g}_K$ (19). Curves were plotted for 20% increments of the nodal density for K^+ channels over the range 40%–200% of the "normal" value (10 times the $\bar{g}_K$ for squid giant axon). Increasing K^+-channel density increased the slope sensitivity of the model fiber to lidocaine while simultaneously decreasing C_b. Thus, with the model, C_b and slope sensitivity were correlated, whereas experimental results on different fibers showed little correlation, suggesting that additional variables as well as channel densities vary from fiber to fiber. Decreasing and increasing K^+-channel density (Na^+-channel density held constant at 100%) altered resting latency over a range of −7% and +11% of the control condition (*bold curve*, $\bar{g}_K$ and $\bar{g}_{Na}$ = 100%). The *dashed curve* shows the effect of increasing the density of Na^+ channels to 180% of control without changing the K^+-channel density (at 100%). This reduced the slope sensitivity (44.6% per mM at $C_b/2$) with a parallel increase in C_b (to 2.10 mM). The maximal latency increase before block was only slightly greater than for the other ratios of channel densities shown. (See text for explanation of variables).

control, and 167.8% per mM for 200% $\bar{g}_K$). It also changed the blocking concentration by >50% (1.30 mM for 40% $\bar{g}_K$, 0.82 mM for control, and 0.41 mM for 200% $\bar{g}_K$), as shown by the family of curves in Figure 4. Note that the rate of increase in latency with LA was steepest as the [LA] approached the C_b, an effect seen also in several of the biological fibers (Figure 2). Increasing the density of Na^+ channels ($\bar{g}_{Na}$) in the model had the effect of reducing slope sensitivity and of increasing the [LA] required to block conduction (dashed curve in Figure 4, where C_b nearly tripled for a 180% increase in $\bar{g}_{Na}$, with $\bar{g}_K$ at the normal value).

The range of slope sensitivities for latency (measured at $C_b/2$) in biological fibers was approximately fourfold (100% per mM to 414% per mM; Table 1; Figure 2). In model fibers with normal $\bar{g}_K$, varying Na^+-channel densities from 0.5 to 2 times the average (control) level, which is in accord with estimates for Na^+-channel densities based on differences among nodes under voltage-clamp (16,17), resulted in slope sensitivities ranging from 331% to 38% per mM, but always with a corresponding change in C_b. Thus, varying channel densities could account for interfiber differences observed in slope sensitivity, but not simultaneously for the independence of C_b.

Effects of Local Anesthetic on Activity Dependence

Membrane voltage and excitability normally undergo afteroscillations following propagation of an impulse, even in the absence of LA. These afterpotentials and excitability changes, which are reflected both in threshold and in latency, occur in central and peripheral axons (see Swadlow et al. [10] for review). The excitability changes are called "activity dependence." Activity dependence is prominent in frog sciatic fibers, where a short-term (<1 s) "superexcitable" phase (see control trace, Figure 5C), corresponding to a depolarizing afterpotential (18), and a longer lasting (several minutes) "depression" phase (Figure 6A) have been distinguished (7). In the intact frog fibers used here, we found that activity dependence was susceptible to low concentrations of LA.

Effects on superexcitability. In frog fibers, superexcitability is near its maximum 20 ms after the conditioning impulse (7). In these experiments, the firing threshold at this 20-ms delay after singlet conditioning pulses (CPs) was reduced by an average of 23.8% ± 6.9% (n = 29), with no LA present. A burst of impulses is known to produce a greater peak superexcitability than a single impulse does, and bursts of 8–10 impulses suffice to maximize this additive effect (7). Therefore, in these experiments maximal peak superexcitability was estimated by the peak superexcitability at the 20-ms delay after the last pulse of a 50-Hz burst of eight CPs and was approximately twice the peak superexcitability after singlet CPs, with the threshold descending by an average of 39.6% ± 19.2% (n = 25). After a 200-ms delay from a singlet CP, the threshold had usually increased from peak superexcitability to within 5%–10% of the resting threshold, but it was always at least slightly below the resting threshold at this delay, ranging from −1% to −28.5% (−8.8% ± 13.6%; n = 28). Stimulating at this 200-ms delay thus was a way of sampling membrane excitability during the recovery of superexcitability. By monitoring the threshold at

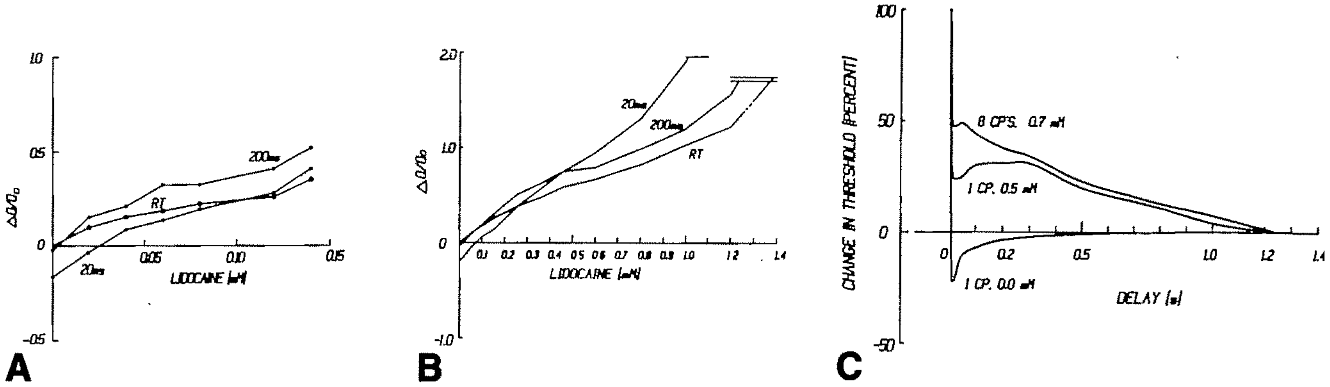

Figure 5. Effect of lidocaine on activity dependence. **A.** Threshold was expressed as the product of intensity and duration (i.e., the charge, Q, delivered) of stimuli at threshold level. The relative increase in threshold (change (Δ) in Q/resting threshold with no lidocaine, Q_0) is plotted after equilibration with 20 μM increments in lidocaine concentration. RT, curve for tonic threshold (threshold level stimuli given every 2 s); 20 ms, thresholds measured 20 ms after singlet conditioning impulses; and 200 ms, thresholds measured at that delay. In two nerves repeatedly exposed to 1 μM increments and washes, no effect on resting threshold was detectable below 10 μM, but superexcitability at 200 ms after an eight-pulse burst was reduced even at 1 μM by >25%. Five fibers exposed to 10 μM initial increments in concentration all showed increased thresholds at 200 and 20 ms after singlet conditioning pulses (CP) and eight-CP bursts. Conduction velocity (CV) = 23.6 m/s. **B.** Threshold versus lidocaine concentration as in **A** but for concentrations from 50 μM to blocking concentration(s). The 20-ms delay threshold shows initial superexcitability of 19.6%. The threshold at this delay crossed the tonic threshold at a lidocaine concentration of 0.25 mM and then crossed the 200-ms delay threshold at 0.37 mM. **C.** The "threshold curve" over the domain of delays from 0 (coincidence) to 1.4 s after conditioning impulses. These curves were plotted relative to the tonic resting threshold for the same fiber given 1 CP in the absence of lidocaine, for 1 CP after equilibration with 0.5 mM lidocaine, and for bursts of eight CPs with lidocaine at 0.7 mM. The progression with local anesthetic concentration from a pronounced superexcitability toward a curve with its highest relative threshold early after the impulse as seen here was consistent with similar plots at various concentrations made on 15 other fibers. CV = 21.1 m/s for part **B**; CV = 17.1 m/s for part **C**.

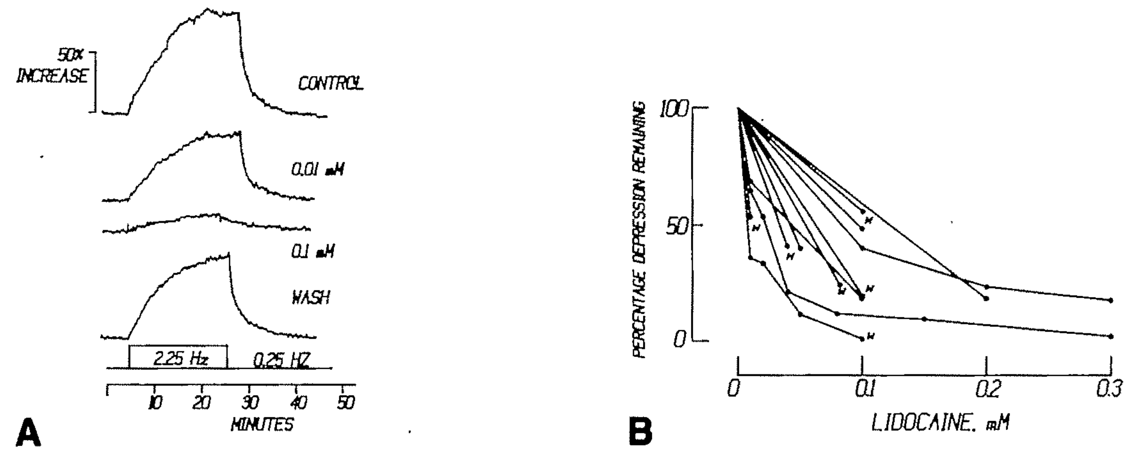

Figure 6. Reduction of depression by lidocaine. Depression was produced by stimulating conditioning bursts at three times threshold intensity. The bursts were timed so that the threshold tracking stimulus, which was given every 2 s, was delivered at a fixed interval >1.5 s after the last impulse of each repeated burst so that superexcitability (and use-dependent transients for lidocaine and 2-chloroprocaine, but not bupivacaine) had decayed. Records of the threshold tracking stimulus (example in part **A**) showed an initial resting level where only test stimuli were given. Then depression occurred, appearing as the buildup and plateau of threshold during the conditioning bursts, followed by a recovery tracked by test stimuli alone. When lidocaine was present, the degree of this depression was measured as the increase above the tonic level of threshold attained by the end of the period of increased impulse activity. This increase in threshold was plotted as the percentage of the increase in threshold seen without drug. Lidocaine reduced depression in all 12 fibers tested in this fashion (part **B**). Washing (W) with lidocaine-free solutions resulted in a recovery of depression; however, unless three or more solution changes were made over the course of several hours, depression was not restored to the control level. Experiments in which a conditioning profile was repeated at several concentrations of lidocaine (*connected data points*) showed a monotonic reduction in depression with concentration.

20- and 200-ms delay while increasing incrementally the lidocaine concentration, it was possible to make the first comparisons of the tonic effects of lidocaine with its phasic effects on the same fiber during the superexcitable phase after impulse activity. At low lidocaine concentrations (Figure 5A), lidocaine elevated the threshold at both the peak of superexcitability (20-ms delay, 1 CP) and during recovery

(200-ms delay, 1 CP) above the tonic "resting" threshold (no preceding impulse within 2 s). Thus, with lidocaine the fibers became transiently less excitable at delays where they would normally be superexcitable.

One way of quantifying the reduction of superexcitability with lidocaine was to determine an ED_{50}, a concentration where superexcitability was 50% of its control value after 1 CP. At the 20-ms delay, the ED_{50} for lidocaine was 107 ± 53 μM, ranging from 31 to 213 μM (n = 13), and at the 200-ms delay, the ED_{50} was 27 ± 22 μM, ranging from 2 to 82 μM (n = 15). As is apparent from the typical records in Figure 5, the tonic threshold increased less steeply with lidocaine than did the postimpulse threshold.

This transient subexcitability induced by lidocaine showed a typical sequence of "events" that could be marked as the concentration increased. At the lowest range of concentrations (21–150 μM, n = 11), the first such event was recorded when the threshold measured at the 200-ms delay crossed the elevated tonic level. The second event in the sequence was that the threshold at the 20-ms delay, corresponding without lidocaine to the peak of superexcitability, crossed the raised tonic level. The "crossing" concentration averaged 294 μM, ranged from 160 to 500 μM (n = 9), and was always greater in any given fiber than the concentration for the threshold at the 200-ms delay to cross the raised tonic threshold (Figure 5A and B). The third event occurred as the [LA] exceeded one-third or more of the C_b and was marked when the threshold at the 20-ms delay became even higher than at the 200-ms delay (Figure 5B). The last three events in the sequence were marked by conduction blocks. The order was consistently (n = 5) that the impulses at the 20-ms delay from a CP failed first, followed by failure of the impulse at the 200-ms delay, and finally by the tonic block of conduction in the fiber at the C_b. Failure of a test impulse (one preceded by a CP) thus occurs at concentrations less than required to produce tonic block and is an indication that a rising lidocaine concentration is approaching the C_b.

In addition to sampling the phasic effects at 20- and 200-ms delays from conditioning activity, plots of the threshold curve over the course of 1 s after CP(s) were made at several concentrations of lidocaine for each of 15 fibers (Figure 5C) to show the changed form of the afteroscillations in excitability. The results indicated that lidocaine has the effect of phasically elevating the postimpulse threshold, progressively transforming the curve as the concentration increased. At low concentrations, the afteroscillation remains one where the threshold is lowest at early delays and then rises before delaying again to the tonic steady-state level. At higher concentrations (e.g., 0.7 mM in Figure 5C), the threshold is highest at the earliest delays, declining progressively over the course of 1 s.

Effects on depression. Frog myelinated fibers differ among themselves in the degree of depression by a factor of >100 (19), but all fibers tested here showed a reduction in the level of depression when impulse activity occurred in the presence of lidocaine. Even 10 μM lidocaine could significantly reduce depression, and the ED_{50}, where fibers showed 50% of their predrug level of depression determined graphically from the data in Figure 6, was 58 ± 38 μM, ranging from 8 to 122 μM (n = 12). This was approximately 1/15th of the mean blocking concentration for fibers, as shown in Table 1 (880 μM). Bupivacaine (n = 7) and 2-chloroprocaine (n = 4) similarly reduced depression at concentrations well below the blocking dose (data not shown).

Effects of Impulse Activity on Local Anesthetic Actions

Activation of impulses in a fiber in the presence of LA also produces "use dependence," which is a different phenomenon from the activity dependence occurring in the absence of anesthetics. With threshold tracking, use dependence after a burst of firing appeared as a transient subexcitability that was strongly shaped by superexcitability. The magnitude of this transient subexcitability depended on both the burst frequency and the number of impulses in the burst (Figure 7), growing with either. It also depended on the agent. Stimulation at intervals of 2 s or more did not result in cumulative increases in threshold with either lidocaine or 2-chloroprocaine (Figures 5 and 7). However, with bupivacaine at concentrations ranging from 10 to 75 μM, the threshold measured by test stimuli separated by 5 s was invariably higher than it was when measured by stimuli at 10-s intervals (n = 8), and that at 2 s averaged 9.9% ± 1.6% more than the threshold at 20-s intervals for concentrations of 50 μM (n = 6).

The duration of the transient subexcitability, which should reflect the integration time for accumulation and recovery of LA-bound channels, was also agent specific (Figure 8A). Recovery of subexcitability after bursts of CPs in the presence of bupivacaine was marked by intervals of as much as 4 s, where no conducted impulse could be generated (Figure 8B). Return of excitability to the tonic threshold after this occluded interval was rapid, descending 200% or more in 200 ms. The occluded period followed a relative superexcitability that often permitted impulses to be conducted when stimulated at 20–50-ms

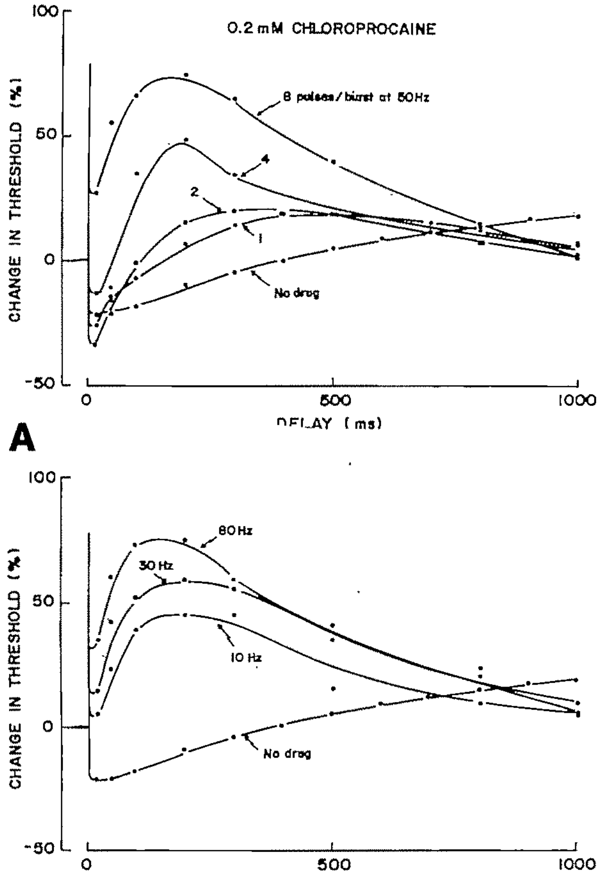

Figure 7. Use-dependent effects of 2-chloroprocaine on fiber excitability after short conditioning bursts. **A.** Effects of number of conditioning pulses (CP) at 20-ms intervals. Without drug, the fiber after one pulse is superexcitable for 800 ms (*No drug* trace in A and B), but after equilibration with 0.2 mM 2-choloroprocaine, the threshold relative to the steady-state level decreases only briefly after 1 CP by 25%, slightly less than the peak superexcitability (−32.8%) in the control trace. With more pulses, the transient subexcitability increases, peaking at 70% above the steady-state level at approximately 200 ms after a burst of eight conditioning pulses. The steady-state threshold is regained with 2-chloroprocaine within 1 s of the last CP, regardless of the degree of subexcitability. **B.** Effects of pulse frequency within a burst of eight conditioning impulses. The peak of the transient subexcitability increases monotonically with rate and is reached earlier after the last impulse: this would be expected if each impulse increased the proportion of bound Na$^+$ channels, which then recovered toward the tonic level between pulses.

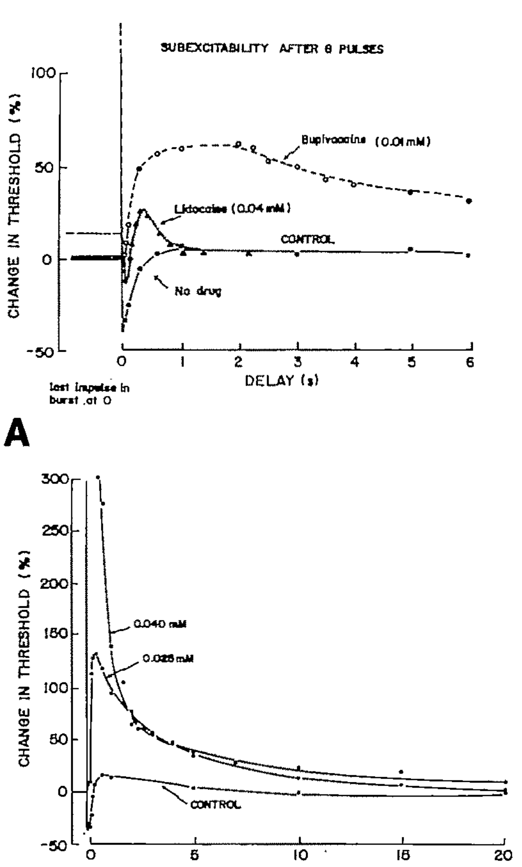

Figure 8. Subexcitability and use dependence with bupivacaine. **A.** Comparison of transient subexcitability with lidocaine versus bupivacaine in one fiber. The change in threshold is shown versus the delay from the last pulse of eight-pulse 50-Hz bursts. The bursts were given infrequently enough to avoid effects on resting threshold, and thresholds (plotted with respect to the drug-free resting level) were bracketed at various delays. Superexcitability was strong after eight pulses in the absence of local anesthetic (*No drug* trace). With lidocaine (40 μM), superexcitability was reduced, resting threshold increased approximately 5%, and a transient subexcitability occurred that recovered within 1 s. Bupivacaine (10 μM) was administered after lidocaine was washed twice for 34 min. The subexcitability with bupivacaine was greater and much more extended than with lidocaine. **B.** Dose dependence of subexcitability with bupivacaine after eight pulses. The change in threshold relative to the elevated tonic level is plotted versus delay from an eight-impulse 50-Hz burst. Note that at the 25 μM concentration, the peak of transient subexcitability was preceded by a pronounced relative superexcitability. At 40 μM, there was an occluded interval lasting 370 ms after the bursts. In nine fibers, four or eight pulse bursts given at concentrations >25 μM yielded intervals after the burst where stimuli three times the duration or twice the intensity could not fire another conducted impulse. An impulse could often be conducted at the 20-ms delay, which was why the bursts themselves were successful (eight conditioning pulses at 20-ms interpulse intervals), but for intervals ranging from 370 ms (shown here) to as much as 4 s (not shown) after the last pulse of a successful burst, one burst could prevent a following conducted impulse. Note the steep recovery of threshold after the occluded period with 40 μM bupivacaine.

delays from the burst but not afterward. Such occluded periods with abrupt recoveries were not observed after bursts in the presence of lidocaine (n = 19) or with 2-chloroprocaine (n = 3). They appeared in every fiber exposed to concentrations of ≥25 μM bupivacaine that could conduct intermittent eight-impulse 50-Hz bursts given at 30-s intervals (n = 9) (e.g., Figure 8B). In none of the three fibers exposed to tonic blocking concentrations of bupivacaine (range 140–400 μM) did the threshold at the 20-ms delay from a burst exceed that at the 200-ms delay as it did with lidocaine. Furthermore, in 15 fibers subjected to bupivacaine concentrations (range 5–100 μM) that did not cause conduction failures, the subexcitability at 200- or 300-ms delays always exceeded that at 20 ms, even after eight CP bursts, suggesting that a transiently increased excitability after a burst persists with bupivacaine but not with lidocaine. With lidocaine, the ED_{50} for peak superexcitability at 20 ms after eight CP bursts (40.1 ± 32.8 μM, range 17–111 μM, $n = 7$) was approximately half that after singlet CPs, reflecting the additive phasic blocking effects of the multiple CPs. With bupivacaine, the average ED_{50} for peak superexcitability after 1 CP was 25.9 μM (range 5.5–44.9 μM, $n = 5$), and it was 10.4 μM (range 1.7–44.3 μM, $n = 11$) after eight CP bursts. The threshold at 200- and 300-ms delays after an eight-CP burst was sensitive to bupivacaine, increasing an average of 51% above the tonic level in seven axons exposed to 10 μM bupivacaine and tested with eight CP bursts.

With 2-chloroprocaine, even at near-blocking concentrations, the threshold at a 20-ms delay never ($n = 4$) exceeded that at a 200-ms delay, as it invariably did with lidocaine (Figure 5). Thus, even though each agent produced a transient subexcitability after an impulse, the kinetic variables of that subexcitability were agent specific.

In frog fibers exposed to subblocking LA concentrations, conditions shown here to suppress activity dependence, the application of trains of electrical stimuli evoked surprising results. With bupivacaine, for example, stimulation at rates of one every 10 s to one every 2 s elicited responses to only every other or to every third stimulus, even over a broad range of stimulus intensities that were 100% successful if given at rates of one every 15 s ($n = 7$). With lidocaine, trains of 32 or 64 stimuli at >5 Hz led to impulse block that was either sporadic and intermittent or to a block that lasted indefinitely as long as the stimulus train itself continued, depending on rate and concentration (20).

Discussion

The principal actions of subblocking [LAs] observed on individually recorded frog fibers were (a) tonic increases of threshold and latency; (b) suppression of activity-dependent superexcitability and depression; and (c) transient subexcitability with agent-specific kinetics and duration following conditioning bursts of conducted action potentials. The results show that at low [LA], neuron intrinsic activity-dependent effects predominate in influencing impulse generation (threshold) and conduction, but as LA concentration increases, its agent-specific use-dependent properties will increase, becoming the dominant modulator of impulse conduction while the intrinsic activity-dependent processes decline because of the inhibiting effects of the agent on activity dependence.

Tonic Effects

Our results incorporated five interrelated but distinct measures of tonic susceptibility of fibers to LA. The first and most familiar is the critical blocking concentration (C_b), corresponding to the [LA] just sufficient to block impulse propagation through a region of nerve equilibrated with a homogeneous solution at a constant concentration. The C_b varied, even among fibers of the same resting conduction velocity, reflecting substantial intrinsic differences in susceptibility to block among axons of similar diameter (21). Two of the remaining measures, the maximal change in latency and the maximal change in threshold, revealed differences among axons in the range over which conduction variables could change in response to an impulse blocking dose of LA. These axonal differences were also not strongly correlated with C_b. The final two tonic measures were the slope-sensitivity measures of latency (Figure 2) and threshold (Figure 5) and revealed interaxonal differences in the degree that subblocking [LA] slowed the velocity of impulse propagation and diminished excitability at an exposed site.

Given that a fiber had relatively high slope susceptibility in latency one could reliably infer that it would also have a high slope susceptibility in threshold, but the C_b could not be predicted from either measure of the slope sensitivity. Some fibers with a moderately high slope sensitivity had such high margins of conduction safety that they nonetheless blocked at relatively high concentrations (Figure 2). The term conduction safety has several operational definitions (22,23) and refers to the current that an action potential provides that exceeds the current just necessary to sustain impulse propagation. Conduction safety is determined by anatomic and physiologic membrane properties governing impulse generation and propagation (e.g., channel type, density, locus, axoplasmic resistivity, membrane capacitance, degree of myelination, internodal spacing, ion concentrations), and we look to variations in these properties to explain axonal differences. Local anesthetics reduce conduction safety in two ways: they increase the current required to excite the local membrane, as shown by the threshold increases (24), and they reduce the current provided by the impulse because they block voltage-gated Na^+ channels. With lower affinity they also block voltage-gated K^+ channels (2), which, in the absence of a secondary depolarizing effect on the resting potential, will act to increase conduction safety by reducing the shunting of depolarizing current. Measuring C_b is thus in essence a measure of fiber conduction safety, and the differences in the maximal changes of threshold and latency among axons of similar C_b indicate that axons incorporate different combinations of the determinants of conduction safety.

Previous studies of C_b for single fibers at steady state for rabbit vagus nerve (4,25), bullfrog sciatic nerve (26), and cat saphenous nerve (3) also found a wide range of interfiber variation in C_b, either in the order in which single units blocked during onset of LA in vivo (3) or in the liminal concentration of LA after equilibration (4,27). In line with the conclusions of authors of previous work with single units, we believe that interfiber variation reflects biological variation from fiber to fiber in the determinants of conduction safety rather than artifacts introduced by dissection or physical injury. On three occasions we have recorded a single unit during exposure to a second sequence of lidocaine concentrations that resulted in a similar slope sensitivity and C_b, which has shown that susceptibility is stable in frog nerve fibers in vitro, at least for 1 or 2 days. Furthermore, we occasionally observed that fibers teased sequentially from the same nerve or recorded at the same time from a fascicle would show wide variation in susceptibility. We did not find that all fibers from a given nerve were of low susceptibility, whereas fibers from another (putatively injured nerve) were highly susceptible. The nerves were handled similarly and were not desheathed. A previous comparison among fibers from desheathed and sheath-intact vagal nerves found no significant differences in C_b (4), suggesting that the relatively substantial stretching and twisting associated with desheathing did not substantially affect conduction safety. Also, the average C_b found here for lidocaine (0.88 mM) was similar to the ED_{50} for the fastest conducting elevation of the frog sciatic compound action potential in bicarbonate-buffered solutions at 16°C (6), which would not be expected if many of the fibers used here had their intrinsic conduction safety reduced by damage.

Size Principle

The data from this population of myelinated frog axons is in accord with previous evidence from compound action potential studies and from studies with single fibers that have contradicted the idea, known as the "size principle," that susceptibility to block by LA is inversely related to axon diameter, as indicated by resting conduction velocity (4,28,29). Indeed, axon diameter, inferred from the resting conduction velocity before exposure to LA, does not seem to be related to any of the indices of susceptibility to LA that we used. A relation between critical blocking concentration and fiber size in 9 myelinated fibers was reported for bullfrog (26) but was not found in 16 unmyelinated or 22 myelinated fibers in rabbit vagus nerve (4) nor in multiple units recorded in dorsal root fascicles (3). Consideration of the implications of decremental conduction (30) for differential block (29) had previously led us to extend the idea of critical length (3) to pertain to LA exposure lengths of several centimeters (6). The results reported here for C_b correspond with results from rabbit vagus nerve, which were also obtained with at least 2 cm of nerve exposed to lidocaine, in showing that diameter cannot explain the differences in tonic susceptibility to conduction block with LA (4,25).

Impulse Slowing and Interfiber Variation

The tonic slowing of impulse propagation during exposure to LA is a well-established result and has been reported in several single-unit studies (3,4,27). The equilibration times observed here are consistent with times measured for slowing of impulse conduction to stabilize in vagal fibers with intact sheath in nerves exposed in vitro to stepwise increases in concentrations of lidocaine (31). As with frog fibers, the range of slope sensitivities in latency in a population of myelinated vagal fibers from rabbits was almost fivefold (Fink and Cairns [4; Figure 5]), although the magnitudes of slope sensitivities of the vagal fibers (180%–920% per mM) were approximately twice those of the frog fibers. The vagal fibers also blocked at approximately half the C_b of frog sciatic fibers (range 0.1–0.7 mM) (4). No plots of the slowing versus anesthetic concentration after equilibration have previously been published, however, and it is interesting to note how linear the relation is, only slightly convex (Figure 2A).

A nearly linear dependence of slowing on concentration also emerged in computer models of myelinated axons (Figure 4) in which node-to-node homogeneity in Na^+-channel density and internodal properties was assumed, suggesting that the linearity derives from the tonic reduction in the availability of voltage-gated channels by LA. In the model axon, adjusting the nodal density of K^+ channels (or the density of Na^+ channels) without changing any other variable yielded a range in C_b and in slope sensitivity for latency that included the range seen in the frog myelinated units studied here. Doubling the channel density and the internodal distance did not much affect (<11% change) the resting conduction velocity in a model fiber (32), although it altered the conduction safety. If biological fibers have independent control of their Na^+ and K^+ channel densities, then the modeling shows that channel densities alone could suffice to account for the observed fourfold span of slope sensitivities reported here. However, slope sensitivity in model fibers was always correlated with blocking concentration, and therefore at least one additional variable, such as internodal distance or axoplasmic resistivity, would need to be varied concomitantly with channel densities to produce a set of model fibers matching each of our biological fibers comprehensively in slope sensitivity, C_b, and maximal change in latency. In modeling impulse conduction in fibers, it is possible to preserve conduction safety by reducing the internodal distance while at the same time adjusting slope sensitivity to LA by altering the channel densities. This suggests one way that nerve fibers could achieve the observed independence between the C_b (dependent on internodal distance) and slope sensitivity (more dependent on the ratio of channel densities). Internodal distance is consistent along a given frog axon, but it varies between axons (19,21), which is consistent with this possibility.

Activity Dependence

The effects of LAs on activity dependence have not been widely studied in other laboratories (29,33). Examples of the inhibition of superexcitability and depression have been reported (15), and data here confirm that lidocaine decreases activity dependence in a dose-dependent manner in myelinated frog fibers. Activity-dependent excitability changes appear to be the axonal processes most sensitive to LAs, with effects appearing at low concentrations that produce little or no change in tonic excitability or conduction velocity. It has not yet been possible to study activity dependence in nodes of Ranvier under voltage-clamp or at the single-channel level, because expression of superexcitability and possibly of depression appears to require intact internodal structure.

Even at physiologically relevant discharge rates of two to eight impulses per second, depression is a powerful modulator of excitability and can more than double the intensity of a threshold level stimulus for some fibers (Figure 6A). As a stimulus of only half the resting threshold magnitude can result in an action potential during the superexcitable phase, the range of the afteroscillations in membrane excitability after an impulse can result in a fourfold change in the magnitude of a threshold level stimulus. These afteroscillations are thought to influence the distribution of impulses among branches in axonal presynaptic arborizations known as teledendra and to govern, at least in part, the discharge patterns for peripheral fibers encoding sensory stimuli or for central neurons encoding presynaptic influences (9,10). The information content of these discharge patterns could be affected by the suppression of activity dependence by low [LA] if the LA were present at peripheral receptors or terminal arborizations. As recognized by Larrabee and Posternak (34), the terminal arborizations of axons are probably areas of reduced conduction safety that would be more sensitive than trunk axons to anesthetics. If activity dependence normally controls the distribution of impulses in axonal teledendra (7,8,10), then LAs at low concentrations may affect information handling among neurons by dynamically altering the invasion of impulses in the terminal branches that precede the presynaptic endings, thus modifying temporal and spatial postsynaptic integration. At blood concentrations of lidocaine corresponding to those used here to suppress depression and superexcitability (10–30 μM), various "central" effects are reported, including dizziness and disorientation, suppression of seizures, drowsiness, analgesia, loss of ocular focus, tinnitis, muscle tremors, and at higher concentrations, seizures and generalized central nervous system depression (35). Whether inhibition of activity dependence is involved in the analgesic or sedative effects of systemic administration of LA (36) is not known, but the possibility should be considered, given the susceptibility of activity dependence to lidocaine on the order of 10–30 μM. Concerning general anesthesia, it has been suggested that afteroscillations in excitability may serve as the neurophysiologic substrate for consciousness by serving as a time-dependent process that puts each sequential impulse in a "context" of the pattern of discharge (37). The disorientation and periods of unconsciousness that occur during systemic lidocaine administration (38) may result from its action described here on activity-dependent processes, which could disrupt normal discharge patterns and suppress the substrate for this temporal context thought to be necessary for interpreting the patterns (37).

Depression has been shown to depend on the Na^+/K^+-dependent adenosine triphosphatase (9,39), and the inhibition of depression may result in part because the net ion transfer of Na^+ per impulse is diminished by LA, thus reducing the substrate driving the increased rate of ion pumping. A lidocaine concentration of 200 μM is sufficient to block approximately 30% of the Na^+ channels at rest in voltage-clamped nodes of Ranvier at 13°C (2,14,40). This mechanism is consistent with the reduction in central nervous system aerobic metabolism, of which a significant fraction is used to sustain ion gradients by metabolic pumping, by systemic LA at subconvulsant doses (41). Alternatively, reduced firing rates in central neurons may account for the reduced metabolism, although this familiar explanation does not seem to be supported by experimental tests for generalized reduction of firing throughout the brain during exposure to systemic LAs or even for exposure to general anesthetic agents.

Use Dependence and Transient Subexcitability

Use dependence in these experiments was revealed by novel measures that mapped the transient increases in threshold and in latency after impulse discharges. Unlike activity dependence, use dependence can be studied in voltage-clamp, where it appears as a phasic reduction of inward currents in voltage-clamped nodes of Ranvier subjected to repeated depolarizing pulses in the presence of LA (42,43). Use dependence underlies the progressive diminution of compound action potentials during trains of stimuli in nerves exposed to LA (11,44,45). Voltage-clamp studies have suggested that use dependence stems from increased binding of LA to Na^+-channel configurations that predominate during the membrane depolarization associated with the impulse, thus increasing the population of drug-bound channels and reducing the capability of the fiber to generate depolarizing currents needed to sustain propagation (2,14,46).

Modeling Use Dependence in Conducting Fibers

In conducting fibers, the membrane voltage before and during the action potential is affected by the LA rather than set by experimental equipment, as it is in voltage clamp. However, it is possible to quantitate the use-dependent effect on slowing and on propagation in mathematical models of uniformly conducting myelinated fibers, both for low discharge rates (no repeated spikes), as done here, and for trains of impulses (33) by using rate constants for forward and reverse binding measured for voltage-clamped amphibian nodes (14). In the model used here (Figure 4), it was assumed that the proportion of available channels in conformations with high affinity to LA is proportional to the instantaneous g_{Na} and that the effect of LA binding can therefore be simulated by reducing the variable for Na^+-channel density (maximal conductance, $\bar{g}_{Na}$). Action potentials in the model conduct at an appropriate rate and show good agreement in sensitivity of impulse conduction to [LA]. They give a good intuitive image of a conducting impulse in the region exposed to LA and provide the capability to explore the relative importance of particular structural or ionic properties in determining sensitivity of latency, threshold, and block to LA. In mathematical models of use dependence, impulse activity in the presence of LA can reduce conduction safety such that only the first propagated impulse in a sustained discharge can be conducted through the anesthetized axon (33). In fibers exposed to lidocaine, particularly after bursts of eight or more impulses rather than single conditioning pulses, the threshold after the last impulse in the burst decayed monotonically with no superexcitable dip, whereas in those fibers exposed to bupivacaine, the threshold after a burst always showed a large relative superexcitability (e.g., Figure 8B at 25 μM vs Figure 5B). The sharply different results in both scale and duration of transient subexcitability with low doses of lidocaine versus bupivacaine are consistent with experimental studies of use-dependent suppression of inward current (14,40). Nonconvulsing systemic doses of lidocaine also suppress ongoing "spontaneous" discharges originating at dorsal root ganglion cells in which the peripheral axons have been previously injured (47,48), and this effect may depend on its use-dependent actions as well as its tonic ones.

Local Anesthetic and "Functional Blockade"

Our findings indicate that the changes in membrane excitability that follow impulse conduction in unclamped fibers exposed to LA are a combination of use-dependent binding of LA, together with the inhibition of superexcitability and depression. These results show that the degree of LA blocking action that any particular impulse will be subjected to as it conducts through a region of axon exposed to LA will depend in agent-specific ways on its timing relative to preceding impulses, thus altering interval codes. For example, at concentrations yielding equivalent tonic effects, lidocaine ought to inhibit burst discharge with interpulse intervals ranging from 15 ms to several hundred milliseconds while allowing repeated discharge at 1 Hz without compromise, whereas bupivacaine might permit occasional, brief high-frequency bursts but block subsequent firing or conduction for several seconds. The possible relation of these disrupted discharge patterns to block of function is intriguing. Human volunteers given a partial block with lidocaine of medial or ulnar nerves such that Aδ fibers could be microneurographically recorded in response to low-frequency single shocks but not to repetitive trains nonetheless reported complete functional sensory loss of cold sensation in the region served by the nerve exposed to lidocaine (1). During the normal response of Aδ cold fibers to skin cooling, the fibers respond for several minutes at frequencies as high as 50 Hz (49), and we propose that infrequent discharges in tonically conducting but phasically inhibited fibers may not be functionally effective. Sustained electrical stimulation at subblocking concentrations of LA can result in a single conducted spike with all subsequent spikes blocked (33,50,51). These observations may explain how effective spinal and epidural block of sensory and motor functions may occur under conditions where infrequent impulses or volleys can nonetheless conduct to cerebral cortex (52).

Prospects for Differential Blockade

These methods are suited to ascertain relative fiber susceptibility, because they yield highly resolved measures for latency and excitability that can be monitored as a function of increasing concentration of LA, not simply one number of relatively low resolution giving the (tonic) C_b. Our results show that tonic C_b and phasic C_b differ. The tools may permit us to address the historic question of the relation of fiber susceptibility to fiber function and to do so with a link, via computer modeling, to the mechanistic basis of the differential susceptibilities.

We have thus formed the following four conclusions:

1. The afteroscillations in membrane excitability that normally follow impulse activity are the feature of conducting axons that is most susceptible to LAs. Lidocaine suppressed superexcitability by 50% at approximately 100 μM and depression by 50% at approximately 60 μM, concentrations less than one-tenth of the concentrations required to block impulse conduction in similar fibers.
2. Excitability following impulses was also distorted by the effects of use-dependent binding, which appeared as an agent-specific transient subexcitability.
3. These processes in tandem determined the likelihood of blockade of impulses, which occurred during high-frequency bursts at [LAs] one-third less than those needed for tonic blockade of infrequent impulses.
4. The increases in tonic threshold and latency grew in approximately linear proportion to [LA]. Interfiber differences in slope susceptibility and blocking concentration did not correlate with resting conduction velocity but were quantitatively similar to simulations of myelinated fibers differing in the membrane densities of voltage-gated ion channels.

I thank Richard Roscoe for technical assistance and Dr. Michael Hines of Duke University for help with the computer simulations. I also thank Dr. Gary Strichartz for helpful comments on the manuscript.

Central Nervous System Toxicity of Local Anesthetic Mixtures in the Rat

David A. Spiegel, Franklin Dexter, MD, PhD, David S. Warner, MD, Max T. Baker, PhD, and Michael M. Todd, MD

Neuroanesthesia Research Group, Department of Anesthesia, University of Iowa, Iowa City, Iowa

Local anesthetics are often administered as mixtures during regional anesthesia. This study investigated whether a synergistic or antagonistic interaction between amide/amide or amide/ester local anesthetic combinations is present with respect to central nervous system toxicity. For surgical preparation, rats were anesthetized with 0.8% halothane in 30% O_2/balance N_2O and mechanically ventilated. Mean arterial blood pressure and the electroencephalogram were continuously monitored. After surgery, the halothane was discontinued for 15 min. An intravenous infusion of solutions containing lidocaine alone, bupivacaine alone, or any of three mixtures of the two drugs was then begun and continued at a fixed rate until seizure activity was observed on the electroencephalogram. Total administered doses of both drugs were compared by isobolographic analysis. After a similar protocol, a second experiment was performed evaluating lidocaine, tetracaine, or any of three mixtures of those two drugs. In both experiments, normocapnia, normoxia, and normothermia were maintained for all rats. For mixtures of lidocaine/bupivacaine ($P = 0.40$) and lidocaine/tetracaine ($P = 0.24$), there was no evidence that a significant degree of either synergism or antagonism was present. At the onset of seizures, mean arterial pressure was lowest in the lidocaine-alone groups in both experiments. Increasing doses of either bupivacaine or tetracaine (with correspondingly decreasing doses of lidocaine) were associated with greater mean arterial pressure values at onset of seizures. We conclude that central nervous system toxic effects of amide/amide or amide/ester anesthetic combinations, such as might occur during accidental intravascular injection, are no more than when the drugs are administered alone. Because such combinations appear to have additive epileptogenic effects, proportional reductions in the dose of one drug must be made if administered in combination with another.

(Anesth Analg 1992;75:922–8)

Local anesthetics are often administered as mixtures so as to combine the rapid onset of one anesthetic (e.g., lidocaine or tetracaine) with the prolonged duration of action of another (e.g., bupivacaine) (1,2). Several studies have examined the interaction of various local anesthetics with respect to systemic toxicity. Some work has found a synergistic relationship for toxicity between either amide/amide or amide/ester combinations (3,4). Other work has failed to support this conclusion (5–8). It is possible that differences in either toxicologic endpoints or physiologic conditions of experimental animals could account for these discrepancies. In this report, we provide additional evidence that, across a range of doses administered, local anesthetics are neither synergistic nor antagonistic with respect to central nervous system (CNS) toxicity.

Methods

After approval by the institutional Animal Care and Use Committee, male Sprague-Dawley rats (Harlan Sprague Dawley, Inc., Indianapolis, Ind.) were anesthetized with 4.0% halothane in O_2. A tracheostomy was performed, delivered halothane was reduced to 0.8% in 30% O_2/balance N_2O, and mechanical ventilation was begun using a small animal ventilator to maintain $Paco_2$ between 38 and 42 mm Hg and Pao_2 between 100 and 150 mm Hg. Catheters were surgically implanted in the right femoral artery and femoral vein. The arterial line was connected to a pressure transducer for monitoring of mean arterial blood pressure (MAP) while venous access was maintained

for fluid and drug administration. *d*-Tubocurarine (0.4 mg) and heparin (100 *USP*) were administered intravenously. Electroencephalographic (EEG) needle electrodes (Grass type E2, Quincy, Mass.) were percutaneously inserted between the temporalis and parietal bones bilaterally, and a ground electrode was placed in the nape of the neck. Pericranial temperature was monitored from a needle thermistor (YSI model 524, Yellow Springs, Ohio) percutaneously positioned adjacent to the parietal bone and servoregulated to 37.0°C by a heat lamp. Forty-five minutes after induction of anesthesia, halothane was discontinued and the inspiratory gas mixture changed to 70% N_2O/30% O_2. A 15-min stabilization period was then allowed, during which time $Paco_2$, Pao_2, arterial pH (pHa), and hematocrit (Hct) were determined.

Test for Lidocaine-Bupivacaine Interaction

Stock solutions of either 1.5% lidocaine HCl, prepared by diluting 2.0% Xylocaine (Astra, Westborough, Me.) in 0.9% NaCl, or 0.5% bupivacaine HCl (0.5% Sensorcaine, Astra) were used. The local anesthetic concentrations for each of the two stock solutions were derived from pilot studies that demonstrated that either solution, administered at the same infusion rate, would produce seizures within 13–18 min after onset of infusion. From these stock solutions, five solutions were prepared. With the investigator unaware of experimental conditions, rats were assigned by chance to one of five groups distinguished by the solution administered: group I (lidocaine alone) received 15.0 mg/mL of lidocaine (n = 10); group II (lidocaine + bupivacaine [6:1 mg]) received a 2.0:1.0-mL mixture of the stock solutions (yielding lidocaine 10.0 mg/mL and bupivacaine 1.6 mg/mL) (n = 11); group III (lidocaine + bupivacaine [3:1 mg]) received a 1.0:1.0-mL mixture of the stock solutions (yielding lidocaine 7.5 mg/mL, bupivacaine 2.5 mg/mL) (n = 10); group IV (lidocaine + bupivacaine [3:2 mg]) received a 1.0:2.0-mL mixture of the stock solutions (yielding lidocaine 5.0 mg/mL, bupivacaine 3.3 mg/mL) (n = 11); and group V (bupivacaine alone) received 5.0 mg/mL of bupivacaine (n = 10). In each group, the solution was infused intravenously at a constant rate of 0.0016 $mL \cdot g$ body $wt^{-1} \cdot min^{-1}$. During surgery, all wounds had been subcutaneously infiltrated with the same solution to be infused for the respective groups (0.4 mL total).

Fifteen minutes after discontinuation of halothane, the respective infusions were begun. The EEG was continuously monitored beginning 5 min before the onset of infusion (Grass model 8-10c). At the onset of EEG seizures, marked by the appearance of high-voltage spike-wave activity, MAP was recorded, and arterial blood (5 mL) was withdrawn. The $Paco_2$, Pao_2, pHa, and MAP were determined. Plasma was frozen for later determinations of lidocaine and bupivacaine concentrations by gas chromatography. The duration of infusion (min) before onset of seizures and total dose of each local anesthetic administered (mg/kg) were recorded.

Test for Lidocaine-Tetracaine Interaction

The surgical preparation and experimental protocol for this study were exactly as described previously (test for lidocaine-bupivacaine interaction), except that in this experiment combinations of lidocaine and tetracaine were evaluated. Stock solutions of either 1.5% lidocaine HCl, prepared by diluting 2.0% Xylocaine (Astra) in 0.9% NaCl, or 0.375% tetracaine HCl, prepared by dissolving 20 mg of Pontacaine (Winthrop Pharmaceuticals, New York, N.Y.) in 5.33 mL of 0.9% NaCl, were used. The local anesthetic concentrations for each of the two stock solutions were derived from pilot studies that demonstrated that either solution, administered at the same infusion rate (0.0016 $mL \cdot g$ body $wt^{-1} \cdot min^{-1}$), would produce seizures within 13–18 min after onset of infusion. From these stock solutions, five solutions were prepared for intravenous infusion. With the investigator unaware of the experimental conditions, rats (n = 10) were assigned by chance to one of five groups distinguished by the intravenous solution administered. In this experiment, plasma concentrations of the local anesthetic agents at onset of seizures were not determined: group I (lidocaine alone) received 15.0 mg/mL of lidocaine; group II (lidocaine + tetracaine [8:1 mg]) received a 2.0:1.0-mL mixture of the stock solutions (yielding lidocaine 10.0 mg/mL, tetracaine 1.3 mg/mL); group III (lidocaine + tetracaine [4:1 mg]) received a 1.0:1.0-mL mixture of the stock solutions (yielding lidocaine 7.5 mg/mL, tetracaine 1.9 mg/mL); group IV (lidocaine + tetracaine [2:1 mg]) received a 1.0:2.0-mL mixture of the stock solutions (yielding lidocaine 5.0 mg/mL, tetracaine 2.5 mg/mL); group V (tetracaine alone) received 3.7 mg/mL of tetracaine.

Statistical Methods

Scaf's test for drug interaction was used (9). The ratio of the potency of the two drugs was estimated from the ratio of the geometric means of groups I and V. Scaf's test converts the isobolic analysis of drug interaction (10) to a one-way analysis of variance (ANOVA). The SYSTAT software package was used to perform the statistical analysis (11,12). Standard tests of the assumptions of ANOVA were performed, with the criteria for statistical significance of $P < 0.01$.

MAP, mean arterial blood pressure; pHa, arterial pH; temp., temperature.
Values are mean ± SD.

Probability plots and Lilliefors tests showed that the residuals followed a normal distribution. By Bartlett's test, the variance of the residuals did not differ among groups. Plots of residuals against estimated doses showed no evidence for dependence. None of Cook's distances were statistically significant. One of the 102 studentized residuals was statistically significant (3.204); however, review of physiologic measurements revealed no basis for rejecting the datum. Furthermore, repeat of the ANOVA without the datum (not shown) did not change the results qualitatively. Power analysis was performed by routine methods for ANOVA (13); $\alpha = 0.05$ and $n = 10$ were assumed to hold for each group. As is appropriate for Scaf's method, the number of between-group degrees of freedom was set to equal 3. Each lidocaine dose was corrected for its corresponding bupivacaine dose using the estimated potency ratio. Then, the antilogarithm of (the root-mean-squared deviation of [the group mean log-corrected lidocaine doses about the grand mean log-corrected lidocaine dose]) was calculated. Scaf's method uses ANOVA on the logarithms of the doses. Therefore, the results of the power analysis are reported as ratios.

The MAP values were analyzed by one-way analysis of covariance, with covariance the baseline MAP. Standard assumptions were tested and satisfied, as described in the preceding paragraph. One MAP value had a statistically significant studentized residual (−4.34). This outlier was not included in the analysis.

Results

Test for Lidocaine-Bupivacaine Interaction

Physiologic values before the start of local anesthetic infusion and at the onset of seizures are reported in Table 1. Values for Pao_2, $Paco_2$, pHa, and Hct were within the normal range. The MAP was similar among groups before onset of infusion. In contrast, at onset of seizures, MAP values differed among groups ($F[4,45] = 12.7$; $P = 5.5 \times 10^{-7}$). The MAP values were substantially greater in the bupivacaine alone (156 ± 22 mm Hg) versus lidocaine alone (99 ± 22 mm Hg) groups, whereas MAP values in the various local anesthetic mixture groups were intermediate.

Examples of typical EEG activity at different phases of the experiment are provided in Figure 1. The duration of local anesthetic infusion necessary to produce seizures is reported in Table 2. The mean duration of drug infusion in the lidocaine-alone group (17.0 min) was 3.5 min greater than in the bupivacaine-alone group (13.5 min). As intended, the total doses of lidocaine and bupivacaine differed among groups based on the infusion regimen. Total doses of lidocaine and bupivacaine required to produce seizures in individual rats are plotted in Figure 2. The isobolic line is shown, indicating predicted values for additivity. Doses of lidocaine and bupivacaine administered in combination fell on both sides of the isobolic line. There was no statistical evidence for an interaction between the two

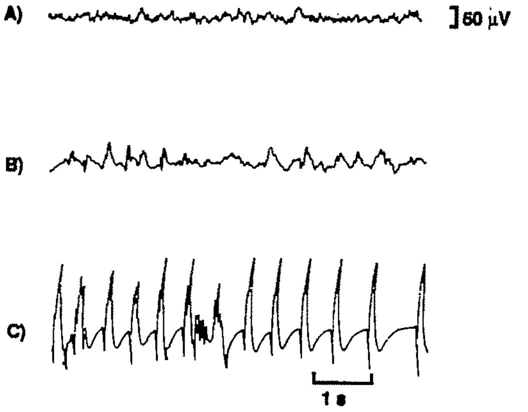

Figure 1. EEG tracings during the experiment: (**A**) typical EEG activity before the start of lidocaine infusion (during 70% nitrous oxide/trace halothane analgesia); (**B**) during lidocaine infusion but before onset of seizure activity; (**C**) seizure activity.

anesthetic agents with respect to epileptogenesis (F[3,47] = 1.00; P = 0.401). A power of 0.80 was present to detect a 10% deviation of mean lidocaine doses from the isobolographic line. For both lidocaine and bupivacaine, larger doses of both anesthetics were associated with greater plasma concentrations, respectively (Figure 3).

Test for Lidocaine-Tetracaine Interaction

Physiologic values before and at the onset of seizures are listed in Table 3. Values for Pa_{O_2}, Pa_{CO_2}, pHa, and Hct were within the normal range. The MAP was similar among groups before onset of infusion. In contrast, at onset of seizures, MAP values differed among groups (F[4,44] = 9.62; $P = 1.1 \times 10^{-5}$). The MAP values were substantially greater in the tetracaine alone (137 ± 18 mm Hg) versus lidocaine alone (73 ± 23 mm Hg) groups, whereas values in the local anesthetic mixture groups were intermediate.

For this experiment, total doses of lidocaine and tetracaine administered at the onset of seizure activity (Table 4) are plotted along with the isobolic line in Figure 4. Less uniformity in the distribution of values is evident than was the case with lidocaine-bupivacaine combinations. Nevertheless, there was no evidence for an interaction between these two agents (F[3,45] = 1.47; P = 0.24). A power of 0.80 was present to detect a 10% deviation of mean lidocaine doses from the isobolographic line.

Discussion

The question as to whether local anesthetics interact is not new. As early as 1912 investigations were carried out to determine whether synergism for potency could be obtained with mixtures of local anesthetics (14). Later work focused on the potential for synergistic toxicity. The first such study identified a more rapid onset of cardiac arrest in rats that had received intravenous infusions of a mixture of 1.0% lidocaine and 0.1% tetracaine versus 1.0% lidocaine alone. However, the effect of tetracaine was absent if combined with 1.5% lidocaine, indicating that significant interactions between local anesthetics might be manifest only within specific ranges of a dose-response curve (4). This conclusion was supported by the work of Brecher et al. (6) who demonstrated, with intraperitoneal injections of lidocaine-tetracaine combinations in mice, that toxicity (mortality) varied significantly with different doses of each drug.

The significance of these interactions can be questioned, however, given the reported broad clinical experience with combinations of local anesthetics for regional anesthesia. In a retrospective study of 10,538 patients who received mixtures of local anesthetics for regional anesthesia, systemic toxicity was observed in only 10 cases (<0.1%) (2).

More recent animal studies are consistent with that clinical experience. Munson et al. (8) measured EEG activity during either a rapid or slow intravenous bolus dose of a fixed ratio of lidocaine-etidocaine or lidocaine-tetracaine administered in rhesus monkeys. That study concluded that mixtures of lidocaine-etidocaine or lidocaine-tetracaine, in proportions equal in potency, have approximately the same epileptogenic potential as either drug administered alone. Those results are convincing but limited in interpretation, because only one mixture of either combination of drug was evaluated. De Jong and Bonin (7) provided further evidence for lack of toxic interaction between local anesthetics by determining the median convulsant dose and median lethal dose for bupivacaine, lidocaine, and choloroprocaine administered independently by subcutaneous injection in mice. Mixtures of these drugs were again found to be no more convulsant or lethal than the parent components administered alone.

Our approach to the question of CNS toxicity from combinations of local anesthetics offers several methodologic improvements over previous studies. First, a variety of doses were evaluated by isobolographic analysis for each pair of drugs. Thus, the possibility that an interaction might be present at one point on the dose-response curve but absent at another could be directly evaluated. Second, the effects of these combinations were monitored on the EEG, perhaps providing a more discrete toxicologic endpoint than motor convulsions (7). Indeed, this may have been successful, because the coefficients of variation for epileptogenic doses in our study (lidocaine 16%; bupivacaine 17%; tetracaine 21%) were approxi-

Values are mean ± SD.

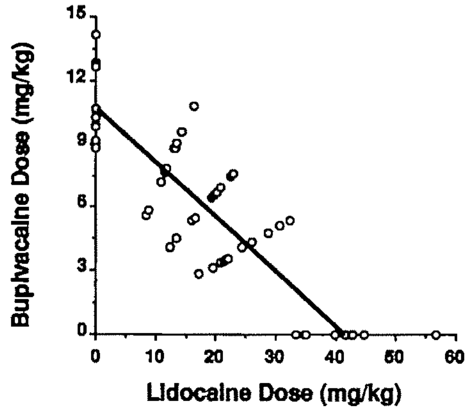

Figure 2. Lidocaine and bupivacaine were administered intravenously either alone or in fixed-ratio doses. Individual values for total doses of lidocaine or bupivacaine, or both, administered at the onset of EEG seizures are depicted. The isobolic line (predicted line of additivity) is provided. As can be observed, the data appear to be equally distributed on both sides of the isobolic line, excluding the possibility of either an antagonistic or synergistic interaction between these two anesthetics.

mately one-half those observed when motor convulsions were previously used as an endpoint for observing epileptogenicity (7). Third, MAP changes associated with CNS toxicity were monitored. Finally, ventilation was supported, thus avoiding any effect of anesthetic-induced respiratory depression on the results (15).

The one limitation of our preparation was the coadministration of nitrous oxide and halothane. To minimize EEG artifacts, spontaneous movement could not be allowed; thus, paralytic agents (*d*-tubocurarine) and appropriate sedation were required. Nitrous oxide has been demonstrated to increase the threshold for lidocaine-induced seizures (16). Halothane, in large doses, has been recognized as an anticonvulsant for status epilepticus (17). We sought to minimize the halothane effect by discontinuing it 15 min before onset of local anesthetic infusion (effectively constituting 30 min before onset

of seizures). At this interval, in a separate group of otherwise identically treated rats, we measured an end-tidal halothane concentration of 0.15% ± 0.06%. The presence of nitrous oxide and trace halothane, although presumably similar across groups, undoubtedly provided some anticonvulsant activity, explaining in part the large doses of local anesthetic required to produce epileptic activity.

The results from our study are consistent with the conclusions drawn by Munson et al. (8) and de Jong and Bonin (7). Across a wide dosage range of combinations of either amide-amide or amide-ester local anesthetics, no evidence for either synergism or antagonism could be detected. These findings, along with the clinical safety and efficacy reported for combinations of local anesthetics in regional anesthesia (2), provide considerable support for the continuation of this practice when indicated by clinical conditions.

The MAP effects of the local anesthetic doses

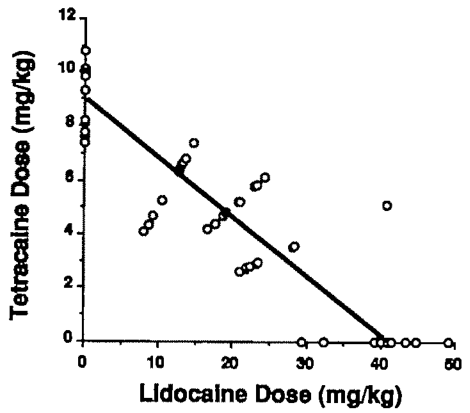

Figure 4. Lidocaine and tetracaine were administered intravenously either alone or in fixed-ratio doses. Individual values of total doses of lidocaine or tetracaine, or both, administered at the onset of EEG seizures are depicted. The *isobolic line* (predicted line of additivity) is provided. As can be observed, the data appear to be equally distributed on both sides of the isobolic line (predicted line of additivity), excluding the possibility of either an antagonistic or synergistic interaction between these two anesthetics.

necessary to cause seizures were somewhat unexpected. In both experiments, the lowest MAP values at onset of seizures were observed in the lidocaine-alone groups. Reduction of the lidocaine dose, by increasing either the bupivacaine or tetracaine dose, ameliorated this effect. De Jong and Bonin (7) similarly observed that the mixtures of lidocaine with bupivacaine or lidocaine with chloroprocaine were less likely to produce death, presumably from cardiovascular collapse, in mice without ventilatory support. Our experiment was discontinued after onset of seizure activity but before hemodynamic collapse became evident. This protocol was established because of the potential confounding influence of drawing blood samples, at the onset of seizures, on subsequent hemodynamic events. Because bupivacaine has been demonstrated to exhibit a narrow margin of safety between onset of convulsions and cardiovascular collapse (18), further work specifically addressing this issue is necessary to allow the conclusion that mortality from local anesthetic overdoses can be reduced by using a combination of local anesthetics as opposed to one anesthetic alone. Further, our observations may be specific to the rat, given the relatively high heart rate found in this species (250–350 beats/min). Because the cardiotoxic effect of local anesthetics is heart-rate dependent (19), observations made in this study may not be relevant in humans, who characteristically have a slower heart rate.

We conclude that the CNS toxic effects of amide-amide or amide-ester anesthetic combinations, such as might occur during accidental intravascular injection, are no greater than when the respective anesthetics are administered alone in the rat. However, because such combinations appear to be additive with respect to CNS toxic effects, proportional reductions in the dose of one anesthetic must be made if administered in combination with another.

Locomotor Activity After Recovery From Hypnosis: Midazolam-Morphine Versus Midazolam

Igor Kissin, MD, PhD, Pamela T. Brown, BS, and Edwin L. Bradley, Jr., PhD

Department of Anesthesiology, University of Alabama School of Medicine, Birmingham, Alabama

This study was performed to test the hypothesis that sedation after recovery from pharmacologic hypnosis is less pronounced if hypnosis is induced with a midazolam-morphine combination compared with midazolam administered alone. Loss of the righting reflex was used as an index for the hypnotic effect and reduction of locomotor activity as an index for the sedative effect. One group of rats received midazolam (20 mg/kg IV) and another group an equipotent (in relation to the hypnotic effect) combination of midazolam (4 mg/kg IV) and morphine (1.3 mg/kg IV). The duration of loss of the righting reflex in the midazolam and midazolam-morphine groups was 30 ± 3 and 28 ± 2 min, respectively (mean ± SE). The difference between the groups in locomotor activity after recovery from hypnosis was very pronounced. The locomotor activity in the midazolam-morphine group at 1 and 2 h was seven and five times greater, respectively, than in the midazolam group ($P < 0.005$). The profound difference in locomotor activity for the two treatment groups was explained on the basis of the difference in the outcomes of midazolam-morphine interactions with regard to hypnosis (synergism) and sedation (summation). When the animals recovered from hypnosis, the synergism of the drug interaction ceased to be a contributing factor.

(Anesth Analg 1992;75:929–31)

Benzodiazepine-opioid hypnotic interaction for induction of unconsciousness in patients was found to be synergistic (supraadditive) (1). Experiments in rats also demonstrated that the diazepam-morphine (2) or midazolam-morphine (3) interactions for pharmacologic hypnosis (4) (loss of the righting reflex index) are highly synergistic. However, when the midazolam-morphine interaction was studied in rats with regard to sedative effect (inhibition of locomotor activity index), instead of the expected synergism, we found a simple summation of the effects (3). Doses of midazolam necessary for sedation are manyfold smaller than those for hypnosis. There is a possibility that when midazolam-morphine synergism develops with high (hypnotic) doses, it would also continue to exist for sedation after recovery from hypnosis. An assessment of the drug interactions for two actions, hypnotic and sedative, in the same experiment when one of the actions is followed by another, would examine this possibility.

The present study was designed to test the following hypothesis: sedation after recovery from midazolam-induced hypnosis should be more pronounced than sedation after hypnosis induced by a midazolam-morphine combination, because when animals recover from the latter, the synergism of drug interaction ceases to be a contributing factor.

Methods

Experiments were performed in 66 male Sprague-Dawley rats weighing 225–275 g. The protocol for this study was approved by the Institutional Panel on Laboratory Care. As an index for hypnotic effect, we used the loss of the righting reflex; as an index for sedative effect, the reduction of locomotor activity. The righting reflex was tested in the following way: the rat was placed in a cylindrical, revolving cage with its paws down; the cage was rotated (1 revolution/15 s) to place the rat on its back, after which the rotator was stopped for 15 s. If the rat could not be placed on its back for 15 s, or could not remain on its back for an additional 15 s, the righting reflex was considered not blocked.

Spontaneous locomotor activity was measured with the use of an activity meter (Opto-Varimex-Mini, Columbus Instruments, Columbus, Ohio) that counted the number of infrared beam interruptions (15 beams with sensors equally spaced [2.65 cm] in the cage at a distance of 5.25 cm from the floor.) Only

ambulatory activity was taken into account; stereotypic movements that caused rapid, repeated interruptions of the same beam (e.g., grooming, digging, scratching) were not considered. Each rat was placed into the activity cage alone, and only once, for 15 min.

Midazolam or a combination of midazolam and morphine was administered intravenously into the saphenous vein. The selected drug doses provided equipotency with regard to hypnotic effect. We used midazolam (20 mg/kg) and an equipotent combination of 4 mg/kg of midazolam and 1.3 mg/kg of morphine (doses according to a previous study [3]). In the combined drug experiments, each drug was injected separately, with an interval of 12 min to synchronize its peak effect.

The righting reflex was determined every 5 min. After recovery of the righting reflex, a rat's locomotor activity was determined at different time intervals in different subgroups of animals. Both midazolam and midazolam-morphine groups had five subgroups of six animals, with locomotor activity determinations at 1, 2, 4, 8, or 16 h after drug administration. A control group receiving no drugs was used for comparison. Morphine sulfate was obtained from Eli Lilly Co. (Indianapolis, Ind.) and midazolam hydrochloride from Roche Laboratories (Nutley, N.J.).

The locomotor activity (beam crossing) was summarized as the mean ± SE. For comparisons of the mean number of beam crossings, a two-way analysis of variance was used (5). Pairwise tests between any two means utilized Fisher's protected least significant difference test (5). Differences were declared statistically significant if $P < 0.05$.

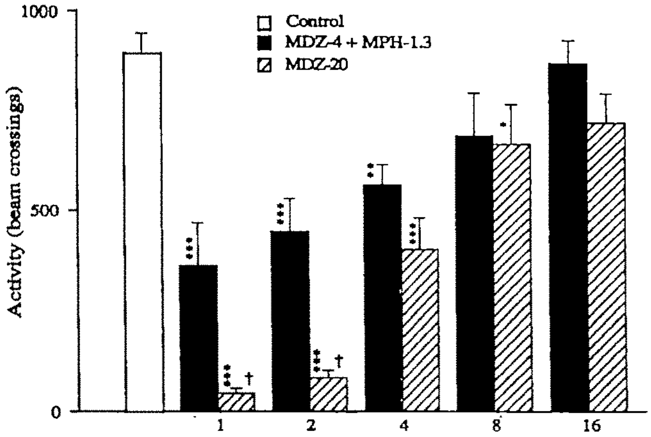

Figure 1. Effect of midazolam (MDZ) and midazolam-morphine (MPH) combination in equipotent hypnotic doses (MDZ 20 mg/kg and MDZ 4 mg/kg + MPH 1.3 mg/kg) on the locomotor activity in rats after recovery of the righting reflex. *Vertical axis*, number of beam crossings for 15 min; *horizontal axis*, time from injection. $^{*}P < 0.05$ versus control; $^{**}P < 0.005$ versus control, $^{***}P < 0.001$ versus control; $^{\dagger}P < 0.005$ versus MDZ + MPH.

Results

The duration of loss of the righting reflex in the midazolam and midazolam-morphine groups was 30 ± 3 and 28 ± 2 min, respectively; that indirectly confirmed the hypnotic equipotency of the chosen doses. The changes in the locomotor activity of the animals after recovery from hypnosis are presented in Figure 1. Figure 1 demonstrates a pronounced difference in the locomotor activity between midazolam and midazolam-morphine in the 1- and 2-h subgroups (46 ± 13 vs 360 ± 109 crossings, $P < 0.005$; 85 ± 18 vs 447 ± 84 crossings, $P < 0.005$, respectively). Although there were numerical differences between the two groups after 2 h, they were statistically insignificant.

Discussions

The results obtained in the present study demonstrated that despite equal duration of loss of the righting reflex caused by equipotent (for hypnotic effect) doses of midazolam and the midazolam-morphine combination, locomotor activity in rats after recovery from hypnosis is depressed more when midazolam is used alone. The difference in locomotor activity for the two treatments is very profound.

Inhibition of locomotor activity in animals is commonly regarded as an index for sedative action (6). The present study gave the opportunity to test two actions, hypnotic and sedative, in the same experiment when one of them was followed by another. As a result, it was possible to demonstrate the abrupt disappearance of the synergy between midazolam and morphine and the long-lasting difference in the sedative effect of the two treatments given in the doses equipotent for hypnotic effect. Differences in the outcomes of the midazolam-morphine interaction with regard to sedation and hypnosis suggest that these two actions should not be regarded as only increasing depths of the same action.

We suggest that the additive midazolam-morphine interaction for sedation is mainly due to the pharmacodynamic mechanisms. Previously reported results (2) with brain concentration-related analysis of the morphine-diazepam hypnotic interaction demonstrated the same degree of synergism as results with dose-related analysis of the same interaction. This outcome decreases the probability that pharmacokinetic factors play a significant role in the morphine-benzodiazepine hypnotic synergism. At the same time, differences in the pharmacokinetic interactions for relatively high concentrations (providing hypnosis) and for lower concentrations of agents (providing sedation), although unlikely, are possible. Therefore, pharmacokinetic aspects of the midazolam-morphine sedative interaction deserve further elucidation. As for the less pronounced depression of locomotor activity following hypnosis with the midazolam-morphine combination versus midazolam alone, it is most likely due to considerably smaller concentrations of midazolam at the target sites at a time when the synergism between midazolam and morphine is lost after recovery from hypnosis.

The clinical implication of these results is that a benzodiazepine-opioid combination in hypnotic doses that are equipotent to a benzodiazepine alone might result in less sedation after awakening. Previously reported results confirmed a profound benzodiazepine-opioid hypnotic synergism in patients (1,7). At the same time, when a midazolam-morphine combination was studied in patients with regard to its sedative effect, only simple summation of the effects was found (8). This difference indicates that the results reported in the present study might be very indicative of what to expect in patients.

In conclusion, the results of the present study confirmed the hypothesis that sedation after recovery from midazolam-induced hypnosis is more profound than sedation after hypnosis induced by mi
morphine combination.

Intramuscularly Administered Dexmedetomidine Attenuates Hemodynamic and Stress Hormone Responses to Gynecologic Laparoscopy

M. Aho, MD, M. Scheinin, MD, PhD, A.-M. Lehtinen, MD, PhD, O. Erkola, MD, PhD, J. Vuorinen, MSc, and K. Korttila, MD, PhD

Department of Anesthesia, Women's Hospital, University of Helsinki, Helsinki; Department of Pharmacology, University of Turku, Turku; and Orion Corporation, Farmos Research Center, Turku, Finland

The hemodynamic and endocrine effects of three different doses of dexmedetomidine (0.6, 1.2, and 2.4 μg/kg), oxycodone (0.13 mg/kg), and saline solution, injected intramuscularly 45–60 min before induction of general anesthesia, were compared in a double-blind, randomized study involving 100 women undergoing gynecologic diagnostic laparoscopy. Anesthesia was induced with thiopental (4.5 mg/kg) and maintained with 0.3% end-tidal isoflurane and 70% nitrous oxide in oxygen. Arterial blood pressure and heart rate increased after endotracheal intubation and during laparoscopy in all groups, but the maximal mean arterial pressure after tracheal intubation was lower in the dexmedetomidine 2.4-μg/kg group (104 mm Hg [SD 19]) than in the saline solution group (130 mm Hg [SD 12]). Dexmedetomidine (2.4 and 1.2 μg/kg) attenuated the maximal heart rate after intubation (84 [SD 11] and 101 beats/min [SD 15], respectively) compared with saline solution (116 beats/min [SD 19]). On the other hand, 40% of the patients in the dexmedetomidine 2.4-μg/kg group received atropine in the postanesthesia care unit for bradycardia (heart rate $\leq$40 beats/min). Preoperative anxiety and sedation before and after preanesthetic medication were evaluated by the patients with the aid of a profile of mood-state questionnaire; only dexmedetomidine 2.4 μg/kg produced significant anxiolysis and sedation. Plasma concentrations of norepinephrine, epinephrine, 3,4-dihydroxyphenylglycol, cortisol, and β-endorphin increased less in the dexmedetomidine 2.4-μg/kg group in response to tracheal intubation and surgery than in the saline solution group.

(Anesth Analg 1992;75:932–9)

Recent studies with α_2-adrenoceptor agonists have demonstrated beneficial effects in anesthetized patients (1–3). Clonidine attenuates hemodynamic responses during laryngoscopy and endotracheal intubation (2,3). It also reduces dose requirements of inhaled anesthetics (4–8) during surgical stimulation. In addition, α_2-adrenoceptor agonists may have clinically significant anxiolytic activity (9).

Dexmedetomidine is a highly specific, potent, and selective α_2-adrenoceptor agonist (10,11). Racemic medetomidine is widely used as a sedative and an anesthetic in domestic animals (12). In humans, dexmedetomidine, the active dextroisomer that exhibits sedative properties, is well tolerated (13,14). Subjective sleepiness appears within 5 min after intravenous administration and reaches its maximum 15 min after the drug injection (14). Dexmedetomidine caused a dose-dependent decrease in arterial blood pressure and heart rate (HR) (13), and reduction in sympathetic nervous activity was manifested as a dose-dependent decline in plasma levels of norepinephrine (13,15). Single intravenous doses of dexmedetomidine administered 15 min before the induction of anesthesia decreased thiopental requirements during cervical dilatation and uterine curettage (16), attenuated the hemodynamic responses to laryngoscopy and endotracheal intubation, and diminished isoflurane requirements during abdominal hysterectomy (17).

Nociceptive surgical stimulation is accompanied by increased sympathoadrenal and hypothalamopituitary activation (18,19), which is generally referred to as the stress response to surgery (19–21). Plasma concentrations of cortisol, immunoreactive β-endorphin, and catecholamines increase in response to

tracheal intubation (22,23) and surgery (24). Local anesthetic techniques (19) and anesthetic drugs modify the release of these stress hormones into the peripheral circulation during surgical stress.

In the present study, we investigated the effects of three different preanesthetic doses of intramuscularly injected dexmedetomidine on hemodynamics during isoflurane anesthesia in patients undergoing gynecologic laparoscopy. For comparison, similar groups of patients were injected intramuscularly with a synthetic narcotic analgesic, oxycodone, or saline solution. This route of administration was chosen because α_2-adrenergic drugs result in smoother hemodynamic response after intramuscular than intravenous administration (13). To gain more information from the simultaneous effect of dexmedetomidine on both the hypothalamopituitary and sympathoadrenal responses to stress during the procedure, we measured plasma concentrations of cortisol, β-endorphin, and catecholamines (norepinephrine, epinephrine, and 3,4-dihydroxyphenylglycol [DHPG]).

Methods

The study protocol was approved by the Ethical Committee of Women's Hospital, University of Helsinki. Written, informed consent was obtained from each patient. The study population comprised 100 women, aged 20–42 yr, undergoing elective diagnostic gynecologic laparoscopy. All were healthy, normotensive, ASA physical status I patients receiving no medication. Demographic characteristics are shown in Table 1.

The patients were randomized into five groups (n = 20 in each group). On the day of surgery, premedication was administered from coded ampules into the vastus lateralis muscle 45–60 min before induction of anesthesia. Patients received either dexmedetomidine hydrochloride (0.6, 1.2, or 2.4 μg/kg) (Orion Corporation Farmos, Turku, Fin-
land), oxycodone chloride (0.13 mg/kg) (
Leiras, Helsinki, Finland), or saline soluti
double-blind design was maintained by h

thesia care unit, intravenous fentanyl was
tered for moderate or severe pain in inc
doses of 0.05 mg.

Arterial blood pressure and HR were
with a noninvasive, automated blood pressu
itor (Datascope Accutor, Datascope Corp.
(baseline) and at 10-min intervals after pre
tion. The measurements were performed
intervals during induction, for the first 10 r
tracheal intubation, and thereafter at 2.5-m

vals throughout the duration of anesthesia. In the postanesthesia care unit, arterial blood pressure and HR were recorded at 15-min intervals. The electrocardiogram was monitored throughout the premedication period, during the laparoscopy, and in the postanesthesia care unit.

Sedation scores (1 = awake, eyes open; 2 = asleep, but arousable) were assessed by a research nurse before premedication and just before induction of anesthesia.

The patients were requested to fill out the Finnish version of the profile of mood-state (POMS) questionnaire, which consisted of seven adjectives related to fatigue and eight adjectives related to tension and anxiety, before administration of a study drug. The questionnaire was repeated immediately before induction of anesthesia. The Finnish version of POMS has previously been standardized in normal female populations (26) and used in the evaluation of premedication (26).

Need of fentanyl doses in the postanesthesia care unit was recorded.

Plasma cortisol was measured in all patients; plasma immunoreactive β-endorphin only in the patients who received either the largest dose of dexmedetomidine (2.4 μg/kg) or saline solution. Plasma concentrations of norepinephrine, epinephrine, and DHPG, a deaminated metabolite of norepinephrine, were measured in patients receiving dexmedetomidine (1.2 or 2.4 μg/kg), oxycodone, or saline solution. Before premedication, control baseline blood samples for plasma cortisol, immunoreactive β-endorphin, DHPG, epinephrine, and norepinephrine determinations were drawn from an intravenous antecubital cannula. Blood samples were collected again just before induction of anesthesia, 5 and 15 min after tracheal intubation, 10 min after the beginning of laparoscopy, and 1 h after the procedure. Blood samples were collected into prechilled K_2-ethylenediaminetetraacetate tubes and promptly centrifuged. Plasma was separated and stored at −70°C. Cortisol analyses were carried out by radioimmunoassay (27), having an intraassay coefficient of variation of 3%, using commercially available reagents (Orion Corporation Farmos). Radioimmunoassays of immunoreactive β-endorphin were performed after extraction of the plasma samples using SEP PAK C18 cartridges (Water Associates Inc., Milford, Mass.), as described previously by Laatikainen et al. (28). The intraassay coefficient of variation for the determination of immunoreactive β-endorphin was 11%. Levels of endogenous catecholamines were determined using high-performance liquid chromatography with electrochemical detection (29). The intraassay coefficients of variation were <2% for norepinephrine, 4% for DHPG, and 10% for epinephrine.

Statistical analyses were performed using two-way analysis of covariance (ANCOVA) for repeated measures to determine whether differences in the response (arterial blood pressure, HR, hormone concentration) varied significantly over time between the study drugs (drug by time interaction) and whether the mean levels of response for the study drugs differed significantly (drug main effect). When a statistically significant drug by time interaction or drug effect was present, the analysis was continued by applying contrasts for each pair of different drugs with Bonferroni correction. For demographic data and single endpoints (e.g., maximal HR and arterial blood pressure), one-way analysis of variance or ANCOVA was used with Bonferroni-corrected *t*-tests for pairwise comparisons. The POMS tension-anxiety and fatigue scores and the nurse's sedation scores were analyzed with nonparametric Kruskal-Wallis one-way analysis of variance using Bonferroni-corrected Mann-Whitney tests for pairwise comparisons. A *P*-value <0.05 was considered statistically significant. The analyses were performed with BMDP software.

Results

The five groups were comparable with respect to age, height, baseline HR, duration of surgery (18 min [SD 9]), and intraoperative fluid requirements (Table 1). The patients in the dexmedetomidine 0.6-μg/kg group were heavier and had higher mean arterial blood pressure (MAP) than most of the other patients. One of the patients enrolled in this group was withdrawn because laparoscopy was followed by laparotomy during the same anesthesia.

There were no statistically significant differences in the need for analgesic medication in the postanesthesia care unit: 90% of patients in the saline solution group, 79% in the dexmedetomidine 0.6-μg/kg group, 85% in the dexmedetomidine 1.2-μg/kg group, 65% in the dexmedetomidine 2.4-μg/kg group, and 60% in the oxycodone group received fentanyl.

Sedation and Anxiolysis

The sedative effect of the largest dose of dexmedetomidine (2.4 μg/kg), as assessed by the research nurse 45–60 min after preanesthetic medication, was significant compared with the saline solution group ($P = 0.02$; Mann-Whitney test) but was not significantly different from that of the lower doses of dexmedetomidine or oxycodone (Table 2).

The POMS tension-anxiety scores decreased in all patient groups after preanesthetic medication, but the decrease was most significant in the dexmedetomidine 2.4-μg/kg group (Table 2). The POMS fatigue

scores increased significantly more after dexmedetomidine 2.4 μg/kg than after saline solution or dexmedetomidine 0.6 or 1.2 μg/kg (Table 2).

Arterial Blood Pressure

The MAP followed similar patterns in all groups (Table 3). After administration of the preanesthetic study drugs, MAP values before induction differed among the groups. Dexmedetomidine caused a significant, dose-dependent decrease in MAP before anesthesia, whereas oxycodone did not. The MAP increased after endotracheal intubation in all groups, but dexmedetomidine attenuated this response in a dose-dependent manner. The highest MAP values observed after intubation in the dexmedetomidine 2.4-μg/kg group (104 mm Hg [SD 19]) were significantly lower ($P < 0.001$; t-test) than in the saline solution group (130 mm Hg [SD 12]), with a 95% confidence interval from −39 to −10 mm Hg for the difference between the two groups. During laparoscopy, MAP increased again in all groups, but there was a significant difference in maximal MAP among them ($P = 0.02$; ANCOVA). The maximal MAP was lowest in the dexmedetomidine 2.4-μg/kg group. In the postanesthesia care unit MAP values were also lowest in patients premedicated with dexmedetomidine 2.4 μg/kg.

Heart Rate

Before induction, dexmedetomidine 2.4 μg/kg decreased HR significantly compared with both saline solution ($P < 0.001$) and oxycodone ($P = 0.02$) (Table 3). The HR increased in all groups after intubation, but the increase was less in the dexmedetomidine 2.4-μg/kg group compared with the oxycodone and saline solution groups, with a 95% confidence interval from −42 to −16 beats/min for the difference versus the saline solution group. Dexmedetomidine 1.2 μg/kg blunted the HR increase significantly compared with the saline solution group. The HR increased in all groups during laparoscopy. The maximal values were significantly greater in the saline solution group compared with the oxycodone ($P = 0.02$) and dexmedetomidine 1.2-μg/kg ($P = 0.001$) and 2.4-μg/kg ($P < 0.001$; *t*-test) groups.

In the postanesthesia care unit, patients premedicated with dexmedetomidine 2.4 μg/kg had lower HR than the others (Table 3). Eight of the 20 patients in this group had HR transiently <40 beats/min and were treated with atropine (0.4 mg). In contrast, there were no atropine-treated patients in the other groups. No electrocardiographic changes other than sinus bradycardia were observed, and the response to atropine was adequate.

Stress Hormones in Plasma

Plasma cortisol concentrations were lowest before induction of anesthesia in the patients premedicated with dexmedetomidine 2.4 μg/kg or with oxycodone. After intubation or during laparoscopy, increases were observed in all groups; in the saline solution group, maximal levels had already been reached after intubation. The cortisol values remained lowest after intubation in the oxycodone and dexmedetomidine 2.4-μg/kg groups (Figure 1). The cortisol concentrations increased postoperatively to similar levels in all groups.

Before induction, there was no difference in plasma immunoreactive β-endorphin between the highest dose of dexmedetomidine and saline solution. In the saline solution group, plasma β-endorphin increased significantly more in response to laryngoscopy and laparoscopy compared with the dexmedetomidine 2.4-μg/kg group (Figure 2).

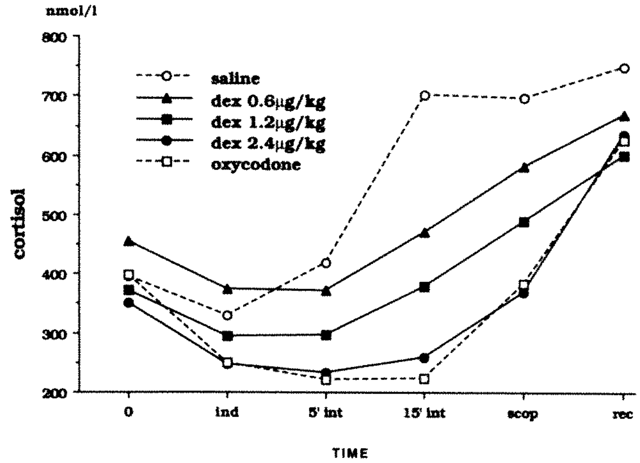

Figure 1. Mean cortisol concentrations in peripheral plasma just before preanesthetic medication (O), just before induction (ind) of anesthesia, 5 and 15 min after intubation ('int), 10 min after beginning of laparoscopy (scop), and 1 hour after operation in the postanesthesia care unit (rec). Standard deviations have been omitted for clarity. *Key to abbreviations*: a = dexmedetomidine (dex) 2.4 μg/kg versus saline solution; b = oxycodone versus saline solution; c = dexmedetomidine 2.4 μg/kg versus oxycodone. Drug main effect: $^{*}P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$. Drug by time interaction: #$P < 0.05$, ##$P < 0.01$, ###$P < 0.001$, NS = not significant. In this figure: a = ***, ###; b = ***, ###; c = NS, NS.

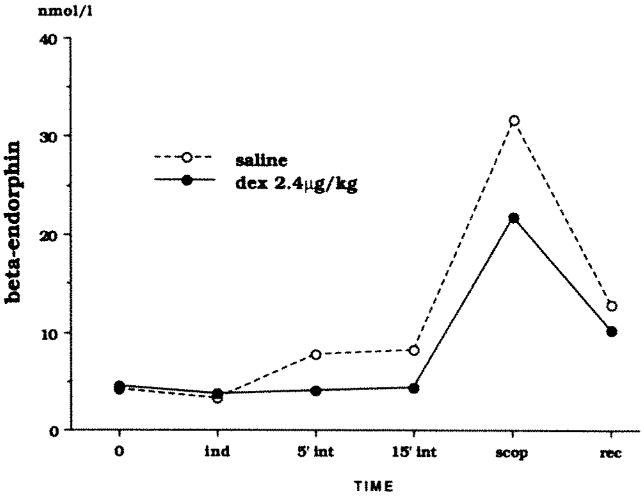

Figure 2. Mean β-endorphin concentrations in peripheral plasma. Standard deviations have been omitted for clarity. In this figure a = *, NS. See Figure 1 for explanation of abbreviations.

Dexmedetomidine induced approximately 70% reductions in plasma norepinephrine concentrations. Both dexmedetomidine 1.2- and 2.4-μg/kg groups differed from saline solution and oxycodone groups (Figure 3). The highest norepinephrine values were observed postoperatively in the saline solution group.

Plasma DHPG was reduced by approximately 20%

in the dexmedetomidine 2.4-µg/kg group immediately after administration of preanesthetic medication. In the saline solution and oxycodone groups, the values remained at the baseline level. This difference was maintained throughout the study period. There was a marked increase in DHPG values postoperatively in the saline solution and oxycodone groups, which contrasted with the stable values in the dexmedetomidine groups (Figure 4).

The plasma epinephrine concentrations increased markedly during laparoscopy in all groups. The increase was smaller in the dexmedetomidine groups compared with the oxycodone and saline solution groups. This difference in epinephrine concentrations was maintained in the postanesthesia care unit (Figure 5).

Discussion

The most important findings in this investigation were related to changes in HR and arterial blood pressure. During the preanesthetic period, the highest dose of dexmedetomidine (2.4 µg/kg) caused a significant reduction in MAP but without provoking any subjective symptoms. Laryngoscopy, endotracheal intubation, and gynecologic laparoscopy induced significant increases in arterial blood pressure in all study groups, but to a lesser extent after dexmedetomidine 2.4 µg/kg than after the other drugs. Dexmedetomidine reduces HR (13), and this was dose-dependently observed in our study at doses of 1.2 and 2.4 µg/kg. The increase in HR in response to intubation and laparoscopy was substantially blunted by dexmedetomidine. This might be beneficial in patients at risk for myocardial ischemia secondary to tachycardia (30). In the postanesthesia care unit, atropine was administered to treat sinus bradycardia (i.e., HR <40 beats/min) in 8 of the 20 patients in the highest-dose dexmedetomidine group and in none in the other groups. Although this indicates that the effect of dexmedetomidine was still apparent during the recovery period, the premedication did not alter the need for analgesics. Bradycardia and a concomitant slight decrease in MAP may be clinically unimportant in ASA physical status I patients but may restrict the use of this drug in patients prone to bradycardia, as has been pointed out concerning another α_2-adrenergic agonist, clonidine (1).

Our findings with regard to surgery-related stress responses are in agreement with several studies on the effects of the prototype α_2-adrenergic agonist clonidine. Oral clonidine (4.5 μg/kg) attenuated the sympathoadrenal response to tracheal intubation in patients undergoing breast surgery under general anesthesia (31). The plasma norepinephrine levels were lower throughout the procedure, and the plasma epinephrine concentrations were lower after intubation in the clonidine-pretreated patients compared with the control group (31). In our previous study, we administered clonidine (3 and 4.5 μg/kg IM) and demonstrated that the increases in arterial blood pressure and HR in response to endotracheal intubation and laparoscopy were attenuated in the clonidine-pretreated patients (32). The α_2-adrenergic agonists exert their sympatholytic effect presumably by activating inhibitory α_2-adrenergic receptors, both in the central nervous system and on peripheral sympathetic nerve endings (presynaptic autoreceptors) (33–35). This action leads to inhibition of release of norepinephrine from sympathetic nerve endings (35,36). The inhibition of sympathetic transmitter release can be measured in humans as a decrease in the concentration of norepinephrine in plasma (13, 15,29,31).

In the present study, dexmedetomidine induced marked and sustained reductions in plasma concentrations of norepinephrine and its deaminated metabolite DHPG. The initial DHPG decrease is in line with our previous observations (29), but the total attenuation of the DHPG increase during surgery by dexmedetomidine appears to be a new finding. It indicates that plasma DHPG measurements may be useful in the evaluation of the sympathoinhibitory effects of preanesthetic medications. Suppression of epinephrine release was not complete during and after laparoscopy, but a difference was observed when the two highest doses of dexmedetomidine (1.2 and 2.4 μg/kg) were compared with either saline solution or oxycodone. When lower doses of dexmedetomidine were administered intramuscularly before minor surgery, similar dose-dependent reductions in norepinephrine concentrations were observed (37).

The attenuation of cortisol and β-endorphin responses to surgical stimulation reflects inhibition of stress responses, comparable to the effects of opioids (24) or deeper levels of general anesthesia (21,22). In our previous study, clonidine 4.5 μg/kg attenuated the β-endorphin response to laparoscopy (32). However, controversial results have been obtained in studies on the noradrenergic control of cortisol release. The α_2-adrenoceptor agonists did not directly influence cortisol secretion under basal conditions (13,38), and oral clonidine premedication did not suppress the release of cortisol in response to anesthesia and surgery (31). Similarly, in a recent study with intravenous dexmedetomidine, plasma cortisol levels were not affected, and a relatively small dose of dexmedetomidine did not inhibit the increase in plasma cortisol concentrations after minor surgery (39). In the present study, the concentration of cortisol in plasma decreased in a dose-dependent fashion. The effect of the highest dose of dexmedetomidine (2.4 μg/kg) was comparable to the effect of oxycodone, although marked postoperative increases in plasma cortisol were observed in all groups. One explanation for our finding, which has not been reported previously, is that we used a large dose of dexmedetomidine before a moderately stressful procedure carried out under relatively light anesthesia.

Dexmedetomidine (2.4 μg/kg) injected intramuscularly produced both sedation and a reduction in anxiety, as measured with POMS; yet patients were responsive and free from subjective side effects. Anxiolytic and sedative effects of dexmedetomidine were comparable to those seen with benzodiazepines (26).

In conclusion, intramuscularly administered dexmedetomidine resulted in sedation and anxiolysis and blunted the hemodynamic and hormonal responses to noxious stimuli during laparoscopy. Sinus bradycardia may be associated with dexmedetomidine premedication, although it was asymptomatic and readily reversed by atropine in our patients.

We are grateful to Antero Kallio, MD, and Harry Scheinin, MD, for providing us with the study drugs. We also thank Pirjo Ojala-Karlsson, MSc, Minna Tiilikainen, and Katariina Salminen, PhD, for technical assistance, and Kaarina Backas, nurse anesthetist, for taking good care of our patients.

---

The usefulness of intravenous dexmedetomidine infusion for maintenance of anesthesia was studied in patients anesthetized with thiopental, fentanyl, nitrous oxide, and oxygen. Isoflurane was added as needed. The study was conducted in two parts, the first of which was an open dose-response study that comprised 14 women undergoing abdominal hysterectomy. After a suitable infusion regimen of dexmedetomidine was determined according to hemodynamic criteria, 20 patients were included in a double-blind, randomized placebo-controlled trial (10 receiving dexmedetomidine, 10 saline solution). Dexmedetomidine was administered as a two-step infusion to rapidly achieve a steady-state plasma concentration. The infusion was started with an initial dose given over 10 min before the induction of anesthesia; at induction the maintenance rate was begun and continued until closure of the abdominal fascia. The infusion regimens of dexmedetomidine tested in the dose-response study ranged from 120 $ng \cdot kg^{-1} \cdot min^{-1}$, followed by 6 $ng \cdot kg^{-1} \cdot min^{-1}$, to 270 + 13.5 $ng \cdot kg^{-1} \cdot min^{-1}$. In the second part of the study, an initial infusion of 170 $ng \cdot kg^{-1} \cdot min^{-1}$ was chosen, followed by 10 $ng \cdot kg^{-1} \cdot min^{-1}$ for maintenance. Anesthesia was induced with thiopental (4.0 mg/kg) and maintained with isoflurane in 70% nitrous oxide and oxygen. Isoflurane was administered according to predetermined hemodynamic criteria. Dexmedetomidine infusion did not completely abolish the need for isoflurane but diminished its requirement by >90% (P = 0.02). The heart rate response to endotracheal intubation was significantly blunted.

(Anesth Analg 1992;75:940–6)

The α_2-adrenergic agonists produce sedation (1) and reduce anesthetic requirements in several animal models (2–5). The prototype α_2-adrenergic agonist, clonidine, has been used for its hemodynamic stabilizing effect (6–8) and for its anesthetic-sparing effect during cardiopulmonary bypass (9), during vascular surgery (10), and in elderly patients (11). Postoperative clonidine infusion reduces heart rate and plasma norepinephrine, epinephrine, and vasopressin concentrations (12).

Dexmedetomidine, an imidazole derivative, is a selective and full α_2-adrenoceptor agonist possessing sedative properties (13–15). It is well tolerated but causes a dose-dependent decrease in arterial blood pressure and heart rate (HR) associated with a decrease in plasma norepinephrine concentrations (14). Sleepiness appears within 5 min after intravenous administration of dexmedetomidine and reaches its maximum within 15 min (16). A single intravenous bolus dose of dexmedetomidine administered 15 min before induction of anesthesia diminished thiopental requirement during cervical dilatation and uterine curettage procedures (17). Dexmedetomidine administered by a single intravenous injection attenuates hemodynamic responses to laryngoscopy and endotracheal intubation and decreases isoflurane requirement for anesthetic maintenance by 30% (18).

In this study, we evaluated the effects of a continuous, two-step intravenous infusion of dexmedetomidine on hemodynamic responses to laryngoscopy and endotracheal intubation and its usefulness during maintenance of anesthesia in patients undergoing abdominal hysterectomy.

Methods

The study protocol was approved by the Ethical Committee of Women's Hospital, University of Helsinki. Written, informed consent was obtained from each patient. The study was conducted in two parts.

This study was supported by Orion Corporation, Farmos Research Center, Turku, Finland.

Accepted for publication June 5, 1992.

The first was an open dose-response study and comprised 14 women undergoing elective abdominal hysterectomy. The second part, accomplished after the suitable infusion regimen of dexmedetomidine had been determined, consisted of a double-blind, randomized, placebo-controlled trial involving 20 patients. All were healthy, normotensive, ASA physical status I or II women.

On the evening before surgery, patients received oral triazolam (0.125 mg). On the day of surgery, they received oral diazepam (0.2 mg/kg) 45–60 min before induction of anesthesia.

On arrival in the operating room, all patients had an intraarterial cannula inserted for arterial blood pressure monitoring and electrodes applied for continuous electrocardiographic monitoring. They were given glycopyrrolate (0.2 mg IV). The study drug was administered as a two-step intravenous infusion, starting at the higher (initial) rate for 10 min just before induction of general anesthesia. At induction, the lower (maintenance) rate was begun and continued until closure of the abdominal fascia. Just before induction, vecuronium (0.6 mg IV) and fentanyl (1.0 μg/kg IV) were administered. Anesthesia was induced with thiopental (4 mg/kg), and succinylcholine (1.5 mg/kg) was administered to facilitate laryngoscopy and endotracheal intubation. Anesthesia was maintained with dexmedetomidine infusion and inhalation of 70% nitrous oxide in oxygen. A second dose of fentanyl (1.0 μg/kg IV) was administered to all patients 2 min before surgical incision. Isoflurane was given, as needed, using the lowest possible end-tidal concentration necessary to maintain mean arterial blood pressure (MAP) within −30% to +15% and HR within −40% to +20% limits of the patient's preoperative baseline values. However, because of the chronotropic effect of glycopyrrolate, HR values were not taken into account until 30 min after the administration of glycopyrrolate. When isoflurane was required, its administration was started at 0.5% end-tidal concentration, and the concentration was increased by 0.2% increments at 2-min intervals until the hemodynamic variables returned to acceptable limits. Isoflurane concentration was also increased if any clinical signs of light anesthesia (e.g., bucking, swallowing, lacrimation, sweating, or movement) were observed. After the hemodynamic values had been maintained within acceptable limits for 4 min, the concentration of isoflurane was reduced by 0.2% decrements. Atropine (0.4 mg) was administered if HR decreased to below 40 beats/min. After the effect of succinylcholine had dissipated, vecuronium bromide (3 mg IV) was administered, with additional 1-mg doses to achieve and maintain 80% relaxation, as assessed with a neuromuscular monitor.

Nitrous oxide was discontinued at skin closure, and neuromuscular blockade was reversed with 2.0 mg of neostigmine, preceded by 0.4 mg of glycopyrrolate. In the postanesthesia care unit, oxycodone was administered intravenously in 0.06-mg/kg increments for postoperative pain relief.

The first part of the study was an open dose-response trial. Dexmedetomidine, diluted in normal saline solution to a concentration of 10 μg/mL, was administered by a continuous, two-step infusion. Infusion rates had been calculated according to the methods previously described by Wagner (19) and were based on pharmacokinetic variables reported by the manufacturer (elimination half-life 2.3 h; plasma clearance 12 $\mathrm{mL \cdot kg^{-1} \cdot min^{-1}}$). The first regimen tested consisted of a 120-$\mathrm{ng \cdot kg^{-1} \cdot min^{-1}}$ loading infusion, administered over 10 min, followed by a 6-$\mathrm{ng \cdot kg^{-1} \cdot min^{-1}}$ maintenance infusion, which was predicted to result in a 0.5-ng/mL steady-state plasma concentration of dexmedetomidine. In subsequent groups of patients, the initial rate was 170, 220, or 270 $\mathrm{ng \cdot kg^{-1} \cdot min^{-1}}$, respectively. The corresponding maintenance rates were 8.5, 11, and 13.5 $\mathrm{ng \cdot kg^{-1} \cdot min^{-1}}$, respectively. The predicted steady-state plasma concentrations of dexmedetomidine were 0.7, 0.9, and 1.1 ng/mL.

Because the classic arterial blood pressure response to a rapid intravenous administration of α_2-adrenoceptor agonists is biphasic (an initial increase followed by a longer lasting decrease [20]), the following hemodynamic cutoff rules for the infusion were used: (a) an increase in MAP >30% (excluding intubation); (b) systolic blood pressure >200 mm Hg or diastolic blood pressure >120 mm Hg; (c) a decrease in MAP of >40% or a MAP <50 mm Hg; and (d) HR <40 beats/min or an arrhythmia other than sinus bradycardia.

For the comparative part of the study, in which 10 patients received a dexmedetomidine infusion and 10 a saline solution infusion in a random, double-blind fashion, the optimal dexmedetomidine infusion rate was chosen such that it would not cause major hemodynamic responses during the initial infusion, but would reduce isoflurane requirements during surgery. A 170-$\mathrm{ng \cdot kg^{-1} \cdot min^{-1}}$ dexmedetomidine initial infusion rate and a 10-$\mathrm{ng \cdot kg^{-1} \cdot min^{-1}}$ maintenance rate was selected (see Results).

Intraarterial blood pressure and HR were continuously recorded throughout the study until the end of the operation. Preoperative baseline HR and arterial blood pressure values were determined in the operating room after a 5-min stabilization period. Postoperative arterial blood pressure and HR were determined with a noninvasive blood pressure monitor at 15-min intervals.

End-tidal isoflurane concentration was continuously assessed in the expired gas using an anesthetic

Table 1. Mean Arterial Pressure and Heart Rate During Initial Infusion of Dexmedetomidine at Four Different Rates in the Dose-Response Study

Dexmedetomidine ($ng \cdot kg^{-1} \cdot min^{-1}$)	Baseline	2 Min	4 Min	6 Min	8 Min	Intubation
120 + 6 ($n = 3$)						
MAP (mm Hg)	110 (7)	109 (5)	110 (4)	111 (9)	117 (6)	125 (17)
HR (beats/min)	67 (18)	82 (24)	77 (22)	72 (22)	67 (19)	81 (18)
170 + 8.5 ($n = 6$)						
MAP (mm Hg)	106 (5)	113 (6)	113 (7)	113 (7)	112 (10)	126 (6)
HR (beats/min)	72 (5)	79 (8)	72 (7)	68 (6)	65 (6)	74 (4)
220 + 11 ($n = 3$)						
MAP (mm Hg)	110 (8)	113 (9)	120 (6)	127 (5)	129 (7)	138 (5)
HR (beats/min)	81 (14)	84 (14)	75 (10)	72 (6)	66 (8)	79 (11)
270 + 13.5 ($n = 2$)						
MAP (mm Hg)	116 (6)	119 (14)	124 (2)	131 (2)	131 (2)	141 (12)
HR (beats/min)	75 (15)	82 (21)	66 (11)	61 (6)	59 (8)	73 (12)

MAP, mean arterial pressure; HR, heart rate; Baseline, values before start of dexmedetomidine infusion; 2, 4, 6, 8 min, values after start of dexmedetomidine initial infusion; Intubation, highest value measured 1–3 min after intubation.

Values are mean (SD).

agent monitor. To determine the intraoperative isoflurane requirements, the area under the end-tidal isoflurane concentration versus time curve was integrated.

In the second part of the study, sedation was assessed at arrival in the operating room and at 5 min after the beginning of the study drug infusion. Sedation was scored as 1 = awake, eyes open; 2 = asleep, easy to arouse.

The time to awakening, as determined by the time interval between the termination of nitrous oxide administration and eye-opening on request, was assessed.

Arterial blood samples were collected into prechilled K_2-ethylenediaminetetraacetate tubes 10, 20, 40, 60, and 120 min after the beginning of the infusion. In the comparative study, samples were also obtained 10, 30, and 120 min after the end of the infusion. The samples were centrifuged, and plasma was separated and stored at −20°C until analyzed. The concentration of dexmedetomidine in plasma was determined by a gas chromatographic/mass spectrometric method (21).

The total amount of oxycodone required for postoperative analgesia was recorded.

Only descriptive statistics are presented for the first part of the study because of the small number of patients in each treatment group. In the comparative part of the study, the statistical analyses for demographic data and single-efficacy variables (maximal HR and arterial blood pressure values, amount of oxycodone, and isoflurane concentration) were performed using the Student's *t*-test or Mann-Whitney test. Analysis of covariance (ANCOVA) for repeated measures (RM) was used for arterial blood pressure and HR. Greenhouse-Geisser adjustment was applied in case of nonsphericity in the correlation matrix of the orthogonal components. A *P*-value <0.05 was considered statistically significant. The statistical analyses were performed with BMDP software.

Results

Dose-Response Study

Four different infusion regimens (initial + maintenance rates) of dexmedetomidine were studied: 120 + 6 $ng \cdot kg^{-1} \cdot min^{-1}$ ($n = 3$); 170 + 8.5 $ng \cdot kg^{-1} \cdot min^{-1}$ ($n = 6$); 220 + 11 $ng \cdot kg^{-1} \cdot min^{-1}$ ($n = 3$); and 270 + 13.5 $ng \cdot kg^{-1} \cdot min^{-1}$ ($n = 2$). The four groups of patients were comparable with regard to age, weight, duration of operation, and the amount of perioperative fluid received.

The MAP increased in a dose-dependent manner during the initial infusion (Table 1). The two patients receiving dexmedetomidine infusion at the highest rate of 270 $ng \cdot kg^{-1} \cdot min^{-1}$ reached the predetermined hemodynamic cutoff endpoints, an increase in MAP of >30%, at 9 and 10 min after the start of infusion (maximal MAPs observed were 146 and 168 mm Hg), and the initial infusion had to be terminated at the induction of anesthesia.

The HR tended to decline with increasing dexmedetomidine dose, the lowest values being observed at approximately 6–8 min of infusion. Postoperatively, only one patient in the 120 + 6-$ng \cdot kg^{-1} \cdot min^{-1}$ group had a HR transiently <40 beats/min and was treated with atropine.

There was a minimal isoflurane requirement in all patients receiving ≥170 + 8.5 $ng \cdot kg^{-1} \cdot min^{-1}$ of dexmedetomidine (Figure 1). For that reason, and

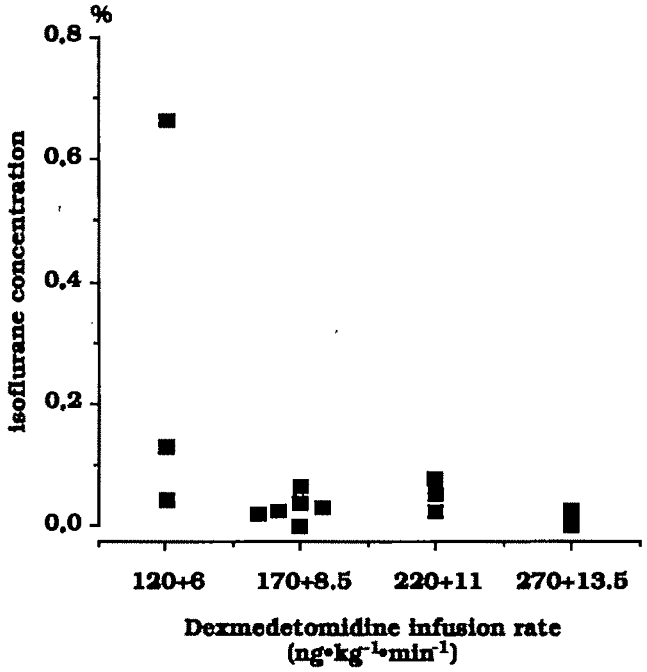

Figure 1. Isoflurane requirement of individual patients receiving different dexmedetomidine infusions (ng·kg^{-1}·min^{-1}): 120 + 6 (n = 3); 170 + 8.5 (n = 6); 220 + 11 (n = 3); 270 + 13.5 (n = 2). The mean isoflurane concentration was measured as the area under end-tidal concentration versus time curve.

because of better hemodynamic stability compared with higher doses, the 170-ng·kg^{-1}·min^{-1} initial infusion was selected for the double-blind study.

With this infusion rate, the plasma concentration of dexmedetomidine was 2.67 (SD 0.66) ng/mL at 10 min. Because subsequent drug plasma concentrations decreased slightly below the 0.7-ng/mL target concentration, in the second part of the study the maintenance infusion was increased to 10 ng·kg^{-1}·min^{-1}.

Comparative Study

The two patient groups were similar with respect to age, weight, height, duration of surgery, and total perioperative fluid administration. Demographic characteristics of the patients are shown in Table 2. There was no difference in the incidence of sedation 5 min after the beginning of the infusion: three patients in the dexmedetomidine group and one patient in the saline solution group were lying with their eyes closed. Likewise, there was no significant difference in the time to awakening (184 s [SD 122]) in the dexmedetomidine group versus the saline solution group (172 s [SD 153]).

Table 2. Clinical Characteristics of 20 Patients in the Comparative Study

	Saline solution group (n = 10)	Dexmedetomidine group (n = 10)
Age (yr)	43 (5)	42 (5)
Weight (kg)	66 (10)	63 (9)
Height (cm)	164 (6)	167 (5)
Duration of surgery (min)	107 (36)	112 (31)

Values are mean (SD).

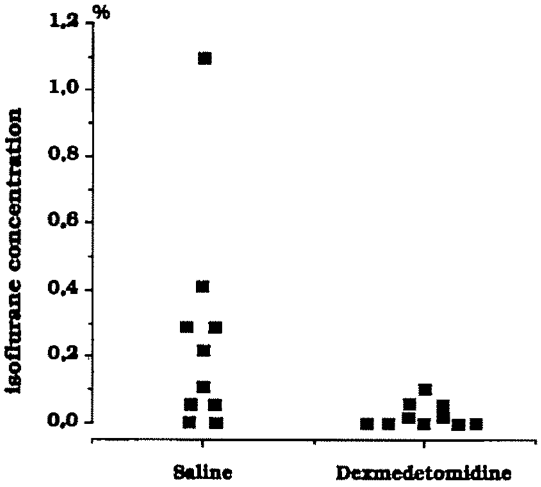

Figure 2. Isoflurane requirement of individual patients receiving normal saline solution or dexmedetomidine infusion (170 + 10 ng·kg^{-1}·min^{-1}). The mean isoflurane concentration was measured as the area under end-tidal concentration versus time curve.

Anesthetic Requirements

In the dexmedetomidine group, 5 of 10 patients did not require any isoflurane supplementation. In the saline solution group, only two patients did not need isoflurane at all. The end-tidal isoflurane concentrations required to maintain HR and arterial blood pressure within the predetermined limits are presented in Figure 2. The median expired concentration of isoflurane required during anesthetic maintenance was >90% less in the dexmedetomidine group (0.01 vol% [quartile deviation, QD 0.02]) compared with that in the saline solution group (0.17 vol% [QD 0.13]) (P = 0.01; 95% confidence interval for difference between median values −0.30 to −0.01). Furthermore, in dexmedetomidine-treated patients, supplemental isoflurane was required over a period that was significantly shorter than in the saline solution group (4.0 min [QD 6.0] vs 55.0 min [QD 39.5]) (P = 0.03; 95% confidence interval for difference between median values −86.0 to 0.0). Even though the study protocol obviously resulted in relatively light anes-

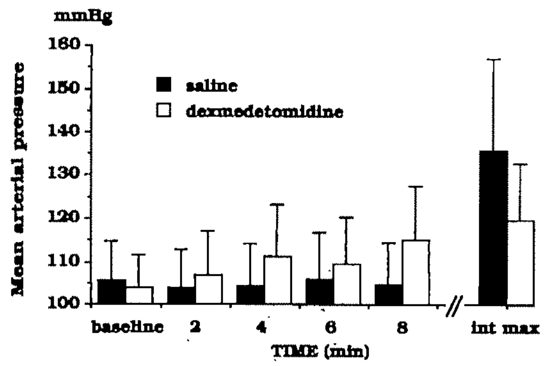

Figure 3. Mean arterial blood pressure (SD) during administration of the initial infusion (baseline) and the highest value obtained after endotracheal intubation (int max). During initial infusion, mean arterial blood pressure values were slightly higher in the dexmedetomidine group (RM ANCOVA, DRUG by TIME interaction; $P = 0.02$).

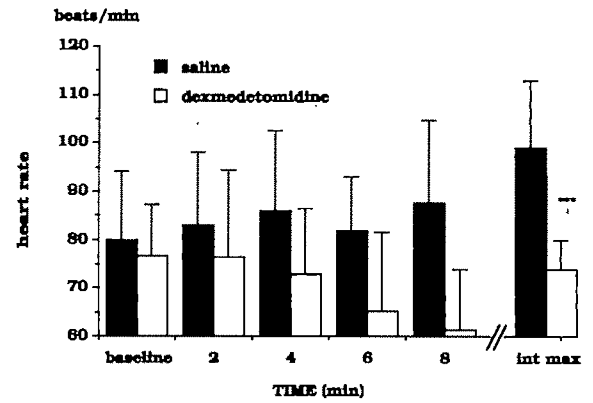

Figure 4. Mean heart rate (SD) during administration of the initial infusion (baseline) and the highest value obtained after endotracheal intubation (int max). ***$P < 0.001$ (t-test); dexmedetomidine differs from saline solution. During loading infusion, dexmedetomidine reduced heart rate (RM ANCOVA, DRUG by TIME interaction; $P < 0.001$).

thesia, none of the patients complained of intraoperative recall when interviewed on the first postoperative day.

Hemodynamic Variables

Baseline MAP values did not differ between groups (Figure 3). During administration of the initial infusion, the MAP values increased slightly in the dexmedetomidine group (~5 mm Hg), whereas in the saline solution group, MAP values remained at the same level ($P = 0.02$, drug by time interaction, RM ANCOVA). The highest MAP values after intubation (119 mm Hg [SD 13] in the dexmedetomidine group, 133 mm Hg [SD 22] in the saline solution group) were not significantly different. Intraoperatively, there were no differences in the arterial blood pressure values. Likewise, 1 h after surgery, the MAP values (82 mm Hg [SD 18] in the dexmedetomidine group and 85 mm Hg [SD 21] in the saline solution group) were similar.

Baseline HR values did not differ between groups (Figure 4). During the initial infusion, dexmedetomidine reduced HR significantly ($P < 0.001$; drug by time interaction, RM ANCOVA), compared with the saline solution group. The highest HR after intubation was lower in the dexmedetomidine group (74 beats/min [SD 6]) than in the saline solution group (99 beats/min [SD 14]) ($P < 0.001$). During the first hour after surgery, HR was significantly lower ($P = 0.05$; drug main effect, RM ANCOVA) in the dexmedetomidine group, and four patients in this group had HRs of <40 beats/min, requiring treatment with atropine (0.4 mg IV). None of the patients in the saline solution group required atropine treatment. There was no difference between the groups.

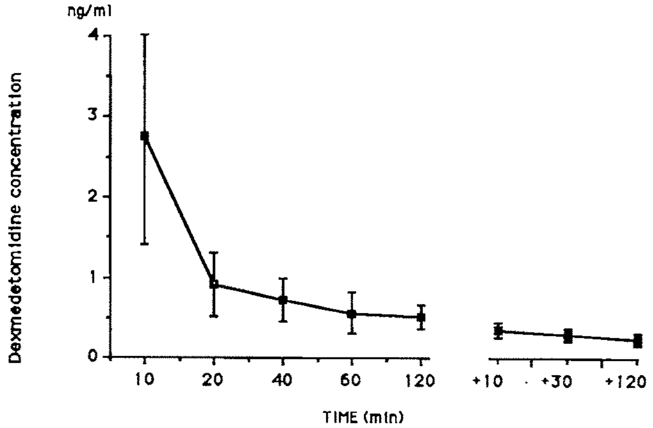

Figure 5. Mean (SD) dexmedetomidine concentration in peripheral arterial plasma versus time; +10, +30, and +120 are the concentrations obtained 10, 30, and 120 min after the end of infusion.

Dexmedetomidine Concentration

Dexmedetomidine plasma concentrations during the $170 + 10\text{-ng}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$ infusion are presented in Figure 5.

Discussion

The major finding of this study was that the chosen continuous dexmedetomidine infusion was not potent enough to provide adequate maintenance of anesthesia when added to thiopental, fentanyl, and nitrous oxide in oxygen, but it did diminish isoflurane requirement during surgery by as much as 90%.

The anesthetic-sparing action of clonidine, a partial α_2-adrenergic agonist, has been previously demonstrated in several clinical investigations (6,9,10,11, 22). Clonidine affected isoflurane requirements less than dexmedetomidine in the present study. Ghignone et al. (6) demonstrated a 40% reduction in isoflurane requirements, using electroencephalography as an index of anesthetic depth, after oral premedication with 5 μg/kg of clonidine. More recently, an oral/transdermal clonidine combination was shown to diminish isoflurane demand by approximately 70% in patients undergoing abdominal surgery, when the inhaled anesthetic was administered using hemodynamic endpoints as criteria of anesthetic depth (22).

In contrast to clonidine, medetomidine and its active dextroisomer, dexmedetomidine, are full α_2-adrenergic agonists (23). Clonidine may not be the most appropriate choice because of its "ceiling effect" (4), followed by a reversal of the initial effect, which occurs at higher doses. This property is attributed to the partial agonistic effect of clonidine at the α_2-receptors (24), or to an α_1-agonistic effect (25). Thus, dexmedetomidine can be expected to be more efficacious in its anesthetic-sparing effect. In dogs receiving dexmedetomidine, the MAC for halothane decreased progressively, and at the highest intravenous dose of dexmedetomidine (10 μg/kg), the anesthetic requirement was reduced by >90% (4). Similarly, Segal et al. (5) showed that in rats, dexmedetomidine decreased halothane MAC in a dose-dependent fashion so that at 100 μg/kg intraperitoneally, halothane could be discontinued for up to 30 min without eliciting a purposeful response to tail-clamping (5). In contrast, with clonidine the maximal reduction in halothane MAC did not exceed 50% (26).

The sedative action of α_2-adrenoceptor agonists has been well recognized (27) to the extent that the sedative effect of clonidine has been a major problem in antihypertensive therapy (1). The site at which these drugs affect sleep mechanisms has been localized in the locus ceruleus (28). Actions other than synaptic norepinephrine depletion must be involved in the anesthetic effect of α_2-agonists, probably at a central postsynaptic α_2-adrenoceptor (5). This interaction could be explained by the fact that general anesthetics and α_2-agonists increase K^+ efflux (29–31) through neuronal cell membranes, causing hyperpolarization and decreased excitability of the neurons. This hyperpolarization may be mediated by a reduction in intracellular cyclic adenosine monophosphate (32), which is regulated through an inhibitory membrane-bound guanine nucleotide-binding protein (G-protein) (33).

Because of the lack of reliable, easily monitored clinical indices to determine anesthetic depth, we used hemodynamic endpoints. One can argue that such endpoints are not optimal, particularly when a hemodynamically active drug is studied. There is a possibility that the diminished isoflurane requirements may have partly been a result of the HR slowing by dexmedetomidine. However, in addition to hemodynamic endpoints, the signs of light anesthesia (e.g., bucking or lacrimation) were used as indicators of light anesthesia.

The MAP increased in a dose-dependent manner during the initial infusion before induction of anesthesia. Although this increase did not cause any untoward effects in our relatively healthy patients, those with preexisting vascular pathology should be studied separately. With a lower initial infusion rate or a longer infusion time, the increase in MAP could be avoided. Although hypertension induced by α_2-adrenergic agonists may have a relatively long duration in some animal models (34,35), the hypertensive response in humans seems to be of short duration and is rapidly overcome by the hypotensive action of α_2-agonists, mediated by α_2-adrenoceptors in the central nervous system (14,36). Pretreatment with a vagolytic glycopyrrolate might have enhanced the initial increase in arterial blood pressure.

The dexmedetomidine initial dose blunted the tachycardia in response to laryngoscopy and endotracheal intubation. A consistent feature of dexmedetomidine administration is the occurrence of bradycardia (14). This effect of dexmedetomidine was observed in our study during the initial infusion, lasting until 10 min after the induction of anesthesia. Thereafter, during the surgery HR was similar in both dexmedetomidine- and saline solution-treated patients. During the first postoperative hour, dexmedetomidine-treated patients again tended to have a lower HR, but the subsequent elimination of the drug and administration of atropine restored normal HR, so that 1 h after the operation, no differences were observed between groups.

Particular attention was paid to the maintenance of double-blindness of the study. After the dose-response study, we expected that the dexmedetomidine infusion would lead to a slight increase in MAP and a reduction in HR. Therefore, before induction, the patient was attended by the research nurse, and the anesthesiologist in charge remained unaware of the hemodynamic changes secondary to the initial dose.

α_2-Adrenergic agonists may provide an alternative to currently used anesthetic adjunctive agents owing to their anesthetic-sparing and hemodynamic stabilizing effects. Overall, the present results suggest that dexmedetomidine warrants further study to evaluate its possible usefulness in clinical anesthesia.

We are grateful to Tuuli Sonck-Simola, MSc, for providing us with dexmedetomidine. Lauri Vuorilehto, MSc, is acknowledged for performing the dexmedetomidine assays. We also thank Jouni Vuorinen, MSc, and Juhani Tuominen, PhD, for performing the statistical analyses, and Kaarina Backas, nurse anesthetist, for taking excellent care of our patients.

Thermoregulatory Vasoconstriction During Propofol/Nitrous Oxide Anesthesia in Humans: Threshold and Oxyhemoglobin Saturation

James M. Hynson, MD, Daniel I. Sessler, MD, Kumar Belani, MD, Denna Washington, MD, Joseph McGuire, BS, Benjamin Merrifield, BA, Marc Schroeder, BA, Azita Moayeri, BA, David Crankshaw, FFARACS, PhD, and Shannon Hudson, BS

Department of Anesthesia, University of California, San Francisco, California; Department of Anesthesiology, University of Minnesota, Minneapolis; and the Department of Surgery, University of Melborne, Victoria, Australia

To determine the thermoregulatory effects of propofol and nitrous oxide, we measured the threshold for peripheral vasoconstriction in seven volunteers over a total of 13 study days. We also evaluated the effect of vasoconstriction on oxyhemoglobin saturation (Spo_2). Anesthesia was induced with an intravenous bolus dose of propofol (2 mg/kg), followed by an infusion of 180 $\mu g \cdot kg^{-1} \cdot min^{-1}$ for 15 min, and maintained with 60% nitrous oxide and propofol (80–160 $\mu g \cdot kg^{-1} \cdot min^{-1}$). Central and skin surface temperatures and Spo_2 (using two different pulse oximeters) were measured continuously; plasma propofol concentrations and arterial Po_2 were measured at 15-min intervals. Volunteers were cooled with a circulating water blanket until definitive peripheral vasoconstriction was detected. The tympanic membrane temperature triggering vasoconstriction was considered the thermoregulatory threshold. Vasoconstriction developed on seven study days during propofol/nitrous oxide anesthesia at a central temperature of 33.3 ± 1.0°C (mean ± SD) and plasma propofol concentration of 3.9 ± 1.1 μg/mL. The thresholds during anesthesia were significantly lower than those during the control period (36.7 ± 0.3°C), but the correlation between plasma propofol concentrations and vasoconstriction thresholds was poor. On the remaining six study days, vasoconstriction did not develop despite central temperatures ranging from 32.1 to 32.7°C. Corresponding propofol concentrations were 4.1–10.9 μg/mL. These data suggest that anesthesia with propofol, in typical clinical concentrations, and 60% nitrous oxide substantially inhibits thermoregulatory vasoconstriction. Vasoconstriction increased Spo_2 by approximately 2% without a significant concomitant change in Po_2. The observed increase in Spo_2 probably reflects decreased transmission of arterial pulsations to venous blood in the finger.

(Anesth Analg 1992;75:947–52)

Hypothermia is common during surgery and anesthesia and results from cold exposure and inhibition of thermoregulatory responses (1). Some protective responses against hypothermia, such as shivering and appropriate behavior, are prevented by anesthesia per se and muscle relaxation. Others, including active vasoconstriction, are centrally inhibited. For example, halothane and isoflurane decrease the threshold for vasoconstriction in humans (i.e., the central temperature triggering vasoconstriction) by 1–3°C in a dose-dependent fashion (2–5).

Some intravenous anesthetics, including barbiturates (6), profoundly inhibit thermoregulatory responses in animals; others, such as ketamine (7,8), urethane (9,10), and fentanyl/droperidol (11), appear to have less effect. Barbiturates also appear to inhibit thermoregulatory responses in humans (12). Thermoregulatory effects of intravenous anesthetics have not been extensively investigated in humans, but fentanyl alone (13) and fentanyl combined with nitrous oxide (14) do inhibit responses. Propofol is a recently introduced anesthetic; however, the thermoregulatory consequences of its administration have not been quantified. Accordingly, we tested the hypothesis

that propofol/nitrous oxide anesthesia inhibits thermoregulatory vasoconstriction in humans.

We (15) and others (16) have observed that thermoregulatory vasoconstriction increases oxyhemoglobin saturation (SpO_2) 1%–2%. However, alterations in SpO_2 produced by thermoregulatory vasoconstriction have not been correlated with changes in arterial PO_2. We therefore measured arterial PO_2 and SpO_2 (using two brands of pulse oximeter) and tested the hypothesis that thermoregulatory vasoconstriction increases systemic arterial PO_2.

Methods

After receiving approval from the University of California, San Francisco, Committee on Human Research, we studied seven volunteers over a total of 13 study days. None of the volunteers was obese, taking medication, or had a history of thyroid disease, dysautonomia, or Raynaud's syndrome. Ambient temperature was maintained at 20.9 ± 0.3°C (mean ± SD) and ambient relative humidity at 42% ± 3% throughout the study period (model HX93 humidity and temperature transmitter, Omega Engineering). The percentage of body fat in each volunteer was determined using infrared interactance (Futrex 1000, Futrex, Inc., Hagerstown, Md.) (17).

Study Protocol

Volunteers fasted during the 8 h preceding each study, which started at approximately 9:30 AM. All were minimally clothed and reclined on a standard operating room table covered by a full-length circulating water mattress set at 37°C (Blanketrol, Cincinnati Sub-Zero Products, Inc., Cincinnati, Ohio). An intravenous catheter was inserted into the left antecubital vein, and lactated Ringer's solution warmed to 37°C was infused at approximately 100 mL/h. A 20-gauge catheter was inserted into the left radial artery to permit sampling of blood for determination of circulating drug concentrations.

After a 15-min control period, anesthesia was induced without any premedication by administration of an intravenous bolus dose of propofol (ICI Americas, Inc., Wilmington, Del.) (2 mg/kg), followed by an infusion of 180 $\mu g \cdot kg^{-1} \cdot min^{-1}$ for 15 min. Neither thiopental nor opioids were administered. Vecuronium (10 mg IV) was administered to facilitate intubation of the trachea. Anesthesia was maintained with 60% nitrous oxide and an infusion of propofol at a rate of 80, 100, 120, or 160 $\mu g \cdot kg^{-1} \cdot min^{-1}$ delivered by a Program 2 syringe pump (Becton Dickinson & Company, Lincoln Park, N.J.); maintenance infusion rates were kept constant throughout each study day. Different infusion rates were used to produce a range of clinically relevant blood propofol concentrations (18).

Four volunteers were studied on more than one day. Of these, two were studied with three different propofol infusion rates: 80, 100, and 160 $\mu g \cdot kg^{-1} \cdot min^{-1}$. One other volunteer was studied at 80 and 100 $\mu g \cdot kg^{-1} \cdot min^{-1}$, and a fourth was studied at 120 and 160 $\mu g \cdot kg^{-1} \cdot min^{-1}$.

Muscle relaxation was maintained with an infusion of vecuronium (Program 2 syringe pump) adjusted to maintain 0–1 twitches in response to supramaximal train-of-four electrical stimulation of the ulnar nerve at the wrist. Mechanical ventilation was adjusted to maintain end-tidal PCO_2 at 34 ± 1 mm Hg, and inspired oxygen concentration was maintained at 30% (monitored by a Capnomac [Datex Medical Instrumentation, Inc., Tewksbury, Mass.]). Routine monitoring throughout the study included arterial blood pressure and heart rate.

After an initial 45 min, central hypothermia was induced by decreasing the circulating water blanket temperature to 10°C. Anesthesia was discontinued when (a) definitive thermoregulatory vasoconstriction was observed; (b) central temperature approached 32°C without evidence of developing vasoconstriction; or (c) 6 h of anesthesia elapsed.

Measurements

Temperatures were monitored continuously with Mon-a-Therm (St. Louis, Mo.) thermocouple probes connected to Mallinckrodt model 8700 (St. Louis, Mo.) two-channel electronic thermometers. One thermocouple probe was placed in contact with the tympanic membrane and the aural canal was carefully occluded with cotton. After induction of anesthesia, temperatures also were recorded from the distal fourth of the esophagus by means of a probe incorporated into an esophageal stethoscope. Because our study design required central temperature measurements before induction of anesthesia, we considered tympanic membrane temperatures to be representative of central tissues. We (3,19) and others (20,21) have previously demonstrated an excellent correlation between distal esophageal and tympanic membrane temperatures. Skin temperature was measured at 10 sites and the area-weighted mean calculated by assigning the following regional percentages: head 6%, upper arms 9%, forearms 6%, hands 4.5%, back 19%, chest 9.5%, abdomen 9.5%, thigh 19%, calves 11.5%, and feet 6% (22).

Skin-temperature gradients were used to measure thermoregulatory vasoconstriction on the right arm. The gradient was calculated by subtracting fingertip skin temperature from midforearm skin temperature. Fingertip temperature can range from near ambient (vasoconstricted) to near core temperature (vasodilated) because of the presence of thermoregulatory arteriovenous shunts and the wide range over which fingertip blood flow varies. Forearm skin does not possess arteriovenous shunts, and therefore its temperature is less affected by thermoregulatory status. We have previously demonstrated that forearm minus fingertip skin-temperature gradients correlate extremely well with volume plethysmography (the most reliable measure of peripheral blood flow) (23). There is also a fair correlation between skin temperature gradients and laser Doppler flowmetry (4,14). The right arm was kept well away from the circulating water blanket and had neither an intravenous catheter nor a blood pressure cuff. As in previous studies, a forearm minus fingertip skin-temperature gradient exceeding 4°C was considered definitive vasoconstriction (2,3,14).

Fingertip Sp_{O_2} was monitored continuously with Nellcor N200 (Hayward, Calif.) and Lifestat 1600 (Physio-Control, Redmond, Wash.) pulse oximeters placed on fingers of the right hand. Central and skin temperatures and Sp_{O_2} were recorded at 5-min intervals using a previously described data-acquisition system (24).

Arterial blood samples were drawn at 15-min intervals, and P_{O_2} was determined using a calibrated Stat Pro 3 (Nova Biomedical, Waltham, Mass.) whole-blood gas analyzer. Blood for propofol determinations was centrifuged and the plasma stored frozen for later analysis. Samples were analyzed using high-pressure liquid chromatography (PharmaKinetics Laboratories, Inc., Baltimore, Md.). This assay has an accuracy >0.1 μg/mL for concentrations ranging from 0.1 to 5.0 μg/mL and an accuracy >0.2 μg/mL for concentrations ranging from 5.0 to 10.0 μg/mL.

Data Analysis

The thermoregulatory threshold for vasoconstriction was defined as the tympanic membrane (central) temperature at which definitive vasoconstriction was first observed. A data-base program was used to average the Sp_{O_2} and P_{O_2} values in each volunteer during the 15-min epoch before and after vasoconstriction. Vasoconstriction thresholds before induction of anesthesia and during propofol/nitrous oxide administration were compared using two-tailed, paired *t*-tests. The correlation between vasoconstriction thresholds and blood propofol concentrations was evaluated using linear regression. Time-dependent changes in Sp_{O_2} and P_{O_2} were analyzed using repeated-measures analysis of variance and Dunnett's tests. Measurements obtained 10–20 min after vasoconstriction were used as the reference for determining statistically significant changes. Differences were considered significant when $P \leq 0.01$. Results are reported as mean ± SD.

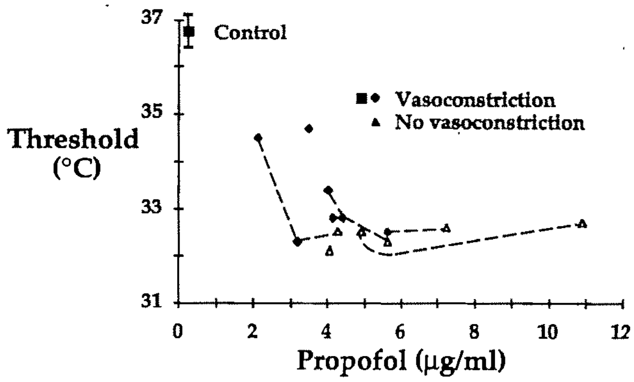

Figure 1. On 7 of 13 study days, vasoconstriction developed during propofol/N$_2$O anesthesia at central temperatures between 32.3 and 34.7°C (*solid diamonds*, 33.3 ± 1.0°C), when plasma propofol concentrations were between 2.1 and 5.6 μg/mL (3.9 ± 1.1 μg/mL). The thresholds during anesthesia were significantly lower than those during the control period (*solid square*, 36.7 ± 0.3°C). Plasma propofol concentrations correlated poorly with vasoconstriction thresholds (Threshold = 35.1 − 0.8[Propofol]; r = 0.53). On the remaining six study days, vasoconstriction did not develop despite central temperatures ranging from 32.1 to 32.7°C, with propofol concentrations of 4.1–10.9 μg/mL (*open triangles*). *Dashed lines* connect data for individuals who participated on more than one study day.

Results

The mean age of the volunteers was 25.9 ± 2 yr, weight 74 ± 15 kg, height 176 ± 7 cm, and body fat 19% ± 3%. Tympanic membrane and distal esophageal temperatures were typically within 0.1°C and rarely differed by >0.2°C.

All volunteers experienced vasoconstriction during the control period before induction of anesthesia. Vasoconstriction developed during propofol/nitrous oxide anesthesia on 7 of the 13 study days at central temperatures between 32.3 and 34.7°C (mean 33.3 ± 1.0°C) (Figure 1). The corresponding mean skin temperature was 27.2 ± 1.0°C, and plasma propofol concentrations ranged from 2.1 to 5.6 μg/mL (mean 3.9 ± 1.1 μg/mL). The vasoconstriction threshold during anesthesia on these seven study days was significantly lower than the threshold during the control period, when central temperature was 36.7 ± 0.3°C and mean skin temperature was 31.1 ± 0.7°C. The correlation between plasma propofol concentrations and thresholds for vasoconstriction was poor (Threshold = 35.1 − 0.8[Propofol]; r = 0.53).

On the remaining six study days, vasoconstriction did not develop despite central hypothermia to between 32.1 and 32.7°C and mean skin temperatures of 27.9 ± 1.6°C (Figure 1). Plasma propofol concentrations measured at the lowest central temperature

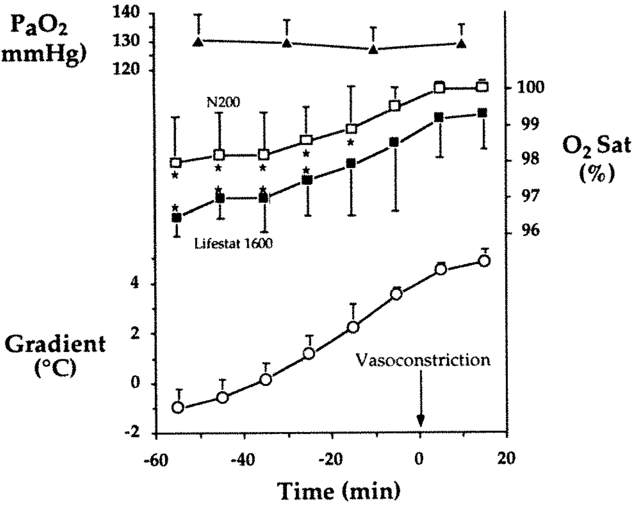

Figure 2. Arterial Po_2 (Pao_2) did not change significantly during vasoconstriction; however, Spo_2 (O_2 Sat) readings from both the Nellcor N200 and the Physio-Control Lifestat 1600 pulse oximeters increased approximately 2%. The time axis is normalized so that definitive thermoregulatory vasoconstriction (a skin temperature gradient = 4°C) occurred at time zero. *Spo_2 values significantly different from those after vasoconstriction (10–20 elapsed min).

before rewarming were generally higher (6.2 ± 2.6 μg/mL [range 4.1–10.9]) than those measured at the time of vasoconstriction during the other seven study days ($P = 0.053$).

In those volunteers who were studied at more than one infusion rate, higher infusion rates were associated with increased plasma propofol levels and either lower thresholds for vasoconstriction or no vasoconstriction at all (Figure 1).

Arterial Po_2 and Spo_2 data from both oximeters were available on only five of the seven study days when vasoconstriction occurred. Thermoregulatory vasoconstriction increased Spo_2 1.7% ± 1.4% on the Nellcor N200 and 2.3% ± 1.6% on the Lifestat 1600. There were no significant changes in arterial Po_2, arterial blood pressure, or heart rate at the time of vasoconstriction (Figure 2).

Discussion

Physiologic responses to MAC-adjusted concentrations of various volatile anesthetics are more notable for their similarities than differences. For example, the thresholds for thermoregulatory vasoconstriction appear only slightly higher during halothane (2) than during isoflurane anesthesia (3). In contrast, thermoregulatory responses to intravenous anesthetics, sedatives, and hypnotics differ considerably (6,7,11,13), making it difficult to predict responses to a new drug without specific experimental evidence.

Our data indicate that anesthesia with propofol in typical clinical concentrations, combined with 60% nitrous oxide, substantially inhibits thermoregulatory vasoconstriction. Although the correlation between propofol concentration and vasoconstriction threshold calculated from the combined data was poor, a dose-dependent effect is apparent from the data obtained from those volunteers given more than one propofol infusion rate. Furthermore, plasma propofol concentrations were generally higher on study days when vasoconstriction did not develop than on days when it did. Presumably, vasoconstriction would have developed in all cases were volunteers permitted to become sufficiently hypothermic. For safety reasons, we rewarmed volunteers when their central temperatures reached 32°C. Clinically, it is rare for patients to become this hypothermic without deliberate cooling.

Poor correlation between propofol concentrations and vasoconstriction thresholds may have resulted because the apparently steep dose-response relationship allowed only a small number of data points to fall within the relatively narrow range of permissible central temperatures. Had we allowed central temperature to decrease sufficiently to trigger vasoconstriction in all cases, the correlation may have been better.

The range of thermoregulatory thresholds in those volunteers who experienced vasoconstriction during propofol/nitrous oxide anesthesia was 32.3–34.7°C, which is similar to the range of thresholds expected from administration of 0.8%–1.7% end-tidal isoflurane (3) and lower than the range observed during anesthesia with 0.86% halothane or 70% nitrous oxide and fentanyl 4 $\mu g \cdot kg^{-1} \cdot h^{-1}$ (2,14).

Nitrous oxide contributed approximately 0.6 MAC in these volunteers. Although nitrous oxide combined with fentanyl significantly inhibits thermoregulatory vasoconstriction (14), the effect of nitrous oxide alone on vasoconstriction has not specifically been determined. Subanesthetic partial pressures of nitrous oxide impair behavioral thermoregulatory responses in mice (25). Similarly, 30% nitrous oxide decreases the shivering threshold approximately 1°C in humans (26). It is thus likely that nitrous oxide also inhibits thermoregulatory vasoconstriction; however, its contribution to the observed profound inhibition with propofol cannot be determined from our data.

The tympanic membrane is not an obvious site for measuring central temperature; it is a small structure, surrounded by air and does not have a particularly high blood flow. Tympanic membrane temperature measurements were popularized by Benzinger (27) in 1959. (In a remarkable investigation, he demonstrated the validity of tympanic membrane temperatures by having thermometers implanted into his own head!) Numerous subsequent studies have demonstrated superb correlations between distal esophageal and tympanic membrane temperatures (3,19–21).

Many mammals possess specialized vascular systems that allow them to maintain a lower brain temperature than core temperature (28). Recently, Cabanac and Caputa (29) have proposed that humans may also have specific brain cooling. The major support for this thesis is an observed decrease in tympanic temperature relative to distal esophageal temperature during heat stress and facial fanning (30,31). (The assumption in these studies is that the apparent relative decrease in tympanic membrane temperature represents true brain cooling, not simply an artifact of the measurement location.) However, even during these special circumstances, the distal esophageal to tympanic membrane temperature difference rarely exceeds 0.2°C. Under circumstances similar to our study (i.e., gradual cooling without facial fanning), the two temperatures usually are virtually identical.

Because of the observed small differences between tympanic membrane and other central temperature measurement sites under some circumstances, most physiologists now prefer distal esophageal temperatures. During general anesthesia, the distal esophagus is usually the easiest and most reliable central temperature monitoring site. However, during the control period, we recorded only tympanic membrane temperatures because esophageal probes would have been uncomfortable for unanesthetized subjects. Consequently, the vasoconstriction thresholds in this study are reported in terms of tympanic membrane temperature to minimize systematic errors. In any case, potential errors in our central temperature measurements are of little consequence compared with the range of thresholds observed in this study.

Our volunteers were not undergoing surgery or comparable pain. Painful stimulation provided by a 100-Hz current increases the thermoregulatory threshold only approximately 0.4°C during enflurane anesthesia (32). However, the extent to which pain and subsequent autonomic activation contribute to thermoregulatory responses during propofol/nitrous oxide anesthesia remains unknown. Therefore, our current results may not necessarily apply to patients during surgery. Nevertheless, in patients whose surgical pain is prevented by regional anesthesia, propofol/nitrous oxide anesthesia would likely produce similar thermoregulatory inhibition.

As in our previous study (15), fingertip pulse oximetry significantly increased Sp_{O_2}. Mean arterial blood pressure remained within the normal range during our study and did not change significantly during vasoconstriction. We have already demonstrated that pulse oximeters continue to function well, even when arterial inflow (33) or venous outflow (34) is substantially reduced.

Systemic or local pulmonary hypothermia impairs hypoxic pulmonary vasoconstriction (35) and would be expected to increase pulmonary shunt and decrease arterial P_{O_2}. However, we speculated that pulmonary blood flow distribution may be altered in conjunction with the activation of thermoregulatory peripheral vasoconstriction, thus leading to an actual increase in arterial P_{O_2}. Nevertheless, our data indicate that no significant changes in arterial P_{O_2} occurred. It is therefore unlikely that the increase in Sp_{O_2} observed with both oximeters resulted from a systemic effect of hypothermia.

More likely, the increase in Sp_{O_2} was caused by a decrease in the venous pulsatile signal resulting from the closure of arteriovenous shunts, as proposed by Kelleher and Ruff (16). Normal (vasodilated) finger blood flow exceeds nutritive requirements more than 10-fold, with most of the volume traversing arteriovenous shunts (36). Because these are relatively large vessels (100 μm), it is likely that arterial pulsations extend to venules just distal to the shunts. However, some of this distal blood is desaturated (having passed through capillaries) and will reduce the apparent arterial saturation (37). After vasoconstriction, fingers resemble most other tissues in that arterial pulsations do not extend to the venous circulation, and pulsatile flow is nearly entirely arterial. As pulse oximeters detect only pulsatile flow, apparent saturation would increase after vasoconstriction.

Manufacturers of pulse oximeters calibrate their devices empirically using data obtained from human subjects. Our results suggest that this calibration would be affected by the thermoregulatory status of those volunteers. It is important to note that this approximately 2% effect may be seen in a large percentage of patients recovering from general anesthesia, because even mild intraoperative hypothermia usually produces intense vasoconstriction on arrival in the postanesthesia care unit.

In summary, on 7 of 13 study days, vasoconstriction developed during propofol/nitrous oxide anesthesia at central temperatures of 33.3 ± 1.0°C and plasma propofol concentrations of 3.9 ± 1.1 μg/mL. Vasoconstriction thresholds during anesthesia were significantly lower than those during the control period (36.7 ± 0.3°C), but the correlation between plasma propofol concentrations and these thresholds was poor. On the remaining six study days, vasoconstriction did not develop, even though central temperatures ranged from 32.1 to 32.7°C, with propofol concentrations of 4.1–10.9 μg/mL. Fingertip Sp_{O_2} measured with two different pulse oximeter models increased approximately 2% during thermoregulatory vasoconstriction without a concomitant increase in arterial PO_2. We conclude that general anesthesia with typical clinical concentrations of propofol combined with 60% nitrous oxide substantially inhibits thermoregulatory vasoconstriction and that vasoconstriction artifactually increases SpO_2.

We thank Mon-a-Therm, Inc., for donating the thermometers and thermocouples; Becton Dickinson & Company for the loan of a Program 2 syringe pump; and Cincinnati Sub-Zero for the loan of a Blanketrol II. Datex Medical Instrumentation, Inc., kindly loaned us the Capnomac gas monitor.

We evaluated the effect of alfentanil on hippocampal glucose utilization and histopathology associated with alfentanil-induced seizures. Three separate experiments were performed. First, anesthetized, paralyzed Long-Evans rats ($n = 15$; 5 rats per group) were mechanically ventilated and randomly assigned to three groups: (a) control, 70% N_2O and 30% O_2 continued for 1 h; (b) low-dose alfentanil (150 $\mu g/kg$ IV bolus), followed by infusion at 15 $\mu g \cdot kg^{-1} \cdot min^{-1}$ for 1 h without N_2O; or (c) high-dose alfentanil (1000 $\mu g/kg$ IV bolus), followed by infusion at 100 $\mu g \cdot kg^{-1} \cdot min^{-1}$ for 1 h without N_2O. After 1 h, [6-^{14}C]glucose was injected intravenously for autoradiography. With high-dose alfentanil, there was increased glucose utilization in the ventral hippocampus and the lateral septal nucleus. In the second experiment, anesthetized, paralyzed Sprague-Dawley rats ($n = 12$; 4 rats per group) were mechanically ventilated, underwent insertion of hippocampal depth electrodes, and were randomly assigned to three groups: (a) control, 70% N_2O and 30% O_2; (b) low-dose alfentanil (150 $\mu g/kg$ IV bolus), with 70% N_2O and 30% O_2; or (c) high-dose alfentanil (1000 $\mu g/kg$ IV bolus), with 70% N_2O and 30% O_2. An epileptiform pattern was observed on hippocampal and subdermal electroencephalographic recordings in both alfentanil groups. In the third experiment, anesthetized, paralyzed Sprague-Dawley rats ($n = 20$) were mechanically ventilated and assigned to two groups: (a) control, 70% N_2O and 30% O_2 ($n = 5$) or 100% O_2 ($n = 5$) continued for 1 h; or (b) alfentanil (2000 $\mu g/kg$ IV bolus), followed by infusion at 33.3 $\mu g \cdot kg^{-1} \cdot min^{-1}$ for 1 h with 100% O_2. After tracheal extubation, the rats recovered overnight. Light-microscopic evaluation revealed hippocampal or amygdaloid damage in 6 of the 10 alfentanil-treated rats. High doses of alfentanil administered to rats can produce limbic system seizure activity with hypermetabolism associated with neuropathologic lesions.

(Anesth Analg 1992;75:953–64)

Epileptiform activity with increased metabolic rate in hippocampal foci has been reported in rats given large intravenous (IV) doses of fentanyl (1) or sufentanil (2) or intracerebroventricular injections of other opiate receptor agonists (3,4). Seizures produce neuropathologic lesions in areas of hypermetabolism (5,6). We designed studies to test the hypotheses that large IV doses of alfentanil in rats would produce (a) an increased hippocampal metabolic rate, (b) an epileptiform pattern on both subdermal and hippocampal electroencephalograms (EEG), and (c) histopathologic lesions in the limbic system. The data presented here support these hypotheses.

Methods

Three sequential studies were performed at two institutions: (a) glucose utilization experiments (Hershey Medical Center), (b) hippocampal depth-electrode recordings (University of Pittsburgh), and (c) histologic investigations (University of Pitts-

burgh). Approvals of the Institutional Animal Care Committees were obtained for all experiments.

Glucose Utilization Experiments

Fifteen Long-Evans rats weighing 250–350 g were fasted overnight. Anesthesia was induced with 5% halothane in O_2 for 3 min, followed by an intramuscular injection of *d*-tubocurarine (0.45 mg), and the trachea was intubated with a 14-gauge Teflon catheter. The rats' lungs were then mechanically ventilated (Analytical Specialties ventilator, St. Louis, Mo.) for the remainder of the experiment, and inspired and expired O_2, CO_2, N_2O, and halothane were continuously monitored by mass spectrometry (Perkin Elmer, Pittsburgh, Pa.) (7). The rats were then mechanically ventilated to maintain a constant end-tidal P_{CO_2}. Biparietal subdermal electroencephalographic (EEG) needle electrodes and a rectal temperature probe were inserted. A femoral vein and artery were cannulated, and arterial blood pressure was continuously monitored. Anesthesia during surgery consisted of 70% N_2O and 1% halothane. Halothane was discontinued on completion of surgery, and sedation was then maintained with 70% N_2O and 30% O_2 for 1 h (no painful procedures were performed during this time). Heparin (200 U) was administered intravenously.

Each rat was randomly assigned to one of three groups: control, low-dose alfentanil, or high-dose alfentanil ($n = 5$ per group). The control group continued to receive the N_2O/O_2 mixture for 1 h, and 0.9% saline was infused intravenously at 4 $mL \cdot kg^{-1} \cdot h^{-1}$. The low-dose group received an intravenous bolus dose of alfentanil (150 μg/kg) over 1–2 min, followed by an infusion of 15 $\mu g \cdot kg^{-1} \cdot min^{-1}$ for 1 h. (In rats, this dose approximates the sedation level achieved with 70% N_2O [8].) The high-dose group received an intravenous bolus dose of alfentanil (1000 μg/kg) over 1–2 min, followed by an infusion of 100 $\mu g \cdot kg^{-1} \cdot min^{-1}$ for 1 h. In the low- and high-dose groups, N_2O was discontinued simultaneously with administration of the bolus dose of alfentanil. At the end of 1 h, 0.2 mL of blood was withdrawn for analysis of plasma glucose. Then, 35 μCi of [6-^{14}C]glucose was injected intravenously over 8–10 s, and 0.2–0.5-mL arterial samples were withdrawn at 30 s and 1, 2, 3, and 4 min. The radiolabeled glucose was injected through a venous cannula that was used only for that purpose and for an intravenous injection of a cardioplegic dose (150 mg) of pentobarbital at 5 min.

The brain was quickly removed and suspended in a two-phase solution of 1-methylbutane and 2-bromobutane chilled to −30°C in Freon-12. Coronal sections (40 μm) were cut, melted onto glass slides, dried at 55°C, and exposed for 20 days to radiographic film (low-dose mammography film, EI DuPont DeNemours, Wilmington, Del.) along with a set of calibrated ^{14}C-methylmethacrylate standards. Optical densities were measured with a pinhole densitometer (Tobias, Ivyland, Pa.) for determination of the cerebral metabolic rate for glucose (CMRgl) in 63 discrete regions. Brain regions were identified using an atlas of the rat brain (9). Regional CMRgl was then calculated using procedures previously described (10,11). Regional brain glucose concentrations were not measured. The brain/plasma glucose ratio was assumed to be 0.2 (10,11). The coefficient of variation for this technique is 12%, and the sample sizes in this experiment were sufficiently large to reveal CMRgl differences of 0.08–0.32 $\mu mol \cdot 100\ g^{-1} \cdot min^{-1}$.

To examine beyond the 63 discrete areas, three-dimensional imaging techniques of CMRgl throughout the brain were used in one control and one high-dose rat (12).

Assays. Glucose was measured spectrophotometrically with hexokinase and glucose 6-phosphate dehydrogenase in neutralized perchloric acid extracts of plasma (13). Plasma radioactivity was determined by liquid scintillation counting. The coefficient of variation for this assay is 16%. The sample sizes used allowed determination of differences in blood glucose of 8–40 mg%.

Chemicals. Alfentanil hydrochloride (for all three experiments) dissolved in isotonic saline (Alfenta, 500 μg/mL) was obtained from Janssen Pharmaceutica (Piscataway, N.J.). Enzymes and coenzymes were supplied by Boerhinger-Mannheim Corporation (New York, N.Y.). [6-^{14}C]glucose (6.8 mCi/mmol) was obtained from Amersham (Arlington Heights, Ill.).

Statistical analysis. Multivariate analysis of variance (ANOVA) was used to compare CMRgl in five hippocampal regions by brain area and by anesthetic group (14). Univariate ANOVA was used to test CMRgl in all of the remaining brain areas. In areas with significant F ratios, least-significant difference tests were used for pairwise comparisons of anesthetic groups. Differences were considered to be significant at $P < 0.05$.

Hippocampal Depth-Electrode Recordings

Twelve male Sprague-Dawley rats weighing 300–450 g were allowed access to food and water overnight. Anesthesia was induced with 5% halothane in 70% N_2O and 30% O_2, and the trachea was intubated with a 14-gauge Teflon catheter. The lungs were then mechanically ventilated (Analytical Specialties ventilator) for the remainder of the experiment, and inspired and expired O_2, CO_2, N_2O, and halothane were continuously monitored by Raman spectrometry (Ohmeda, Salt Lake City, Utah) (7). Mechanical ventilation was adjusted to maintain constant end-tidal CO_2. Pancuronium (0.6 mg IV) was administered as needed to prevent movement. A femoral vein and artery were cannulated, and arterial blood pressure was continuously monitored. A rectal temperature probe was inserted. The rat was placed in a stereotaxic frame, a burr hole was made, and a bipolar EEG electrode was inserted into the dentate gyrus at the following coordinates (15): rostrocaudal, −3.3 mm (relative to the bregma); mediolateral, 1.8 mm right; dorsoventral, 3.3 mm (relative to the dura). The dentate gyrus was chosen for electrode placement because evidence indicates that this region exerts a critical regulatory role in the passage of paroxysmal activity through hippocampal circuits (16). Anesthesia during surgery consisted of 1%–2% halothane in 70% N_2O and 30% O_2. Halothane was discontinued on completion of surgery, and sedation was maintained with 70% N_2O and 30% O_2 for the remainder of the experiment.

After 1 h, each rat was randomly assigned to one of three groups: control, low-dose alfentanil, or high-dose alfentanil ($n = 4$ per group). Control rats were given 0.9% saline (2 mL/kg IV). The low-dose group received an intravenous bolus dose of alfentanil (150 μg/kg) plus 0.9% saline to a total volume of 2 mL/kg over 1 min. The high-dose group received an intravenous bolus dose of alfentanil (1000 μg/kg) to a total volume of 2 mL/kg over 1 min. Nitrous oxide was continued because of concerns that the epileptiform activity seen in glucose utilization studies could be exacerbated by hyperoxia (17) and N_2O withdrawal (18). Subdermal and hippocampal EEGs were recorded for 30 min after injection of alfentanil or saline in all rats. Thirty minutes after opioid injection, arterial blood gas tensions and blood glucose levels were determined, and animals were then killed with aortotomy under deep halothane anesthesia.

Histologic Examinations

Twenty male Sprague-Dawley rats weighing 250–350 g were allowed access to food and water overnight. Anesthesia was induced with 5% halothane in 70% N_2O and 30% O_2; the trachea was intubated with a 14-gauge Teflon catheter; and 0.6 mg of pancuronium was injected intravenously as often as needed to maintain neuromuscular blockade. The lungs were then mechanically ventilated (Analytical Specialties ventilator) for the duration of the opioid administration and up to 3 h afterward, and inspired and expired O_2, CO_2, N_2O, and halothane were continuously monitored by Raman spectrometry (Ohmeda) (7). Mechanical ventilation was adjusted to maintain constant end-tidal CO_2. Biparietal subdermal needle electrodes and a rectal temperature probe were inserted. A femoral vein and artery were cannulated, and arterial blood pressure was continuously monitored. Anesthesia during surgery consisted of 1.5% halothane in 70% N_2O and 30% O_2. Halothane was discontinued on completion of surgery, and sedation was maintained with 70% N_2O and 30% O_2 for 1 h.

After 1 h, each rat was randomly assigned to one of two groups: control or high-dose alfentanil. In the alfentanil group, an intravenous bolus dose of alfentanil (2000 μg/kg) was administered over 1–2 min, followed by an infusion of 33.3 $\mu g \cdot kg^{-1} \cdot min^{-1}$ for 1 h (twice the loading dose used in the CMRgl and EEG experiments). As the bolus dose was injected, N_2O was discontinued and replaced by O_2. The first five control rats received 100% O_2 with 0.9% saline administered intravenously at 4 $mL \cdot kg^{-1} \cdot h^{-1}$ for 1 h, and the second five control rats continued to receive the N_2O/O_2 mixture, with 0.9% saline solution administered intravenously at 4 $mL \cdot kg^{-1} \cdot h^{-1}$ for 1 h. (The initial experimental design called for randomization of five hyperoxic control and five alfentanil-treated rats. However, after observing brain damage in two of the alfentanil-treated rats, we repeated the study using five N_2O-treated control and five alfentanil-treated rats to control for the possible influence of hyperoxia [17] and N_2O withdrawal [18] on brain injury. No difference in brain damage was evident between the two series of experiments [i.e., that with hyperoxic controls versus that with N_2O-treated controls]. Thus, the groups were combined [10 controls, 10 alfentanil treated].) After 1 h of anesthetic or control, all rats received 100% O_2 and underwent extubation when alert. They were placed in an O_2-infused enclosure for 1 h and then moved to a cage overnight.

Approximately 18 h after the anesthetic or control period, the rats were anesthetized with halothane and underwent cerebral perfusion-fixation with 10% neutral buffered formalin via a thoracotomy with left ventricular cannulation. The calvaria were removed, and the exposed brains were further immersion fixed in neutral buffered formalin for at least 24 h before their removal. The brains were sliced at approximately 3-mm intervals and the slices embedded in paraffin by routine techniques. Six-micrometer sections of each brain block were prepared, stained with hematoxylin and eosin, and evaluated by light microscopy. Degrees of neuropathologic alterations within a given anatomic region were based on subjective assessment of the number and distribution of eosinophilic neurons and severity of tissue edema.

Table 1. Physiologic Variables

Study group	MAP (mm Hg)	Pao$_2$ (mm Hg)[a]	Paco$_2$ (mm Hg)	pHa	T_R (°C)	Glucose (mg%)
Glucose Utilization Experiments[b]						
Control	134 ± 12	133 ± 12	38 ± 2	7.36 ± 0.03	37.9 ± 0.1	71 ± 4

High-dose alfentanil	145 ± 4	435 ± 18	30 ± 3	7.39 ± 0.02	38.0 ± 0.1	106 ± 7

MAP, mean arterial blood pressure; T_R, rectal temperature; pHa, arterial pH; Pao$_2$, arterial Po$_2$; Paco$_2$, arterial Pco$_2$.

[a] Significant difference between groups for Pao$_2$.

[b] Values were measured at the time of administration of [6-^{14}C]glucose and are mean ± SEM; $n = 5$ for each group.

[c] Values were measured just before injection of alfentanil or saline solution (control); $n = 4$ for each group.

[d] Values were measured 15 min before alfentanil infusion, 30 min after the start of alfentanil infusion, and 30 min after the termination of alfentanil infusion; $n = 10$ for each group.

Scores were assigned by a pathologist, who was unaware of the experimental treatment, as follows: 0 = none, 1 = minimal, 2 = mild, 3 = moderate, 4 = marked, and 5 = severe. These grades are semiquantitative in that they reflect the approximate percentage of degenerating neurons present in an affected neuroanatomic area as follows: 1 (<5%), 2 (6%–20%), 3 (21%–50%), 4 (51%–75%), 5 (76%–100%). Photomicrographs were taken with 35-mm Panatomic-X film (Eastman Kodak Co., Rochester, N.Y.).

Results

Physiologic variables measured after the anesthesic or control period in the three studies are listed in Table 1. Only Pao$_2$ values differed among experimental groups and in only the glucose utilization experiments.

Glucose Utilization Experiments

Electroencephalography. A sustained epileptiform pattern occurred in all rats in the high-dose alfentanil group and in none in the control group. Transient discharges occurred with the initial bolus dose of low-dose alfentanil (Figure 1A–D).

Autoradiography. Mean control values and percent change from control for CMRgl in brain regions with significant differences are listed in Table 2. In areas where change was observed, one of four patterns was identified: increased CMRgl after high-dose alfentanil; decreased CMRgl after high-dose alfentanil; increased CMRgl after low-dose alfentanil; or decreased CMRgl after low-dose alfentanil. In the hippocampal subregions, the primary area of interest of the study, CMRgl was significantly changed with high-dose alfentanil ($P = 0.03$; multivariate ANOVA). Subsequent analyses of these areas demonstrated increased CMRgl in the ventral hippocampus ($P = 0.0005$). In addition, increased CMRgl was evident in the lateral septal nucleus ($P = 0.0006$; univariate ANOVA). In the telencephalon and diencephalon, numerous areas of decreased CMRgl after high-dose alfentanil were present. In the telencephalon, this pattern occurred in the cortical areas, particularly the insular, piriform, and cingulate cortices and the caudate nucleus. In the diencephalon, this pattern occurred in most of the thalamic nuclei and the supraoptic and gelatinous nuclei. In the habenula, layers 4 and 5 of the cerebellum, and dorsal tegmental nucleus, increased CMRgl after low- but not high-dose alfentanil was apparent. In ventral, ventroposterior, and geniculate nuclei of the thalmus and in the gelatinous nucleus, decreased CMRgl occurred with low-dose alfentanil. There were differences ($P < 0.05$) between the high- and low-dose alfentanil groups in insular and pyriform cortices, caudate nucleus, lateral septal nucleus, ha-

[a] Cerebral metabolic rate for glucose (CMRgl) was measured in three groups of ventilated, paralyzed rats: N_2O (control), low-dose alfentanil, and high-dose alfentanil. Alfentanil CMRgl values listed are for high- or low-dose groups, as indicated in the left column; $n = 5$ in all groups. Only areas with $P < 0.05$ on univariate analysis of variance and subsequent least-significant difference testing versus N_2O-treated control rats are listed. Data are grouped as described in the text. Control and alfentanil values are reported as mean ± SEM, expressed in $\mu mol \cdot 100\ g^{-1} \cdot min^{-1}$. *P* values, univariate analysis of variance testing. CMRgl values from an earlier study in unstressed, unanesthetized rats using similar autoradiographic methods are in parentheses next to regions where such data are available (20).

Three-dimensional reconstruction of a series of representative autoradiograms (Figure 2) (12) shows many of these alfentanil-induced effects, including ventral hippocampal activation and thalamic depression of CMRgl after high-dose alfentanil.

Hippocampal Depth-Electrode Recordings

Electroencephalography. The control group showed no epileptiform activity in either subdermal or hippocampal EEG recordings. All rats given alfentanil exhibited epileptiform activity on both EEG recordings (Figure 1E and F).

Histologic Investigations

Electroencephalography. Subdermal electrodes indicated sustained epileptiform activity in all rats receiving alfentanil but in none of the control rats.

Histology. No microscopic lesions were observed in any of the 10 control brains examined. Evidence of acute neuronal degeneration on light microscopy was seen in 6 of 10 alfentanil-treated rats. The distribution of severity grades for the various foci is shown in Table 3. Neuronal degeneration was observed primarily in the limbic system and its areas of association. Two of the rats with lesions had minimal degeneration. In both of these, the lesions occurred in the dorsal amygdala adjacent to the lateral ventricle. Two others had mild to moderate degeneration. In one of these (rat 79), the lesions were found in the amygdala, the piriform cortex, and the ventral lateral septal nucelus. In the other (rat 73), a similar distribution of lesions was seen, but these were more severe and extended from the piriform cortex to the entorhinal cortex. Mild neuronal degeneration was observed in the anterior ventral cingulate cortex.

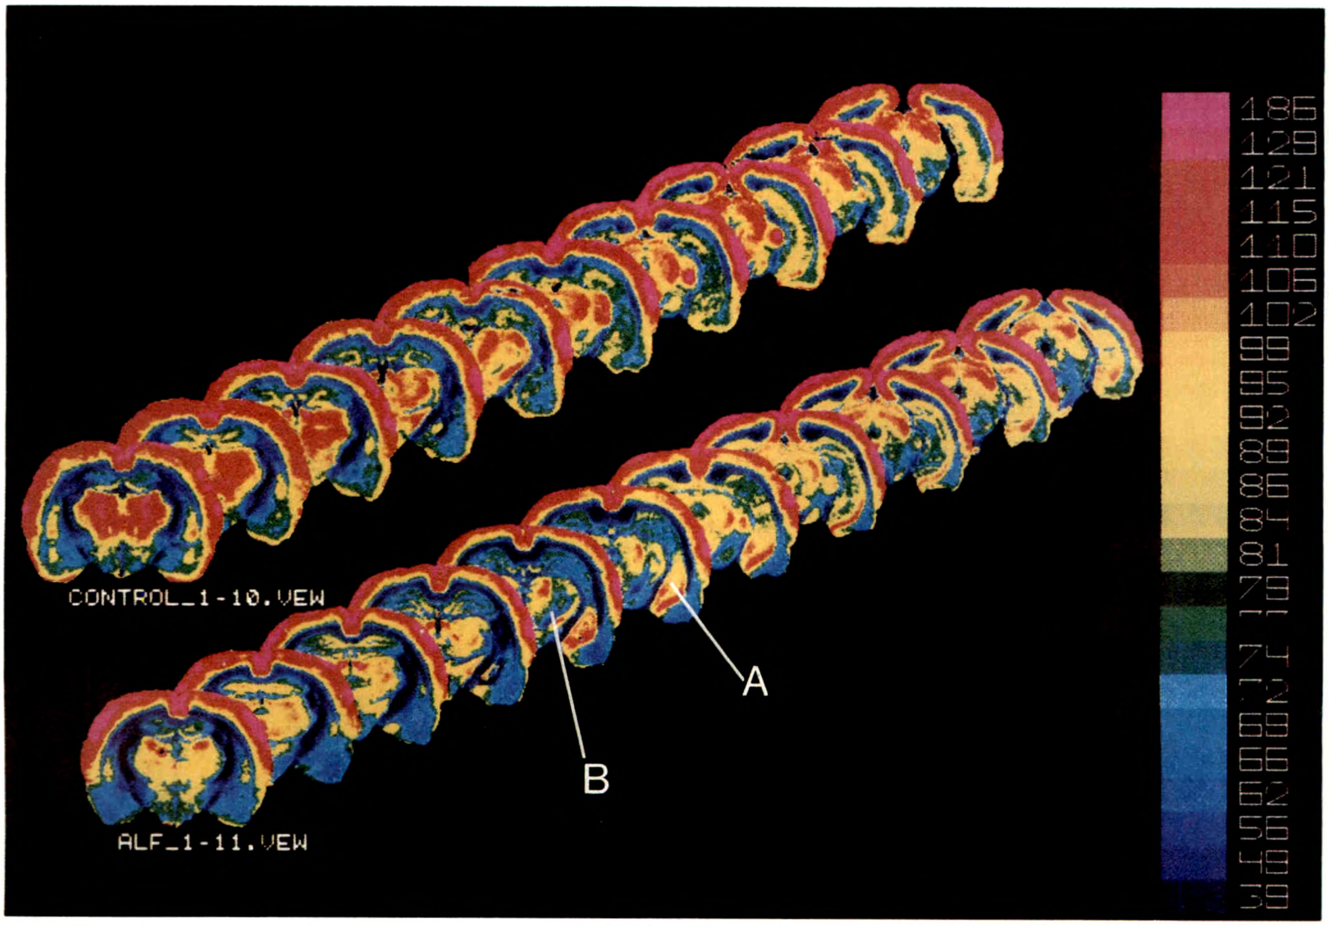

Figure 2. Computer-reconstructed images of CMRgl (μmol·100 g^{-1}·min^{-1}) in paralyzed, ventilated rats receiving either N_2O or high-dose alfentanil. Ventral hippocampal activation **(A)** and thalamic depression **(B)** are depicted. Images were made using computer programs written by L. S. Hibbard and J. S. McGlone (12).

Two of the 10 rats receiving high-dose alfentanil had moderate to severe neuronal degeneration that, as in the other rats, appeared only in the limbic system and its areas of association. The most consistently damaged regions were the amygdala, the adjacent piriform cortex, and the entorhinal cortex. The damage within the piriform cortex extended anteriorly to the level of the olfactory bulbs and involved the olfactory nuclei as well. The cingulate cortex, particularly the anterior and ventral portions, was also affected but less so than the piriform and entorhinal cortices. Multiple foci of neuronal degeneration were present within the pyramidal layer of the hippocampus, including at least some portions of CA1, CA2, CA3, CA4, and the subiculum. Within the thalamus, the most severely affected region was the medial dorsal area, although the medial middle and ventral portions of the thalamus and the dorsolateral thalamic area were also characterized by foci of acute degeneration. A moderate degree of degeneration was also evident within the ventral lateral septal nuclei of these two rats.

In all affected rats, areas of histopathology were characterized on low-power magnification (40×) by pallor and vacuolation of the neuropil (Figure 3), and on slightly higher magnification (100×) by perineuronal retraction spaces (Figures 4 and 5). On high-power magnification (430×), neurons with pyknotic nuclei and with retracted brightly staining eosinophilic cytoplasm could be seen (the characteristics of acute eosinophilic neuronal degeneration) (Figure 6). Some of the degenerating neurons within the pyramidal layer of the hippocampus were characterized by basophilic surface granules that may represent early mineralization of the cytoplasmic membrane or enhanced staining of terminal nerve boutons (Figure 7).

Discussion

In the present study in rats, doses of alfentanil that may be clinically relevant (i.e., 10- to 20-fold more than basal analgesic) produced limbic system hypermetabolism, epileptiform activity, and histologic evi-

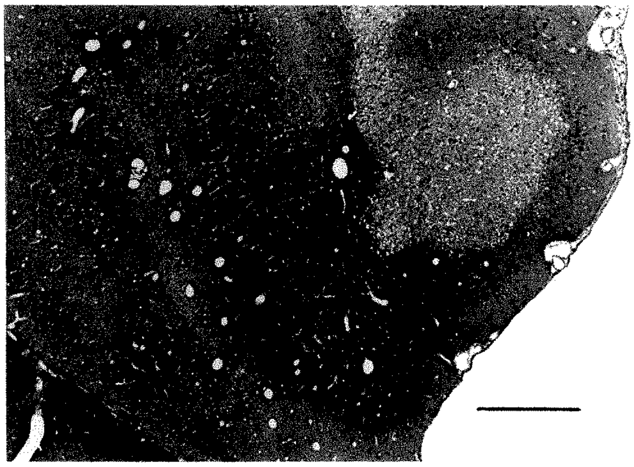

Figure 3. Amygdala, piriform cortex, and ventral hippocampus of alfentanil-treated rat 59. A prominent area of pallor (acute necrosis) is evident within the amygdala, and this extends to involve the piriform cortex (hematoxylin-eosin, original magnification, ×40; *bar* = 500 μm; dorsal aspect on left side of figure).

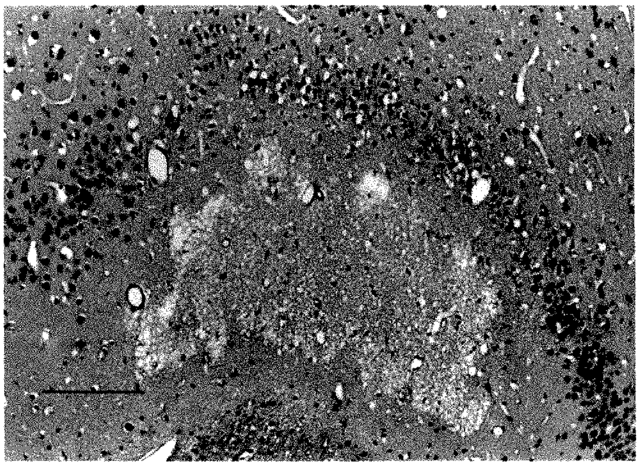

Figure 4. Piriform cortex adjacent to the lateral olfactory tract (*bottom*) of alfentanil-treated rat 73. A central area of pallor and vacuolation is present. Perineuronal retraction spaces are evident within the neuron layer of the piriform cortex, which is above this area of pallor (hematoxylin-eosin, original magnification, ×100; *bar* = 200 μm).

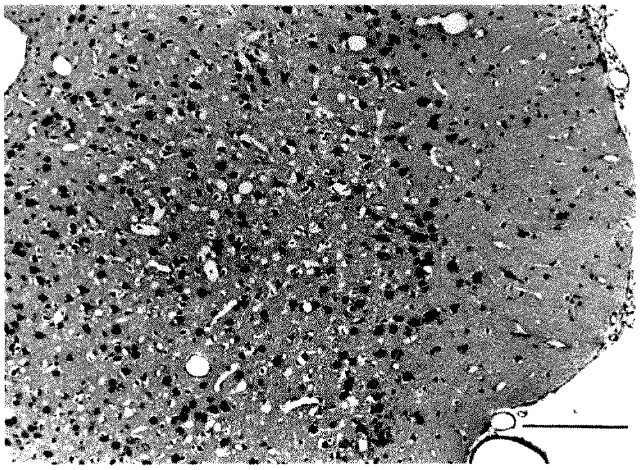

Figure 5. Anterior olfactory nucleus of alfentanil-treated rat 59. Marked, acute neuronal degeneration is evident, with prominent perineuronal retraction spaces (hematoxylin-eosin, original magnification, ×100; *bar* = 200 μm; dorsal aspect on left side of figure).

dence of brain injury. The metabolic and EEG effects of alfentanil are not surprising, because similar observations have been made with other μ-agonist opioids (1,2). Because intense, sustained seizures produce histologic evidence of brain damage (5,6,19), it was appropriate to use this rat model to assess the potential for damage produced by alfentanil-induced seizures. We believe that this is the first experimental evidence of histologic brain damage produced by a drug used in the clinical practice of anesthesia.

Methodologic Considerations

We used [6-^{14}C]glucose instead of a glucose analogue, such as deoxyglucose, as a tracer of CMRgl for the following technical reasons. The calculation of CMRgl using deoxyglucose requires the use of a factor (lumped constant) that can change with elevated CMRgl (10,11,20). Glucose requires no such constant. Exposure to [6-^{14}C]glucose, however, can result in loss of radiolabeled carbon in CO_2; therefore,

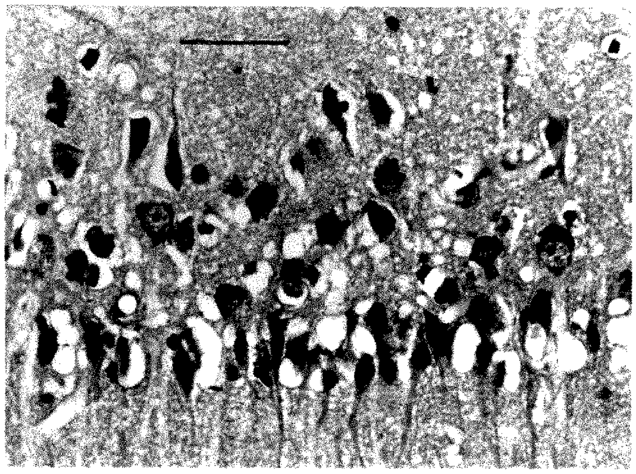

Figure 6. Pyramidal neuron layer of the hippocampus (CA1 region) of alfentanil-treated rat 59. Most neurons are undergoing acute degeneration, indicated by nuclear pyknosis, perineuronal retraction spaces, and prominently stained (eosinophilic) cytoplasm (hematoxylin-eosin, original magnification, ×430; *bar* = 50 μm).

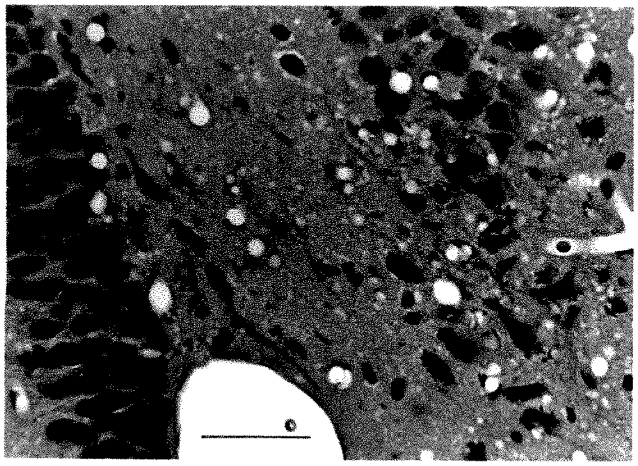

Figure 7. CA4 region of the hippocampus of alfentanil-treated rat 71. Acute neuronal degeneration involves the neurons in the pyramidal cell layer, present on the *right portion* of the photomicrograph. Some neurons, in addition to having pyknotic nuclei and eosinophilic cytoplasm, have small, surface basophilic "granules." These granules may represent foci of mineralization or enhanced staining of swollen or stretched terminal nerve boutons. A portion of the granule cell layer of the dentate gyrus is present at the *left margin* of the photomicrograph (hematoxylin-eosin, original magnification, ×430; *bar* = 50 μm; dorsal aspect on left side of figure).

the duration of exposure must be limited. Moreover, when a steady state is not present, autoradiography should be done as rapidly as possible. With the use of [6-^{14}C]glucose, autoradiographic procedures can be completed in 5 min rather than the 45 min necessary for the use of glucose analogues (20).

The influence of N_2O on glucose utilization in the control animals should be considered in the interpretation of these data. Comparison of the control CMRgl values with values obtained previously from unstressed, unanesthetized animals (20) (Table 2) suggests that N_2O sedation is associated with generalized, mild cerebral stimulation. This reinforces the conclusion that alfentanil induces hypermetabolism in some regions. Data suggesting no effect or metabolic depression in other regions, however, are more difficult to interpret.

Opioid-Induced Seizure Activity

Alfentanil administration after cessation of N_2O produced low-frequency, rhythmic, high-voltage spike activity, an epileptiform pattern (21,22), in subdermal recordings. This epileptiform pattern did not occur in the absence of alfentanil administration when N_2O was withdrawn in hyperoxic controls. Alfentanil also produced an epileptiform pattern when administered with N_2O. Thus, we conclude that the epileptiform pattern that we observed cannot be attributed to hyperoxia (17) or to N_2O withdrawal (18) and was induced by alfentanil. A possible hippocampal focus was suggested by the pattern of increased glucose utilization in the ventral hippocampus. Because depth electrodes were not used in the first experiments, we could not conclude with certainty that alfentanil produced hippocampal seizure activity (4). Thus, subsequent experiments were performed with recordings from depth electrodes placed in the hippocampus and with histologic investigation after overnight recovery.

Intracranial electrodes were placed in the dorsal hippocampus because of the regulatory role of this region on passage of paroxysmal activity into the entire hippocampus (16). This maximized the likelihood of detecting increased hippocampal activity. We observed seizure activity in these electrodes immediately after administration of a single injection of alfentanil, although after 1 h of alfentanil, hypermetabolism compared with N_2O-treated control rats was not apparent in the dorsal hippocampus but was present in the ventral hippocampus. Deoxyglucose autoradiography (which requires longer time) with sufentanil (2) and fentanyl (1) shows hypermetabolism of the entire hippocampus. These observations suggest that μ-opioid-induced seizure with concurrent hypermetabolism in these preparations occurs at temporally distinct times in different areas of the hippocampus.

Other studies have found conflicting evidence of both proconvulsant and anticonvulsant properties specific to opiate-receptor agonists. Snead and Bearden (4) used depth EEG electrodes and injected various doses of μ-, δ-, κ-, ϵ-, and σ-opiate-receptor agonists into the cerebral ventricles of rats. They reported proconvulsant properties of all five classes of agents with descending potency $\epsilon > \delta > \mu > \sigma >> \kappa$. Distinct EEG patterns occurred with each opiate subtype. The μ-opiate-induced seizures originated in the subcortex and the hippocampus and then generalized. Other published data provide evidence that fentanyl and its congeners are μ-agonists (23–26) and that nonopioid seizures are generally associated with hypermetabolism (5,6,27). These data, added to our findings of limbic system hypermetabolism, EEG epileptiform patterns, and neuronal lesions after high doses of alfentanil, lead us to conclude that opioid-induced seizures occurred in the limbic systems in our rats.

Opiatergic Systems

Increased glucose utilization occurred in the ventral hippocampus after high-dose alfentanil. This is consistent with observations of the effects of other opioids (1–3,28). Chugani et al. (3) observed effects with enkephalin similar to our findings: increased ventral hippocampal and lateral septal metabolic rate with depression of most thalamic structures and the piriform cortex. Tommasino et al. (1), with higher doses of fentanyl administered in rats, observed decreased thalamic CMRgl and increased ventral hippocampal CMRgl (compared with values in unanesthetized controls), although they noted little change in the septal nucleus and decreased CMRgl in the habenula. They also noted decreased CMRgl in numerous other areas not observed by us. Young et al. (2), in rats given sufentanil, also observed increased hippocampal CMRgl involving the ventral hippocampus and decreased thalamic CMRgl (compared with values in N_2O-sedated controls). Thus, autoradiographic measurements of CMRgl suggest a distribution of μ-receptors in rats associated with metabolic stimulation in the ventral hippocampus and depression in the thalamus. However, the presence of thalamic lesions in 3 of our 10 alfentanil-treated rats implies that thalamic metabolic depression could have resulted from injury rather than through a specific receptor-mediated mechanism.

Hippocampal GABAergic interneurons are known to exert inhibitory control over pyramidal cells. These interneurons are inhibited by a μ-receptor agonist (29) and are activated (made more inhibitory) by peptidergic afferents arising in the amygdala (30). Thus, one reasonable cellular mechanism can be posited for the observed hippocampal excitatory effects of μ-agonist opioids (i.e., direct inhibition of hippocampal interneurons) and injury-induced loss of amygdala-mediated inhibition.

Opioid-Induced Brain Damage

Data from a variety of models and species support the thesis that seizures without hypoxia can permanently damage neural tissue (5,6,19,31,32). Lothman and Collins (5) and Ben-Ari et al. (6) observed a qualitative correlation between regional increases in glucose utilization produced by kainic acid, pentylenetetrazole, or bicuculline and regional neuropathologic changes. Our data demonstrate a similar phenomenon with alfentanil. That is, hypermetabolic areas such as the hippocampus and lateral septal nucleus are prone to alfentanil-induced damage. However, our rats with high-dose alfentanil had only a 5-min exposure to radiolabeled glucose after 1 h of epileptiform activity. Thus, areas of the brain that had already been injured would exhibit decreased CMRgl, whereas areas that were still functional could exhibit hypermetabolism. It is not surprising, therefore, that the pattern of neuropathology that we observed is not precisely congruent with the autoradiographic pattern of hypermetabolism. Nevertheless, our data are consistent with the conclusion that alfentanil in doses sufficient to produce regional epileptiform activity and hypermetabolism in rats can produce neuronal lesions.

The autoradiography experiments were performed first. We chose to test alfentanil because it was a recently released fentanyl analogue with unknown effects on regional CMRgl. The doses chosen were intended to model clinical practice. Published data indicated that the low dose we chose was moderately analgesic and sedative in rats (8). Thus, we set our high dose at 10- to 20-fold greater, modeling clinical recommendations for high-dose anesthetic opioid techniques (Janssen Pharmaceuticals. Sublimaze and Sufenta product information. Physician's desk reference. Oradell, N.J.: Medical Economics, 1990: 1089–92). This was done empirically, fully cognizant that rodent and human dose-response relationships may not necessarily be parallel. In previous studies (19), we found that seizure activity in rats occasionally caused a decrease in Pa_{O_2}. Thus, we elected to use 100% O_2 in alfentanil-treated animals, although this does raise the issue of whether N_2O withdrawal (18) and hyperoxia (17) contributed to the observed seizure activity or brain damage. These two issues were addressed in the design for the subsequent hippocampal depth-electrode recordings and histologic investigations. The data suggest that neither N_2O withdrawal nor hyperoxia contributed to the alfentanil-induced epileptiform activity or to resultant brain damage. Finally, in the histologic studies, the alfentanil loading dose was further doubled with moderate hypocapnia to maximize the likelihood of brain damage. Clearly, further studies are needed to ascertain the dose-response relationship among alfentanil administration, seizures, and brain damage.

Not every rat receiving a high dose of opioid in our study sustained brain damage. Other clinically relevant factors, such as genetic predisposition, Paco_2, or cerebral perfusion pressure, may have contributed to the development of brain injury in the affected rats. Of note, fentanyl in rats has been reported to exacerbate cerebral ischemic injury (33). Thus, one might speculate that if opioid-induced seizure activity coincides with a low cerebral blood flow situation, the risk of ischemia-induced neural injury may be increased.

We have demonstrated that an opioid, in the circumstances described, can be a neurotoxin. Several lines of evidence support the notion that opioids have the potential to be neurotoxic in rodents in an excitotoxic manner analogous to that reported with kainic acid (5,6,31,34) and domoic acid (35–37):

1. Both kainic acid (31,34) and alfentanil produce hippocampal seizure on EEG recordings from intracranial electrodes.
2. Autoradiographic studies with deoxyglucose of kainic acid (5,31) and opioids (1,2) reveal a striking similarity in the pattern of hypermetabolism.
3. The pattern of brain damage in rodents produced by domoic acid (35–37) is very similar to that produced by alfentanil in our most severely affected rats and by kainic acid. Domoic acid is a structural and functional analogue of kainic acid (34).
4. In rodents, limbic system seizure produces a stereotypic behavior, "wet dog" shakes. This behavior can be produced with domoic acid (35), kainic acid (31), and μ-agonist opioids (38). Kainic acid-induced wet dog shakes are potentiated by μ-agonists in a naloxone-reversible manner (39). Indeed, there are reports that this stereotypic manifestation of limbic seizure in rats is mediated by endogenous μ-agonist peptides (40).
5. Kainic acid and domoic acid are both thought to be neurotoxic via excitatory mechanisms (34) involving activation of glutamate receptors (41–43). Opioids have been reported to also activate glutamate channels (44–46).

These observations might ordinarily be considered nothing more than interesting laboratory phenomena. However, domoic acid has been ingested inadvertently by humans (47,48), producing lesions comparable to those seen in domoic acid-treated and alfentanil-treated rats. Victims exhibited neurologic symptoms including seizures and coma, had permanent memory deficits (47), and sustained large, delayed decrements in CMRgl in the hippocampus and amygdala on positron emission tomography (47). Neuropathologic evaluation in victims who died (47) and in monkeys under controlled conditions (49) also revealed limbic system (hippocampus and amygdala) damage.

Although debated for several years (50–52), recent reports document that exogenously administered opioids can produce brief epileptiform activity on EEG recordings in humans (53,54) and that endogenous opioids may contribute to seizures in some epileptic humans (55,56). However, the usual prerequisite for seizure-induced brain damage, prolonged and intense seizure activity, has not been reported in humans given opioids. Thus, the potential for opioids to be neurotoxic in humans at this point must be considered highly speculative.

The authors thank John M. Graybeal, CRTT, and Regina Joseph, BS, for technical assistance; J. Robert Boston, PhD, and Thomas Rudy, PhD, for suggestions concerning statistical analysis; Charlotte Dietrich for preparation of the manuscript; Elizabeth Cohn for editorial review; and Rosalyn Garman for the histologic preparations. Richard Dasheiff, MD, is gratefully acknowledged for his critical comments during manuscript preparation and for providing the depth electrodes used in some of the experiments.

Time-Course of Respiratory Depression After an Alfentanil Infusion-Based Anesthetic

Michael E. Goldberg, MD, Marc Torjman, MEd, Richard R. Bartkowski, MD, PhD,
Christina T. Mora, MD, Thomas Boerner, MD, and Joseph L. Seltzer, MD

Department of Anesthesiology, Jefferson Medical College, Thomas Jefferson University, Philadelphia, Pennsylvania

Postoperative respiratory depression after alfentanil administration has been described in several case reports. The effects of a prolonged alfentanil infusion on the CO_2 response curve or cognitive function have not been studied. Twenty-one ASA physical status I or II patients were studied after a prolonged alfentanil infusion (>90 min) to determine the incidence of postoperative respiratory depression, arterial O_2 desaturation, and impairment of cognitive function. Each patient's recovery was observed at 30-min intervals for evidence of respiratory depression (utilizing the Read CO_2 rebreathing method), desaturation by pulse oximetry (severe desaturation defined as arterial O_2 saturation <90%), and cognitive function (utilizing Trieger dot and digit substitution tests). Plasma samples were also examined for secondary elevations in alfentanil plasma concentrations. Significant depression of the CO_2 response curve and cognitive function was found up to 1 h postoperatively. Arterial O_2 desaturation was seen in 11 of 21 patients (52%). No correlation was found between arterial O_2 desaturation and cognitive function scores or CO_2 rebreathing results. Increased depression of the CO_2 response curve was not necessarily associated with severe desaturation episodes. A secondary increase in plasma alfentanil concentration was detected in 5 of the 21 patients (24%), but these patients did not experience further depression of the CO_2 response curve. We conclude that prolonged alfentanil administration may result in severe arterial O_2 desaturation with significant depression of the hypercapnic respiratory drive during the first hour in the postanesthesia care unit, even though the majority of our patients were easily aroused in response to verbal stimuli.

(Anesth Analg 1992;75:965–71)

Postoperative respiratory depression is a recognized complication after opioid anesthesia. Fentanyl, a relatively short-acting opioid, causes respiratory depression that may be associated with a secondary peak in plasma fentanyl concentration (1,2). The time-course of this respiratory depression can be an important factor in governing postoperative risks and recovery room stay. Alfentanil, a short-acting fentanyl analogue, might have an advantage over other opioids if it leads to a more rapid return to normal consciousness and respiration (3–5). There is, however, the potential for prolonged recovery when the duration of administration of alfentanil is extended. Recently, several case reports have described delayed postoperative respiratory depression after alfentanil infusion (6–8). The purpose of this study was to determine the extent and time-course of respiratory depression, as well as the recovery of consciousness, after alfentanil/N_2O/O_2 anesthesia in procedures lasting longer than 90 min.

Methods

Twenty-one ASA physical status I or II patients scheduled for elective lumbar discectomy gave written, informed consent to participate in this protocol approved by our institutional review board. Patients were excluded from the study according to the following criteria: history of pulmonary disease, CO_2 retention, obesity (weight >110 kg), athletes in training, pregnancy, allergy to opioids, substance abuse, or renal failure.

Instrumentation and Data Collection Procedures

Respiratory data were collected using a Medical Graphics System 2001 (Medical Graphics Corpora-

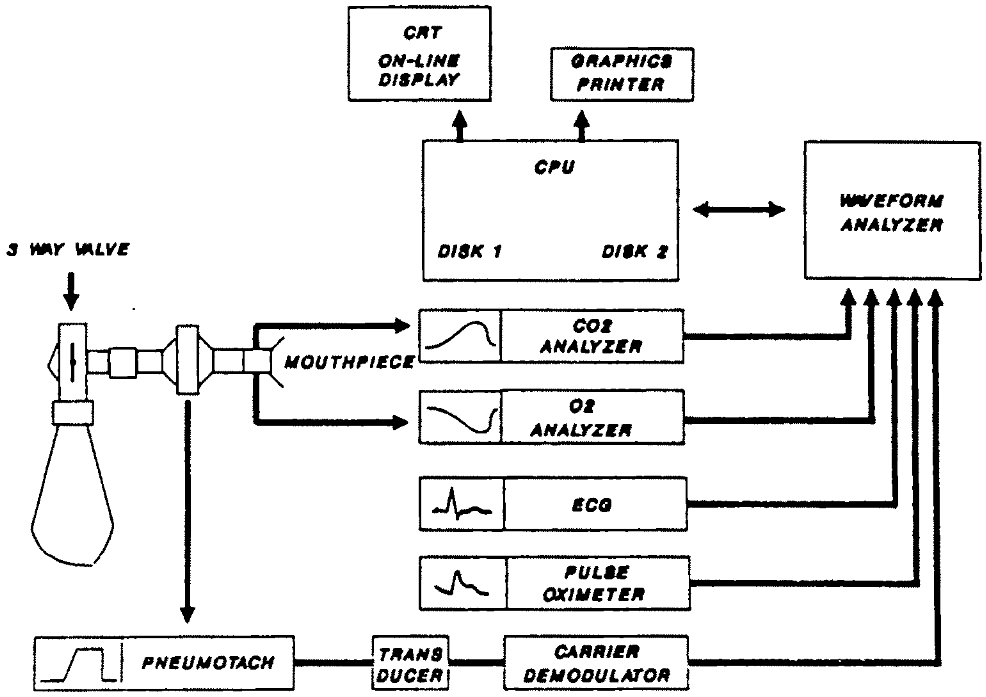

Figure 1. Schematic of the computerized CO_2 modified Read breathing flow circuit. CRT, cathode-ray tube; CPU, central processing unit; ECG, electrocardiogram.

tion, St. Paul, Minn.) (Figure 1). Oxygen and CO_2 gas analyses were performed with Sensors (Dynatec Electro-optics, San Luis Obispo, Calif.) rapid analyzers requiring a total of 150 mL of gas sample per minute. The O_2 analyzer operates with a zirconia fuel cell sensor heated to maintain a temperature of 75°C. The analyzer has a linearity range of 0%–100% O_2, with an accuracy of ±0.05% O_2 or 1% of the reading, whichever is smaller.

The CO_2 analyzer is an infrared absorption type with a linearity range of 0%–10% CO_2 and an accuracy of ±0.2% at full scale. Both analyzers have a response time of <100 ms. The analyzers were calibrated with certified gas mixtures of 16% O_2 and 7% CO_2 (Puritan Bennett, Baltimore, Md.), accurate to ±0.03%.

Flow was measured with a heated linear pneumotach (Hans Rudolph model 3813), with a flow range specification of 0–800 L/min. The pneumotach was calibrated using a 3-L calibration syringe. Five injections of room air were performed with an average error not >1.5% of injected volume.

The rebreathing circuit resistance was 0.5 cm H_2O at a flow rate of 1 L/s. Gas and flow signals were processed by an eight-channel microcomputer for real-time data. Phase delays from gas transport time and from body temperature, pressure, saturated volume corrections were applied for every breath. The processed data were written onto the computer hard disk and instantly displayed on the screen.

A complete system calibration (analyzers, pneumotach, and phase delays) was performed before each CO_2 response test.

Testing Procedures

Each patient was transported to the postanesthesia care unit (PACU) on a hospital stretcher approximately 1.5 h before the scheduled surgery. The patient was positioned supine in a semirecumbent position, and once comfortably resting on the stretcher, he or she was familiarized with the cognitive function tests (Trieger dot [9] and digit substitution [10]), a linear analogue pain scale, and the respiratory apparatus used for the CO_2 response measurements. A 15-min relaxation period was allowed before performing each baseline test. During that period, the rebreathing bag (13 L) was flushed three times with the rebreathing gas mixture (93% O_2, 7% CO_2). The bag was filled with a volume equal to the patient's predicted vital capacity plus 1 L via a 9-L water seal spirometer (Warren E. Collins Inc., Braintree, Mass.). The cognitive function tests and pain assessment scale were performed first, followed by the rebreathing test. This test was performed with the patient breathing through a large mouthpiece and wearing noseclips. These tests were performed over a 15-min period preoperatively and postoperatively. On completion of all baseline tests, an arterial catheter was inserted into the radial artery to facilitate

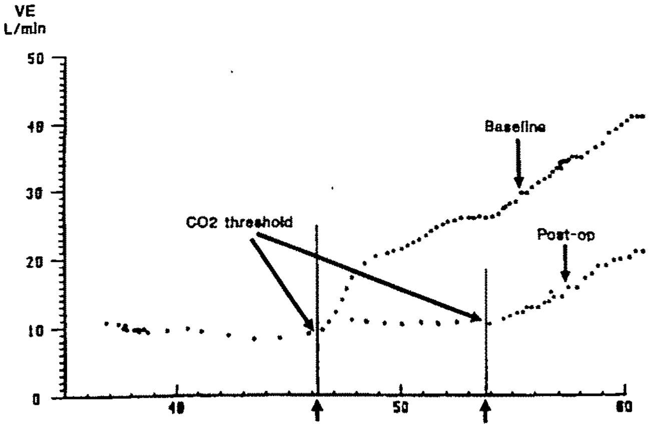

Figure 2. Representative CO_2 response curves from one patient. Each *dot* represents a single breath.

serial blood collection for determination of alfentanil plasma levels. The first postoperative test was performed once the patient was awake and responsive to verbal commands.

Evaluation of the CO_2 Response Curve

The CO_2 response was analyzed after each test from the corresponding breath-by-breath computer graph. Swallowing and coughing were recognized by a computer algorithm and excluded during the performance of the test. The slope of the CO_2 response curve was determined for the linear portion of the curve, beginning at the CO_2 "threshold" (11,12) (Figure 2), which was visually identified as the point at which ventilation began to increase linearly with increasing CO_2. The corresponding end-tidal Pco_2 ($P_{ET}co_2$) value was selected from the x-axis and entered into the computer for subsequent calculation of the slope, beginning at the "threshold" value.

The slope of the CO_2 response was computed via linear regression analysis by the method of least squares. The correlation coefficient (r) and coefficient of determination (r^2) were calculated for each line. We selected the breath-by-breath technique for this evaluation, because it has been reported to be more powerful than segmental-time averaging in this application (13). The slope estimation thus obtained yields the highest statistical confidence. This is particularly important when only a single trial is available for each experimental state. This approach therefore minimizes the chance of missing a real empirical difference and provides the narrowest confidence limits for each estimate (14).

Anesthetic Technique and Postoperative Data Collection

Premedication consisted of either intravenous midazolam (2–4 mg), administered 10 min before induction, or oral diazepam (5–10 mg), administered 30 min before induction. After breathing O_2 for several minutes, anesthesia was induced using pancuronium (0.015 mg/kg IV), alfentanil (75 μg/kg IV) over 90 s, and thiopental (1–4 mg/kg). Succinylcholine (1.5 mg/kg IV) was utilized to facilitate endotracheal intubation.

Anesthesia was maintained with 60%–70% N_2O in O_2 and an alfentanil infusion (1.5 $\mu g \cdot kg^{-1} \cdot min^{-1}$) that was adjusted in increments of 0.25–0.5 $\mu g \cdot kg^{-1} \cdot min^{-1}$ in response to a change in arterial blood pressure or heart rate of 10% or greater, or both, as clinically indicated (e.g., arterial blood pressure, heart rate, and sympathetic signs). Neuromuscular blockade was achieved by administration of pancuronium that was titrated to maintain a twitch response of 2/4 utilizing a peripheral nerve stimulator. Neuromuscular blockade was reversed with neostigmine (2.5 mg) and atropine (1 mg) intravenously. The alfentanil infusion was discontinued 20–30 min before the anticipated end of surgery. Nitrous oxide was discontinued on completion of skin closure.

Every patient was breathing O_2 by mask on admission to the PACU. Once the patients were awake, stable, and appeared to be breathing well, O_2 administration was discontinued. If arterial O_2 desaturation occurred (arterial O_2 saturation [Spo_2] <95%), the patients were given supplemental O_2 until their Spo_2 returned to 95% or more. Postoperative measurements (Trieger dot, digit substitution, rebreathing tests, and the visual analogue pain assessment) were started within the first 30 min after arrival in the PACU, once the patient became alert and cooperative. The measurements were continued at approximately 30-min intervals until pain medication was requested or the patient was discharged from the PACU. A final measurement was obtained at 120, 150, or 180 min postoperatively, depending on when the patient received supplemental pain medication or was discharged from the PACU. The actual discharge time varied from patient to patient but reflected the time to awakening when each patient could maintain an Spo_2 >95% on room air. These final data were combined into one time point and labeled "last." Blood specimens were obtained from the arterial catheter for determination of alfentanil plasma levels. Alfentanil levels were determined by a radioimmunoassay (15) that uses rabbit antialfentanil antibodies and has a sensitivity of 0.1 mg/mL and an interassay and intraassay coefficient of variation that is <5%. The CO_2 response curve was immediately plotted

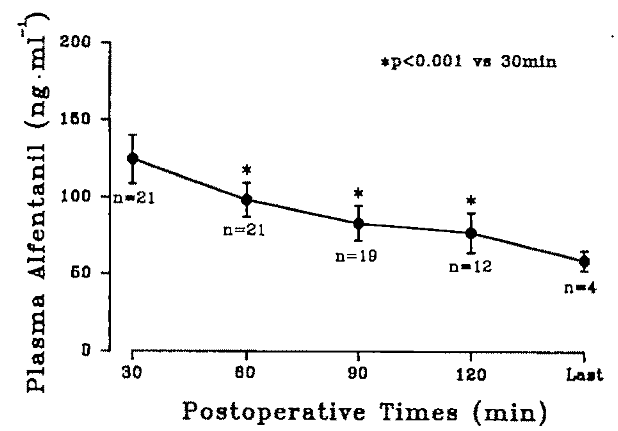

Figure 3. Mean ± SEM plasma alfentanil levels obtained at 30, 60, 90, 120, and 150 (Last) min postoperatively.

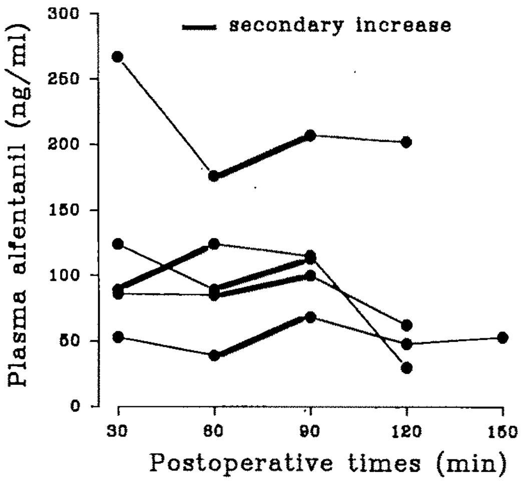

Figure 4. Alfentanil plasma concentrations in the five patients with a secondary postoperative elevation in alfentanil level.

from the simultaneous breath-by-breath minute ventilation and P_{ETCO_2} values. The two measures of respiratory drive, described earlier, were then calculated: the slope of the ventilation versus P_{ETCO_2} curve and right displacement of the curve. Incidences of arterial O_2 desaturation were defined as moderate (Sp_{O_2} 90%–95%) and severe (Sp_{O_2} <90%) while the patient was breathing room air. The Sp_{O_2} measurements were recorded only when the pulse oximeter reading was consistent over a 5-min observation period. When arterial O_2 desaturation was rapid and severe (Sp_{O_2} <80%), the patient was given O_2 to breathe for a 5-min period after which a second reading was obtained with room air to ensure against artifact errors. Changes in the CO_2 response curves, plasma alfentanil levels, and Trieger dot and digit substitution tests were analyzed using analysis of variance for repeated measures, with $P < 0.05$ considered statistically significant. A protected least-significant difference test was used to identify differences between means. A Pearson correlation matrix was used to determine whether there were relationships among alfentanil plasma levels and respiratory and cognitive function variables. The Bartlett χ^2 statistic was used to determine significance. All values are presented as mean ± SEM.

Results

The average age of the patients was 36 ± 1.6 yr, and mean surgical time was 186 ± 6.5 min (range 120–240). The average alfentanil dose of 18.9 ± 1.6 mg (range 10.7–38.5) yielded postoperative plasma alfentanil levels ranging from 124.5 ± 15.6 ng/mL to 58.9 ± 6.4 ng/mL (Figure 3). Alfentanil concentration decreased significantly ($P < 0.001$) for the first 120 min. Statistical significance was not achieved ($P = 0.114$) when including the 150-min time point as a result of the smaller n value ($n = 4$). Five of 21 (24%) patients demonstrated a secondary increase in plasma alfentanil concentration postoperatively (Figure 4). A significant correlation ($r^2 = 0.84$) was found between alfentanil plasma levels and the percent change from baseline to 30 min postoperatively in the CO_2 response curve. No significant correlations were found between plasma alfentanil levels and the change in the CO_2 response curve from baseline to each of the other three postoperative time points. There were also no significant correlations between plasma alfentanil and Sp_{O_2} at any of the measurement periods in those patients. The mean coefficient of determination r^2 for the CO_2 responses was 0.95, and there were no significant differences between r values at each measurement period. The mean CO_2 response slopes were depressed 40%, 28%, 19%, and 17% from baseline at 30, 60, 90 min, and the last measurement, respectively ($P < 0.001$) (Figure 5). Further evidence of respiratory depression was indicated by a significant increase ($P < 0.05$) in right displacement of the CO_2 response curve during the postoperative period compared with baseline. The mean CO_2 threshold increased significantly ($P < 0.001$) from 46 ± 0.70 mm Hg at baseline to 50 ± 0.72, 50 ± 0.73, 51 ± 0.73, and 49 ± 0.70 mm Hg at 30, 60, 90 min, and the last measurement, respectively.

Eleven of 21 patients (52%) experienced desaturation (Sp_{O_2} <95%) during the first postoperative hour. Eight of 21 patients (38%) demonstrated severe desaturation (Sp_{O_2} <90%). The latter required intervention by an investigator in the PACU to arouse the patient to take deep breaths. The patients who experienced severe postoperative desaturation did not necessarily have the highest alfentanil plasma concentration nor evidence of a secondary increase in plasma alfentanil (Table 1).

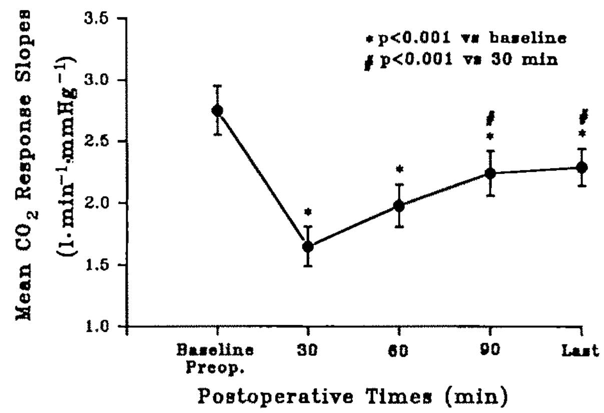

Figure 5. Mean ± SEM CO_2 response slopes measured preoperatively and at 30, 60, and 90 min postoperatively. Last, measurement taken before PACU discharge at 120, 150, or 180 min.

We compared the percent change from baseline in the CO_2 response curves in patients experiencing severe postoperative arterial O_2 desaturation with those who did not experience desaturation and found no significant difference between the two subgroups. In the eight patients who experienced severe postoperative desaturation, we found nonsignificant correlations (r^2 = 0.13, 0.47, 0.19) between postoperative respiratory depression, quantitated by the percent change from baseline in the CO_2 response curve, and postoperative desaturation measured by pulse oximetry at 30, 60, and 90 min, respectively. By 120 min postoperatively, 19 of the 21 patients had Spo_2 >97%. Two patients continued to show lower Spo_2 (93% and 94%), but these values returned to normal at 150 min. Only at 30 min postoperatively was there a significant correlation (r^2 = 0.58) between plasma alfentanil and Spo_2 in those eight patients.

Digit substitution and Trieger dot tests were significantly lower at all postoperative times compared with baseline (Figures 6 and 7). Impaired cognitive function was greater during the initial 30 min, with return to baseline by 120 min. All patients performed significantly below their baseline on the digit substitution and Trieger dot tests for the first 120 min of their postoperative stay in the PACU. Episodes of severe desaturation were not associated with lower scores on the digit substitution or Trieger dot tests compared with patients with normal Spo_2. The percent change from baseline in that subset of patient scores was not significantly different between those two groups.

Pain scores, as determined by a linear analogue pain scale, were significantly higher than baseline throughout the postoperative period. At the final assessment, they were significantly increased above all other times (Figure 8).

Discussion

Respiratory depression after fentanyl administration may be associated with a secondary increase in plasma concentration (1,2). Stoeckel et al. (1) and Becker et al. (2) demonstrated delayed respiratory depression after fentanyl administration. Owing to its short elimination half-life, the alfentanil plasma concentration might be expected to decrease steadily, avoiding the secondary peaks in plasma concentration and possible respiratory depression. Three recent reports have described delayed respiratory depression after an alfentanil infusion (6–8). In these reports, alfentanil was titrated clinically to effect. These studies, however, did not consistently examine CO_2 response curves, cognitive recovery, or alfentanil plasma concentrations.

In this study, we found statistically significant depression of the CO_2 response curve for 120 min postoperatively (Figure 5). This was accompanied by a significant right shift of the slope. Accurate measurement of ventilation was made possible by the real-time integration and processing of CO_2, O_2, and flow waveforms under the dynamic conditions of a CO_2 Read rebreathing challenge. Using this technology, we were able to clearly demonstrate that on average, P_{ETCO_2} had to increase to 50 mm Hg to provoke a ventilatory response. Furthermore, we found that 52% of our patients had an Spo_2 <95%. Often desaturation occurred when the patients fell asleep, even though they appeared awake and alert immediately before these episodes while tests were being performed. This is consistent with the effects of sleep on the CO_2 response curve, as reported by Belville et al. (16), as well as the combination of opioid potentiation and sleep on the depression of the CO_2 response curve (17).

In their study of respiratory depression with alfentanil, Mahla et al. (6) obtained a single plasma sample to determine the concentration of alfentanil at the time of the respiratory depression (45 min after discontinuation of alfentanil) and reported a mean of 87 ng/mL. Their postoperative alfentanil plasma concentrations at 30 min (±10 min) ranged from 40 to 289 ng/mL. These concentrations are in the range reported by Ausems et al. (18) at which spontaneous ventilation resumes (99–223 ng/mL). Only two of our study patients exceeded that range. We observed a secondary increase in plasma alfentanil concentration in 24% of the patients studied. Because we did not find a consistent correlation between alfentanil plasma concentration and the CO_2 response curve or arterial O_2 desaturation (Spo_2 <90%) in the patients who demonstrated a secondary increase, we could not attribute arterial O_2 desaturation or depression of the CO_2 response curve to this mechanism.

It is possible that the duration and degree of respiratory depression reported in this study were affected

by the interaction of diazepam, midazolam, or thiopental with alfentanil. Our study was designed to examine the effect of an alfentanil-based infusion on ventilation and recovery when used in a clinical setting. Bailey et al. (19) have shown that the combined use of fentanyl and midazolam for sedation resulted in a 92% incidence of hypoxemia and apnea and 50% with fentanyl alone. Obviously, the hypoxic drive to ventilation may be depressed further by the addition of midazolam to our alfentanil-based technique.

Other studies have demonstrated that benzodiazepines can cause depression of the CO_2 response curve; however, the clinical significance of these effects has been questioned (20–23). Power et al. (23) examined the CO_2 response curve in seven healthy volunteers receiving either intravenous diazepam (0.15 mg/kg) or midazolam (0.075 mg/kg), and found that both drugs resulted in transient nonsignificant depression in the slope of the CO_2 response curve in their subjects. Bailey et al. (22) demonstrated that 0.1 mg/kg of diazepam, as an intravenous bolus dose, did not cause significant depression of the ventilatory response to CO_2. These and other studies (20,21) suggest that the clinical effects of the benzodiazepines, administered at the time of induction, can be expected to be short-lived. The duration of surgery averaged 2–3 h, and tests were performed up to 3 h postoperatively. In this study, we found that the CO_2 response slopes were significantly depressed from control values over all measured time periods. Although the benzodiazepines did not have a direct respiratory effect, it is possible that their residual sedative effects, coupled with those of thiopental, may have led to more sleep episodes, which are

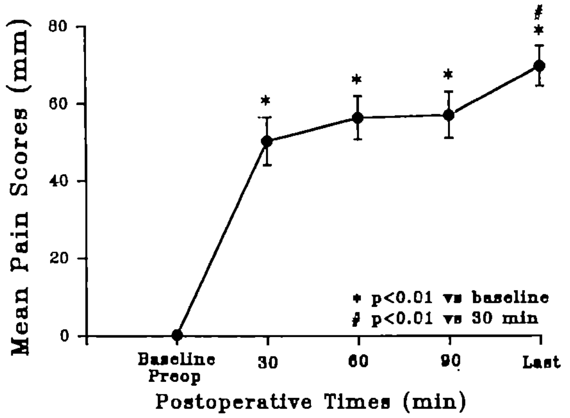

Figure 8. Mean ± SEM pain scores (min) measured on a 10-cm linear analogue scale. Last, measurement taken before PACU discharge at 120, 150, or 180 min.

known to enhance respiratory depression (16,17). The episodes of desaturation observed in this study most often occurred when the patients were asleep but arousable to verbal stimuli.

Postoperatively, the ventilatory response to CO_2 in our patients was depressed to a greater extent at 30 and 60 min postoperatively despite increasing pain scores on the visual analogue pain scale (Figures 5 and 8). Pain scores were highest at the last measurement, whereas the respiratory response to CO_2 did not further improve compared with the 90-min measurement.

Postoperative respiratory depression is a problem that can occur after administration of any opioid. The alfentanil pharmacokinetic profile (shorter elimination half-life and more rapid clearance) may limit this problem. The depressed CO_2 response and arterial O_2 desaturation reported here are of concern, particularly during the first hour in the PACU. The effects were reversed with stimulation and encouragement to breathe. Clinical observation alone did not predict these events. A secondary increase in plasma alfentanil concentration did occur in some of our patients; however, this did not seem to influence respiration. Of note, formal cognitive testing around the time of the desaturation episodes showed no relationship between patients who had arterial O_2 desaturation and those who did not. This confirmed our observations that patients who had arterial O_2 desaturation often appeared as alert and awake as others who did not.

We are grateful to Alexander Marr, CRNA, and Jennifer Lessin, RN, for their invaluable assistance with this study, and Hugh Schieren, PhD, for critical reading of the manuscript.

R-Phenylisopropyl-Adenosine Increases Spinal Cord Blood Flow After Intrathecal Injection in the Rat

Rolf Karlsten, MD, Jens D. Kristensen, MD, and Torsten Gordh, Jr., PhD
Department of Anesthesiology, University Hospital, Uppsala, Sweden

---

The A1-adenosine receptor agonist, R-phenylisopropyl-adenosine (R-PIA), demonstrated antinociceptive properties in animal studies after intrathecal administration. In the evaluation of a drug for possible spinal injection in humans, the effects of intrathecal R-PIA on spinal cord blood flow (SCBF) were investigated using the laser-Doppler flowmetry technique in anesthetized rats. In low doses (0.1–1 nmol), no change in SCBF was recorded, whereas larger doses (10–100 nmol) caused a significant increase in SCBF. No change in systemic arterial blood pressure could be seen, except for a decrease after administration of the largest dose of R-PIA (100 nmol). It is concluded that R-PIA in doses of 10 nmol and larger induces an increase in SCBF after intrathecal injection in anesthetized rats and that an increase in blood flow is seen before any effect on the systemic circulation is detected. It can also be deduced that the antinociceptive effects of R-PIA after intrathecal injection are not a consequence of spinal ischemia and that disturbances in local blood flow cannot be expected to constitute a neurotoxic factor.

(Anesth Analg 1992;75:972–6)

Intrathecal injection of the adenosine analogue R-phenylisopropyl-adenosine (R-PIA) induces antinociceptive effects in several nociceptive tests in rats (1–8) and mice (9–12). The effects are mediated through activation of extracellular adenosine receptors that have been classified according to Van Calker et al. (13) as A1- and A2-receptors. Both types have been identified in the rat spinal cord using autoradiographic methods (14). The antinociceptive effects of intrathecally administered adenosine agonists are probably mediated through activation of spinal A1-adenosine receptors (12). R-Phenylisopropyl-adenosine, which has a high affinity for the A1-receptor (15), also induces motor impairment in rats after intrathecal injection of large doses (>10 nmol), but it is possible to separate the antinociceptive effect from the motor impairment using smaller doses (8). This has indicated that R-PIA is a potential drug for future pain treatment in humans (8,12).

Before using new drugs for spinal administration in humans, animal studies on neurotoxicity must be performed. These should include histologic examination of the spinal cord after long-term exposure to the test drug, as well as evaluation of the effect of the drug on spinal cord blood flow (SCBF) (16–19). The reason for investigating the effects on SCBF is that severe vasoconstriction may produce spinal cord ischemia and thus give rise to structural lesions. Another reason for studying SCBF is that disturbances in local blood flow in the spinal cord could influence the results of behavioral and physiologic experiments (20).

With this background, the present study was conducted to evaluate the effects of increasing doses of R-PIA on SCBF measured with laser-Doppler flowmetry technique after intrathecal administration in rats.

Methods

The study was approved by the local ethical committee for animal experiments. Nine male Sprague-Dawley rats (obtained from ALAB, Sollentuna, Sweden) weighing 350–430 g were housed in animal rooms thermostatically maintained at 20°C, with artificial lighting (12 h/day) and free access to food and water, for 5–7 days before the experiment. The animals were anesthetized with O_2/N_2O (1 L/min of each) and enflurane (4% during induction of anesthesia, then reduced to 2% during the surgical procedure and to 1.5% during measurements). The animals were breathing spontaneously through a mask. The temperature was kept constant at 37°C throughout the experiment by use of a heating blanket placed under

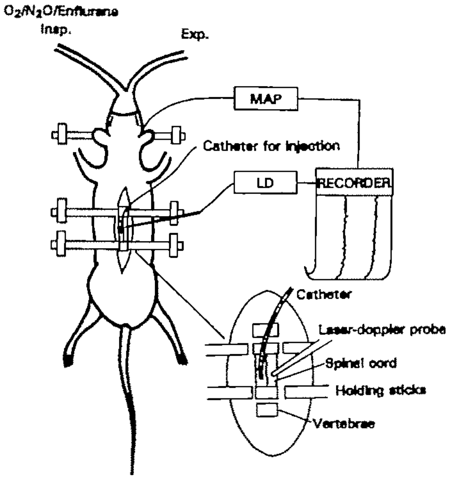

Figure 1. Experimental setup. The rat is held by a stereotactic frame. Mean arterial blood pressure (MAP) and the laser-Doppler signal (LD) are monitored on a two-channel strip-chart recorder.

the rat and controlled by a temperature probe placed in the rectum of the animal. A catheter was inserted into the right common carotid artery for continuous measurement of arterial blood pressure and for analysis of arterial blood gases. The spinal cord was exposed by bilateral laminectomy over the lumbar T13 to L2 region without rupturing the dura. The animals were then placed in a stereotactic frame, allowing fixation of the vertebrae to make certain that there were minimal respiratory movements of the spinal cord. A dissection microscope was used to guide the intrathecal insertion of a polyethylene catheter (PE 10, previously stretched in warm water to reduce the outer diameter) approximately 5 mm through a slit in the dura to the left side of the central vein.

The SCBF was measured using laser-Doppler flowmetry technique (21,22). This method records the relative change in blood flow over time in a tissue volume constituting a hemisphere with a radius of approximately 1 mm (21). We used a Perimed model Pf2b laser-Doppler instrument (Stockholm, Sweden). The laser-Doppler probe (Pf 303) was positioned to the right side of the central vein, just above the surface of the spinal cord, to give a high-quality signal. The readings were recorded on a two-channel strip-chart recorder. Mean arterial blood pressure was continuously monitored, and the readings were recorded on a two-channel strip-chart recorder. This was done to ascertain that changes in SCBF were not secondary to changes in central hemodynamics. The experimental setup is shown in Figure 1.

Arterial blood samples (200 μL) were drawn before intrathecal injections started and at the end of the experiment before injection of epinephrine. Blood gases were analyzed because changes in $Paco_2$ and Pao_2 have profound effects on cerebral and spinal vascular resistance and blood flow (23–25).

The R-PIA (Boeringer, Mannheim, Germany) was dissolved using a few drops of HCl, buffered to a pH of 7 with NaOH and then diluted in 0.9% saline to concentrations of 0.01, 0.1, 1.0, and 10 μM. When the experimental setup had stabilized, usually after 30–45 min, an arterial blood sample was drawn for blood gas analysis, and 25 μL of 0.9% saline was injected intrathecally as a control (each animal served as its own control). Twenty minutes after the injection of saline, R-PIA was injected in increasing doses of 0.1, 1.0, 10, and 100 nmol, with 20–25-min intervals between the doses. This time interval was chosen to allow stabilization of the readings. After the injection of 100 nmol of R-PIA, a blood sample for blood gas analysis was drawn. Each rat received a dose of 1 μg of epinephrine at the end of the experiment as a positive control for vasoconstriction (26,27). All drugs were injected in a volume of 10 μL, followed by a flush of 15 μL of 0.9% saline to clear the catheter. The temperature of the injected solutions was constantly 20°C. The animals were then killed by inhalation of 100% N_2O to achieve a zero baseline for the recordings of SCBF and arterial blood pressure.

The results of the laser-Doppler and blood pressure measurements are presented as percent of predrug values ± SEM. These data were analyzed using one-factor analysis of variance for repeated measures (Scheffé F-test). The arterial blood gas data are presented as mean ± SEM. Wilcoxon's signed rank test was used to calculate statistical differences. A statistically significant difference was assumed at $P < 0.05$.

Results

Spinal injection of saline and low doses of R-PIA (0.1–1 nmol) had no effect on SCBF. After administration of 10 and 100 nmol of R-PIA, a statistically significant increase in SCBF was seen. The increase occurred during a 15–20-min period, after which the blood flow stabilized and stayed at an increased level (Figure 2). When epinephrine was injected, a significant reduction in SCBF was recorded that stabilized at a lower level after 5 min (Figure 2). The systemic arterial blood pressure was unchanged until the highest dose (100 nmol) of R-PIA was administered. This caused a significant reduction (Figure 3) that also stabilized at a lower level within 20 min. Intrathecal injection of 1 μg of epinephrine did not alter the arterial blood pressure, which had already been decreased by 100 nmol of R-PIA. The arterial oxygenation was stable throughout the experiment, and $Paco_2$ and pHa were unchanged (Table 1).

Discussion

The present study shows that R-PIA induces a significant increase in SCBF after intrathecal injection of 10 and 100 nmol in the rat. The increase occurred within 20 min and stayed at an increased level compared with the predrug recording. With smaller doses, no significant change in SCBF could be seen.

These results clearly indicate that the antinociceptive effects of R-PIA, which reach their maximum in the rat within 15–30 min after intrathecal administration (8), are not accompanied by a decrease in SCBF. The laser-Doppler probe was situated just above the dorsal horn of the spinal cord, and for this reason we conclude that the nociceptive effects of R-PIA are not due to neuronal ischemia. The increase in SCBF after 10 nmol of R-PIA was probably not a consequence of altered systemic circulation, because no effect could be seen on the systemic arterial blood pressure during the 20-min observation period. Conversely, injection of 100 nmol of R-PIA was followed by a significant decrease in systemic arterial blood pressure. This large dose induces severe motor impairment and sedation in the rat after intrathecal administration (8). It is 100 times larger than the smallest dose (1 nmol) of R-PIA that induces antinociception in the rat after intrathecal injection (7). The effect is probably systemic, because adenosine and its derivatives in large doses have profound effects on the systemic circulation (28–31), but it may also be mediated through spinal mechanisms as the decrease in arterial blood pressure could be seen almost immediately after the intrathecal injection (data not shown).

Freedman et al. (32) reported that the substance-P antagonist [D-Arg,D-Trp,Leu]-substance P (Spantide) decreased SCBF, as assessed using laser-Doppler and iodoantipurine tests. It was proposed that this may be the reason for neurotoxic effects seen after intrathecal administration of Spantide in rats. As no decrease in SCBF could be seen in the present study with R-PIA, disturbances in SCBF cannot be expected to constitute a neurotoxic factor.

No change in arterial blood gases could be seen after intrathecal injection of R-PIA. The slight increase in Pa_{CO_2} throughout the experiment is probably due to the respiratory depression caused by inhaled anesthetic.

There are advantages in using the laser-Doppler method when studying SCBF. It provides a continuous recording over time in the same animal, thus allowing increasing doses to be administered. However, because it only measures the relative change in blood flow in a tissue hemisphere of approximately 1 mm in radius (21), no conclusions can be drawn about the distribution of blood flow in the spinal cord. The method also includes measurements of blood flow in the dura, but the significance of this is probably small, because blood flow in the dura is relatively low compared with the spinal cord. Using the radioactive microsphere technique in dogs, Kozody et al. (33) have shown that the lumbosacral SCBF was approximately 25 mL·100 g^{-1}·min^{-1}, whereas the dural blood flow in the same region averaged approximately 4.3 mL·100 g^{-1}·min^{-1}.

The laser-Doppler probe measures a restricted volume within the spinal cord. In the present study, we attempted to place the probe at the site of the dorsal horn. It is not possible to place the probe in exactly the same spot in all animals, and the distance between the tip of the intrathecal catheter and the laser-Doppler probe cannot be standardized. The differences in the location of the laser-Doppler probe influence the ratio of gray/white substance in the tissue volume under the probe. Taking these factors into account, we used the individual animal as its own control and compared the injection of saline with the different doses of R-PIA. The intention of the study was not to produce a true dose response, but to screen for potential reduction in SCBF that might

Table 1. Arterial Blood Gases Before Intrathecal Injection of R-Phenylisopropyl-Adenosine (Predrug) and at the End of the Experiment, After Administration of 100 nmol R-Phenylisopropyl-Adenosine (Postdrug)

Values are expressed as mean ± SEM.

have neurotoxic effects. The SCBF did not return to baseline between injections, but the incremental doses were 10-fold higher, making the previous dose almost negligible. If we had permitted the SCBF to return to baseline, the experiment would have been several hours longer. The antinociceptive effect of R-PIA after intrathecal injection in the rat reaches its maximum within 15–30 min (8). If the antinociceptive effect of R-PIA was a consequence of spinal ischemia, then an observation period of 20 min after each dose should be sufficient.

Because the laser-Doppler method does not measure the distribution of blood flow within the spinal cord, other methods should also be used before drawing conclusions about the effects of a drug on SCBF. One such method is the iodoantipurine method, in which the absolute change in blood flow and the distribution within the spinal cord can be studied (24,34). Using this method, we have demonstrated that intrathecal injection of 10 nmol of R-PIA induced a significant increase in the gray matter in the lumbar spinal cord (J.D. Kristensen et al., unpublished observations). These results are compatible with the results in the present laser-Doppler experiment.

Adenosine induces vasodilation in most tissues, except the placenta and the kidney (35). Several authors have reported the effects of adenosine and adenosine analogues on cerebral blood vessels and cerebral blood flow. The results are conflicting. There have been reports that adenosine analogues either increase (36) or decrease (37,38) cerebral blood flow. In a study by Norlén (30), the infusion of adenosine in pigs for deliberate hypotension increased SCBF, whereas cerebral blood flow was unchanged.

It was previously shown by Edvinsson and Fredholm (39) that adenosine and adenosine analogues dilate cerebral arteries. The rank order of potency indicated that the dilation was mediated through activation of adenosine A2-receptors. This might explain why, in the present study, the A1-agonist R-PIA increased SCBF to 30%, at most, above the predrug value.

R-phenylisopropyl-adenosine administered intravenously in rats induces a decrease in blood flow in some areas in the brain, as was demonstrated in a recent study by Nehlig et al. (38). In that study, R-PIA also decreased arterial blood pressure by 48%, which makes it difficult to conclude whether the effects on the cerebral circulation are direct or indirect. The dose of R-PIA administered was 0.1 mg/kg, which corresponds to the highest dose in our study (100 nmol). This should be compared with the smallest dose needed for antinociceptive effects after intrathecal injection in the rat (1 nmol).

It must be emphasized that the present study was conducted to screen for potential decrease in SCBF after intrathecal injection of R-PIA. No conclusion can be drawn about other possible toxic effects of the drug. Even if the arterial blood gases drawn at the end of the experiment were normal, this does not constitute evidence that R-PIA, even in small doses, is without effects on respiration or central hemodynamics. The observation period after the largest dose was not sufficiently long in the present study, nor was it the focus of the study to evaluate this.

In the present study, epinephrine induced a significant decrease in SCBF compared with saline. It is still not clear whether epinephrine induces a decrease in SCBF when injected alone intrathecally. Using the microsphere technique in dogs, Kozody et al. (40) demonstrated that the intrathecal injection of epinephrine did not alter SCBF. In another study by Kozody et al. (41), using the same technique in dogs, tetracaine was shown to increase SCBF. When tetracaine was injected together with epinephrine, no change in SCBF compared with controls could be seen. For this reason, we cannot draw any conclusions as to the effects of epinephrine on SCBF other than that it did reduce SCBF, which had previously been increased by R-PIA. Dohi et al. (27) reported that ephedrine decreases SCBF, and in a study by Edvinsson and Owman (26), it was shown that epinephrine was a potent mediator of vasoconstriction in cerebral arteries.

In summary, the adenosine receptor agonist R-PIA in doses of 10 nmol and larger induces a significant increase in SCBF within 20 min after intrathecal injection in the rat. In doses up to 10 nmol, no effect could be seen on systemic arterial blood pressure, but a large dose (100 nmol) significantly decreased arterial blood pressure. We also conclude that the antinociceptive effects of R-PIA after intrathecal injection are not a consequence of spinal ischemia and that disturbances in SCBF cannot be expected to constitute a neurotoxic factor.

The respiratory performance of the diaphragm may be altered by changes in mechanical or neural factors, or both, induced by upper abdominal surgery. We conducted this study to examine the effects of upper abdominal surgery on postoperative respiratory function. We studied resting lengths of four diaphragm regions, three in the costal and one in the crural diaphragm, with biplane videoroentgenography in six dogs immediately after upper abdominal surgery and up to 30 days postoperatively. Functional residual capacity was 16.7% smaller immediately after surgery compared with values obtained in the same animals after 30 days. Simultaneously measured resting lengths of each of the diaphragm regions immediately after surgery were longer, on average by 8.3%, than 30 days postoperatively. During the postoperative course, resting diaphragm lengths gradually and uniformly decreased as functional residual capacity increased. Phrenic nerve stimulation in four other dogs immediately after identical surgery resulted in large diaphragm shortening (from 42% to 55%), indicating that neither the diaphragm nor phrenic nerves were injured by the surgical manipulation. We hypothesize that respiratory dysfunction after upper abdominal surgery may be, at least in part, attributed to a decreased central drive for breathing caused by activation of the afferent limb of an inhibitory reflex owing to stretching of the diaphragm.

(Anesth Analg 1992;75:977–82)

Postoperative respiratory dysfunction occurs after upper abdominal surgery (UAS) (1–6) and is caused by inhibition of central respiratory drive, not mechanical dysfunction of the diaphragm (2,7,8). Afferent traffic from the diaphragm, if it is stretched, inhibits breathing (9). Because functional residual capacity (FRC) is decreased in patients after UAS (3), and because we have found that diaphragm length varies inversely with lung volume in dogs (10), we postulated that part of the respiratory dysfunction may be attributed to the inhibition of breathing secondary to an increase in diaphragm stretch. However, results from the two previous studies that have measured diaphragm resting length using sonomicrometry during recovery from UAS seem to contradict this. In awake, standing sheep, there was no change in resting length of the crural diaphragm, and there was a shortening of the costal region after UAS compared with recovery (8). In awake dogs, there were no significant changes of the crural or costal diaphragm compared with 22 days after surgery (11). Because FRC was not measured in these studies, it is difficult to evaluate the applicability of these results to humans. Presently, there is no study that simultaneously correlates FRC and resting diaphragm length after UAS.

In this study, we quantified resting lengths of four regions of the diaphragm by using computerized biplane-videoroentgenography (12) immediately after UAS and during the 30-day recovery period. We were able to correlate postoperative regional length changes in FRC. We conclude that postlaparotomy respiratory dysfunction is, at least in part, due to decreased central respiratory drive caused by reflex inhibition originating from afferents in the stretched diaphragm.

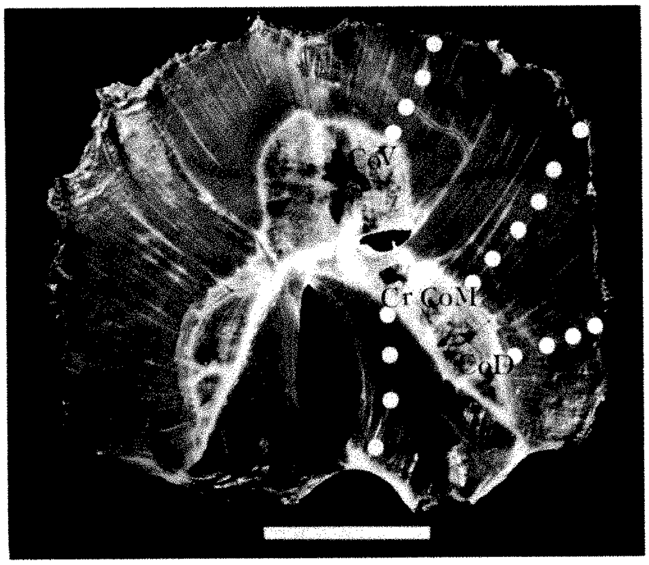

Figure 1. Excised canine diaphragm (abdominal side) showing schematically the typical location of markers sutured along muscle bundles in the ventral (CoV), middle (CoM), and dorsal (CoD) regions of the costal diaphragm and in the crural (Cr) diaphragm. The actual markers were lead beads, 2 mm in diameter, relatively smaller than the *white dots* shown here. The regional diaphragm length was calculated as a cumulative sum of all intermarker distances. *White bar* = 8 cm.

Methods

Study approval was obtained from the Institutional Animal Investigation Committee. Ten beagle dogs (10–13 kg) were anesthetized with pentobarbital (30 mg/kg, supplemented as needed), tracheally intubated with a cuffed endotracheal tube (inner diameter 9 mm) without neuromuscular blocking agents, and mechanically ventilated. After induction of anesthesia, a midline laparotomy was performed under sterile conditions. Silicone-coated lead spheres (2-mm diameter) with central holes were stitched with 5-0 Prolene to the peritoneal serosa of the left hemidiaphragm. The rows of spheres, which served as radiographic markers, were placed along muscle bundles from the insertion of the diaphragm on the rib cage to their origin on the central tendon. The spheres were spaced at 1.5–2.0-cm intervals so that the sum of the intermarker distances would closely approximate the arc length along the diaphragm region (12). Figure 1 shows the four regions in which the markers were located: the ventral, middle, and dorsal portion of the costal diaphragm and the crural diaphragm region.

All measurements of resting diaphragm lengths and FRC were made with the dogs anesthetized and spontaneously breathing. Anesthesia was induced with pentobarbital (30 mg/kg); sufficient supplemental doses (10%–20% induction dose) were administered to abolish spontaneous movements. Regional diaphragm resting length was measured in six dogs on the same day of marker placement, 4–8 h after surgery (OD) and on postoperative day (POD) 30. In addition, measurements were made on POD 3 and 15 in four of the dogs. The dogs were placed supine in a radiolucent volume-displacement body plethysmograph in the center of an orthogonal biplane videoroentgenographic system. The lower rib cage and upper abdomen, with the diaphragm markers, were scanned during consecutive breaths. If fluoroscopy revealed signs of residual postlaparotomy pneumoperitoneum, the air was evacuated with needle aspiration before studies of the diaphragm were attempted. The animals breathed through a Fleisch pneumotachograph that measured flow, and thoracic gas volume was measured at FRC by Boyle's law during inspiratory efforts against an occluded airway. The fluoroscopic images were encoded on a stop-action videotape. We also measured regional diaphragm shortening during 15 spontaneous breaths and during mechanical ventilation (Harvard pump). For the latter measurements, the same tidal volume as spontaneous breathing was used. Initially, a respiratory frequency more rapid than spontaneous breathing was used to ensure inhibition of breathing efforts. Then, the frequency was reduced to that observed during spontaneous ventilation, and 15 mechanical breaths were recorded. During these breaths, there was no evidence of spontaneous respiratory efforts in any of the dogs. After all data were recorded, each of the six dogs was killed with an overdose of barbiturate. Macroscopic and microscopic (histologic slides) examination of the diaphragm did not show any signs of significant inflammation or other abnormalities.

In four additional dogs, the phrenic nerves were electrically stimulated to determine the extent of maximal diaphragm shortening shortly after surgical manipulation identical to that used in the other six dogs. The cervical roots comprising the phrenic nerve (C5–7) were identified and isolated on both sides of the neck. Insulated hook electrodes were placed under the nerve roots and covered with mineral oil. The phrenic nerves were stimulated with 50 Hz using a Grass S88 nerve stimulator. Diaphragmatic shortening was measured during three consecutive phrenic nerve stimulations.

The projection of each marker in the two orthogonal fluoroscopic images was identified by an operator-interactive computer program. A cursor was moved in regular numerical order along the rows of markers on both views of the same video frame. Once the geometric coordinates of all the parenchymal markers in the first frame had been entered, at FRC, the same sequence was repeated at the end of inspiration. The distance between individual markers was computed from the three-dimensional spatial coordinates of each marker using solid geometry. The regional diaphragm length was calculated as the sum of individual intermarker lengths. Regional diaphragm shortening was expressed as relative changes in length at end-inspiration from the length at FRC (resting length). "Average" diaphragm shortening was calculated by finding the mean shortening of the four regions in each dog and then finding the average of this mean in the six dogs.

The biplane videoroentgenography technique does not allow preoperative control values to be established, because the diaphragm markers require surgical placement. However, in a previous long-term study in dogs (12), diaphragm regional length and shortening 2 mo postoperatively were similar to that 30 days after surgery, indicating that 30 days after UAS, diaphragm function has recovered to its preoperative baseline level. Because there were no significant differences among regional diaphragm shortening or lengths on POD 15 and 30 in this study, we assume that recovery was achieved by POD 15.

All data are presented as mean and SEM. One-way analysis of variance for repeated measures was used for all paired comparisons for each variable. The Fisher Least Square Difference test was used to compare the statistical significance between repeated measurements. A level of $P < 0.05$ was considered statistically significant.

Results

Mean respiratory frequency immediately postoperatively was 7.5 ± 1.5 breaths/min, less frequent ($P < 0.05$) than on POD 30 (16.9 ± 5.8 breaths/min). Tidal volumes gradually increased from 135 ± 31 mL on OD to 160 ± 33, 235 ± 43, and 240 ± 46 mL on POD 3, 15, and 30, respectively. Significant differences ($P < 0.05$) in tidal volume were found between OD and all other days and among POD 3, 15, and 30.

The regional diaphragm lengths and FRC after UAS are shown in Figure 2. The FRC was lower on OD compared with POD 3, 15, and 30 ($P < 0.05$). Although there was a trend for FRC to further increase after POD 3, this increase was not statistically significant. Immediately postoperatively, all diaphragm regions were longer than on POD 30 ($P < 0.05$). The average length of the four diaphragm regions on OD was 8.3% ± 0.8% longer than on POD 30 (range 7%–11%). Diaphragm resting lengths in the postoperative period were inversely correlated with FRC. The correlation coefficients between FRC and the diaphragm lengths were as follows: $r = -0.98$ for the ventral and middle, -0.92 for the dorsal, and -0.97 for the crural portions.

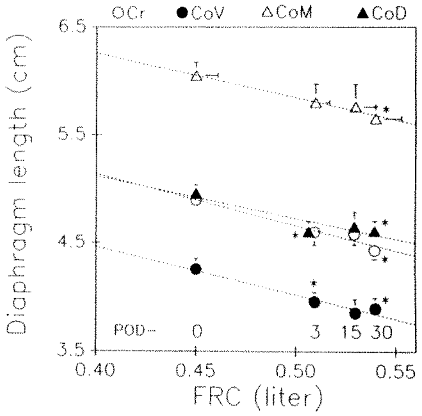

Figure 2. Resting diaphragm lengths at functional residual capacity (FRC) and corresponding FRC after upper abdominal surgery; linear regressions are indicated by *dashed lines*. The FRC was significantly lower on the day of surgery compared with postoperative days (POD) 3, 15, and 30. POD 0 and 30, $n = 6$; POD 3 and 15, $n = 4$. *Difference from POD 0 ($P < 0.05$). SEM indicated by *vertical and horizontal bars*. Other abbreviations as in Figure 1.

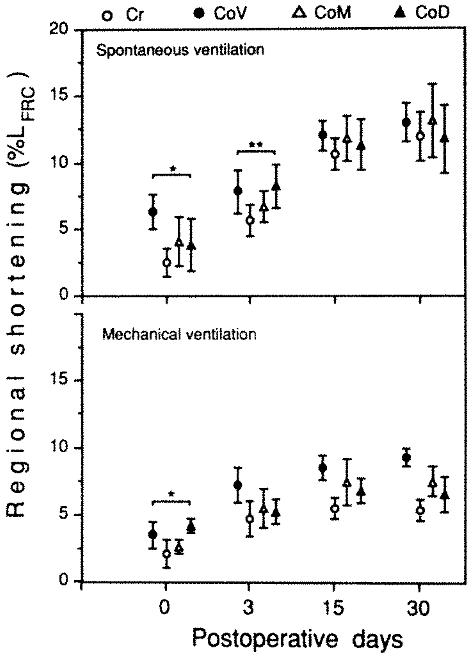

Figure 3. Regional diaphragmatic shortening, expressed as percent resting length at functional residual capacity (%L_{FRC}), during spontaneous and mechanical ventilation after upper abdominal surgery. SEM indicated by *vertical bars*. Postoperative days 0 and 30, $n = 6$; postoperative days 3 and 15, $n = 4$. *Difference in average tidal breath shortening from postoperative days 3, 15, and 30 ($P < 0.05$). **Difference in average tidal breath shortening from postoperative days 15 and 30 ($P < 0.05$). Other abbreviations as in Figure 1.

Figure 3 shows regional diaphragmatic shortening during spontaneous and mechanical ventilation. "Average" diaphragmatic shortening during spontaneous breathing was decreased ($P < 0.05$) in the immediate postoperative period compared with

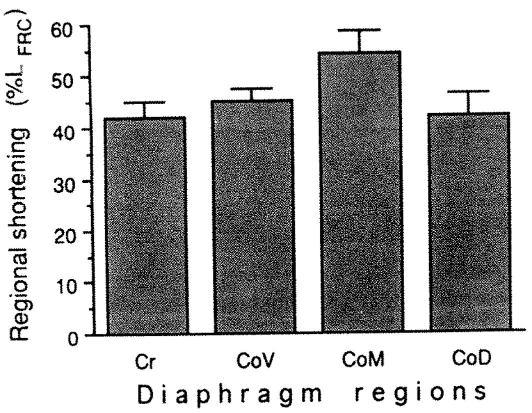

Figure 4. Regional diaphragmatic shortening during bilateral phrenic nerve stimulation in four dogs, expressed as percent resting length at functional residual capacity ($\%L_{FRC}$). SEM indicated by *vertical bars*. Other abbreviations as in Figure 1.

PODs 15 and 30. Over the first 15 PODs, the diaphragmatic shortening gradually increased, and by POD 15 the diaphragmatic shortening was comparable to POD 30 ($P > 0.05$). Diaphragmatic shortening during mechanical ventilation was decreased on OD compared with PODs 3, 15, and 30 ($P < 0.05$). The ratio of the average shortening in the four diaphragm regions to tidal volume increased during spontaneous ventilation from 31% ± 3% per liter on OD to 49% ± 2% per liter on POD 30. During mechanical ventilation, the ratio increased from 23% ± 3% per liter on OD to 32% ± 3% per liter on POD 30. Figure 4 shows regional diaphragmatic shortening after phrenic nerve stimulation in four dogs. All regions shortened at least 42% after the stimulation.

Discussion

Biplane videoroentgenography necessitates the use of anesthetized animals because any gross body movement may result in erroneous measurement. However, barbiturate anesthesia does not affect FRC in supine dogs (13), and the changes in FRC displayed by the anesthetized dogs in our study were similar to those seen in most patients after UAS (3). In contrast, in awake animals FRC does not seem to change after UAS, as inferred from only small, inconsistent changes in resting diaphragm lengths (8,11). Thus, the anesthetized dog seems a fitting model for the clinical situation. It is also probable that the prolonged period of anesthesia and surgical trauma on the day of marker implantation in the dogs is roughly comparable to those encountered in many abdominal surgeries, because one could expect wide variabilities in patient response to anesthesia and in difficulty of surgery. It is unlikely that the presence of the marker beads on the diaphragm exerted effects on afferent stimulation independent of the surgery, because extreme care was taken during surgical implantation, and the markers were sutured to the serosa of the diaphragm undersurface, thus sparing muscle bundles. In summary, the protocol used in the present study offers some advantages over other animal studies, and the results should be reasonably applicable to the clinical situation.

According to Craig (3), during POD 1 after UAS, the FRC decreases up to 30% and gradually returns toward normal over 7–10 days. This change in FRC is probably not immediate, because Dureuil et al. (2) did not find significantly reduced FRC 4 h after cholecystectomy. We found a distinct decrease in FRC 4–8 h after UAS that gradually recovered by POD 15. In our study, the regional diaphragm length at FRC was inversely related to FRC and decreased relatively uniformly throughout the recovery period. In contrast, Torres et al. (8) found that after laparotomy in awake sheep, costal resting length was decreased 17% ($P < 0.01$) on POD 1 compared with POD 7, whereas the crural resting length remained unchanged throughout the recovery. Easton et al. (11) found different trends in awake, resting dogs: costal resting length at FRC increased 1.56 mm, whereas crural length decreased 1.93 mm, both approximately 11% compared with recovery. However, these length changes were not significant. The videoroentgenography technique allows us to measure length change of a relatively large diaphragm segment (4–6 cm) compared with the small segment (1–1.5 cm) measured with sonomicrometry. In our previous study (12), as well as in this one, we found that there were significant differences in intraregional fractional shortenings and that no single location was representative of the shortening of the entire diaphragm. This is in contrast to the report of uniform shortening across the diaphragm segment (14). Videoroentgenography, which measures the length of the entire diaphragm region by summing all intraregional separations between markers, should give a more accurate estimate of global regional diaphragm behavior than sonomicrometry. However, because the studies using sonomicrometry (8,11) did not measure FRC, it is not possible to decide whether discrepancies among resting lengths in their and our experiments were due solely to limitations of sonomicrometry technique or additionally due to species differences and protocol.

The decreased FRC and increased diaphragm length after upper abdominal surgery may be at least partly due to activation of expiratory muscles. Duggan and Drummon (15) reported increased expiratory activation of the abdominal external oblique muscle in humans after cholecystectomy. Farkas and De Troyer (16) found that expiratory activation of the triangularis sterni muscle was maintained or increased after laparotomy in dogs. Activation of expiratory muscles may cause cephalad displacement of the diaphragm. The cephalad diaphragm displacement will result in decreased FRC and elongated crural and costal diaphragm parts (17). Whether other factors also contribute to the decrease in FRC after UAS is not clear.

Although some workers have suggested that mechanical diaphragm dysfunction due to local irritation, inflammation, or trauma secondary to UAS may be responsible for alteration in contractile properties of the diaphragm (1,5), recent evidence suggests that decreased respiratory drive due to afferent inhibitory traffic is primarily involved (7,8,18). Immediately postoperatively, the dogs in our study displayed much lower minute ventilation (owing to reduction of both tidal volume and respiratory frequency) than on POD 30, which suggests a centrally mediated mechanism of respiratory dysfunction. In addition, evidence from our results is consistent with the conclusion that respiratory dysfunction is not primarily due to mechanical impairment of the diaphragm. First, regional shortening to phrenic nerve stimulation on OD was at least 42% in each region of the diaphragm. The shortening that we found is in a range similar to that described in dogs or sheep during phrenic stimulation after recovery from surgery (8,11). This indicates that our method, which uses implantation of up to 18 markers on the diaphragm undersurface, did not physically impair diaphragmatic ability to contract. Second, during both spontaneous and mechanical ventilation, the ratio of average regional shortening to tidal volume was less on OD than on POD 30. One might expect that the ratio would be increased if a given amount of diaphragmatic shortening was less effective in increasing lung volume. It is possible, but unlikely, that an extremely abnormal pattern of respiratory muscle activation could cause such a change during spontaneous breathing; however, this might not be the case during mechanical ventilation. Rather, passive changes in chest wall mechanics, such as the observed decrease in FRC, and the likely decrease in abdominal compliance (15) probably affected the ratio. In any case, the results indicate no gross mechanical dysfunction of the diaphragm.

There is evidence that increased diaphragmatic stretch, as observed in the present study, could lead to decreased respiratory drive. Cheeseman and Revelette (9) demonstrated that an increase in diaphragmatic operating length decreases phrenic nerve efferent drive, an effect abolished after bilateral cervical dorsal root transection. The increase in diaphragm length tested was approximately 17%, measured with sonomicrometry. It is difficult to directly compare localized sonomicrometric measurements with our more global measurements. However, the range of immediate postoperative stretch in our study was only slightly less, between 7% and 11%, and it is likely that increased diaphragmatic stretch activated inhibitory diaphragmatic afferents. Such a conclusion is consistent with the report by Jammes et al. (19) that muscle spindle and Golgi tendon organ receptors in the diaphragm reflexly inhibited phrenic motor output through phrenic afferents. It should be mentioned that in addition to afferent inhibition from the diaphragm, afferents from other sources could be involved. For example, it has been demonstrated that intercostal and abdominal muscle proprioceptors (20), afferents from the gallbladder (21), and cutaneous afferents in an area of the chest wall where the diaphragm inserts on the ribs (22) could decrease respiratory drive. However, epidural block with local anesthetic up to the T4 level only partially reversed respiratory dysfunction after UAS (17), whereas epidural analgesia had no effect (5,23). Because suppression of vagal inputs and spinal afferents below C8 does not prevent the inhibition of phrenic motoneuron activity due to stimulation of phrenic afferents (19), it is probable that a phrenic-phrenic reflex is involved with inhibition of breathing after UAS.

In conclusion, decreased central respiratory drive after UAS could be due in part to reflex inhibition originating in receptors in the stretched diaphragm, such as Golgi tendon organs.

The authors are indebted to Dr. Claude Deschamps, who performed the surgery in the dogs.

Ethanol Monitoring of Transurethral Prostatic Resection During Inhaled Anesthesia

Holger P. Stalberg, MD, Robert G. Hahn, MD, PhD, and A. Wayne Jones, PhD

Department of Anesthesiology, Huddinge University Hospital, Huddinge, and Department of Alcohol Toxicology, National Laboratory of Forensic Chemistry, Linköping, Sweden

The purpose of this study was to examine the precision of a method of breath-alcohol analysis used to monitor absorption of irrigating fluid during transurethral resection of the prostate performed under inhaled anesthesia. A breath-alcohol analyzer (Alcolmeter SD-2) was placed between the endotracheal tube and the Bains' circuit. The concentration of ethanol in the breath, serum sodium concentration, and volumetric fluid balance were measured at 10-min intervals during 38 operations when the irrigating fluid contained 1.5% glycine and 1% ethanol. Ethanol monitoring detected absorption rates that exceeded 14 ± 8 mL/min (mean ± SD). In 17 patients in whom hyponatremia developed immediately in connection with absorption, the volume of irrigating fluid absorbed (up to 1950 mL) could be predicted from a single expired-breath test with a standard error of 325 mL. When the alcohol measurements were corrected for absorption time, the standard error was 215 mL. Seven other patients received 2.2% wt/vol glycine as irrigating fluid, and ethanol (0.35 g/kg) was administered by intravenous infusion. The direct and indirect measurements of the blood-alcohol concentration agreed well. These results confirm that ethanol monitoring is a viable technique during inhaled anesthesia for transurethral resection of the prostate.

(Anesth Analg 1992;75:983–8)

Transurethral resection of the prostate (TURP) is usually performed under regional anesthesia. In 5%–10% of patients, symptoms associated with absorption of irrigating fluid occur that may develop into the potentially life-threatening "TUR syndrome" (1–3). The use of irrigating fluid containing a trace amount of ethanol and the subsequent measurement of ethanol in the patient's exhaled breath (EB) is a reliable, noninvasive method to detect absorption of irrigating fluid (1–5).

The aim of the present study was to evaluate the precision of ethanol monitoring in patients undergoing TURP performed under inhaled anesthesia. We measured the volumetric fluid balance and the serum sodium concentrations during 38 TURPs. The results were compared with the ethanol in EB (EB-ethanol) concentration, which was measured by an Alcolmeter device that was connected between the endotracheal tube and the breathing circuit. Furthermore, the accuracy of the EB measurements in patients under general anesthesia was examined by comparing the concentration-time profiles of ethanol in venous blood and breath in seven patients who received an intravenous infusion of ethanol.

Methods

We studied 45 patients (mean age 69 yr, range 43–87; mean body weight 79 kg, range 60–103) who underwent TURP for benign prostatic hypertrophy. All of the patients gave informed consent to participate, and the study protocol was approved by the Ethics Committee of the Huddinge University Hospital.

Oxycodone (2.5–12.5 mg) and scopolamine (0.1–0.5 mg) ($n = 40$) or meperidine (50 mg) ($n = 5$) were administered intramuscularly 30 min before arrival in the operating room. Anesthesia was induced with thiopental (2.5–5 mg/kg IV) and fentanyl (0.1 mg IV). Tracheal intubation was facilitated with succinylcholine (1 mg/kg), sometimes preceded by pancuronium (1 mg) or atracurium (5 mg). Anesthesia was maintained with a 6–8-L/min fresh gas mixture of nitrous oxide/oxygen (70%:30%) and 0.5%–1.5% of inspired enflurane ($n = 42$) or isoflurane (0.5%–1.0%) ($n = 3$) provided through a Bains' circuit. Ventilation was controlled, and electrocardiography was monitored continuously. Ringer's acetate solution (sodium 130 mmol/L, potassium 4 mmol/L) was administered

by intravenous infusion at a rate of 50–150 mL over 10 min during TURP, depending on the amount of blood lost. In six patients, where blood loss exceeded 500 mL, 500 mL of dextran 70 in normal saline was also administered.

The EB-ethanol concentration was measured every 5 min during the operation by an a fuel cell-type alcohol sensor (Alcolmeter S-D2, Lion Laboratories Ltd., South Glamorgan, Wales). The presumed venous blood alcohol concentration was estimated based on a calibration factor of 2300:1 for the blood/breath ratio of ethanol. The Alcolmeter device was calibrated using alcohol-in-air gas standards at 0.80 mg/mL equivalent blood alcohol, and readings could be taken to within 0.05 mg/mL. A 2-mm hole was drilled in a Capnomac straight T-adapter (Datex, Helsinki, Finland), which was placed between the endotracheal tube and the ventilation system (Bains' circuit). The inlet to the Alcolmeter device was directly connected to the hole in the T-piece and positioned on the patient's forehead, as shown in Figure 1. Before an EB sample was taken, a triple tidal volume was inflated, and the EB-ethanol concentration was measured at the end of the passive expiration. Preliminary experiments showed that the Alcolmeter readings were not affected by nitrous oxide, isoflurane, or efrane.

In 38 of the patients, a solution of 1.5% glycine and 1% ethanol was used to irrigate the bladder. Blood loss and volumetric fluid balance were measured every 10 min during TURP, always at the same time that a breath sample was analyzed. The irrigating fluid bags were weighed to the nearest gram before and after use. Approximately 1000 IU of heparin was added to each collecting bucket to prevent clotting. Special care was taken to avoid spillage of irrigating fluid on the floor. At the end of each 10-min period of each operation, the bladder was emptied, and the irrigating fluid bag and the collecting bucket were changed. The irrigating fluid returns were measured to the nearest 20 mL. Blood loss was calculated as the product of the volume of the irrigating fluid used and the hemoglobin concentration, which was measured with the HemoCue system (HemoCue AB, Ängelholm, Sweden), divided by the existing blood hemoglobin concentration (6). The accuracy of the blood loss measurement was 98%–102%, and the coefficient of variation was <5%, as determined by dispersion of known amounts of blood into irrigating fluid. The volumetric fluid balance was calculated as the difference between irrigating fluid input and output after correction for blood loss (the weight and volume measurements gave the same results) (7).

The blood-hemoglobin concentration, serum sodium (S-Na) and serum potassium (S-K) concentrations, and serum osmolality (S-osmolality) were measured at the end of each 10-min period during TURP, at exactly the same time that a breath sample was taken. The blood-hemoglobin concentration was measured in a Coulter Counter S Plus (Counter Electronics). The S-Na and S-K were analyzed on a Hitachi 737 Automatic Analyser (Hitachi Ltd., Tokyo, Japan). The S-osmolality was determined by freezing-point depression. The coefficients of variation for these analyses were 1.0%, 1.0%, 1.5%, and 1.0%, respectively. Blood-ethanol concentration was analyzed with a Perkin-Elmer headspace gas chromatograph (Perkin-Elmer Corp.), with a standard deviation of 0.01 mg/mL at a mean blood-ethanol concentration of 1.0 mg/mL.

In seven patients, the irrigating fluid consisted of 2.2% glycine in water (without ethanol). A venous cannula was placed in the antecubital vein of both arms. One cannula was used for blood sampling and the other for infusion. When the operation was completed, an intravenous infusion of 0.35 g/kg of ethanol was administered over 20 min. The ethanol was administered as a solution containing 5% glucose and 10% ethanol, using an IVAC 560 infusion pump (IVAC, San Diego, Calif.). Concentrations of ethanol in venous blood and the EB-ethanol concentration were determined at exactly timed 5-min intervals immediately before the infusion started and up to 30 min after it was completed.

The results are presented as mean ± SD or, in the case of skewed distribution, as median and range. Simple and multiple linear regression analysis, repeated measures analysis of variance, the F-test, and the paired Student's *t*-test were used for statistical analysis.

Results

The volumetric fluid balance indicated that irrigating fluid was absorbed in 37 of the 38 patients. Ethanol

was detected in the 23 patients with the largest absorption (in 126 of 324 tests of EB).

A comparison between the volumetric fluid balance and EB-ethanol concentration indicated that the lower limit for detection of irrigating fluid absorption with the Alcolmeter was 14 ± 8 mL/min. Patients with absorption below the limit of detection for the ethanol-monitoring method had a coefficient of variation of 0.4% ± 0.2% for S-Na and 0.7% ± 0.3% for S-osmolality. Thus, the baseline for these variables was stable for the 10-min periods when ethanol monitoring indicated that absorption had not taken place.

In 17 patients, there was an increase in the EB-ethanol accompanied by a significant decrease in the S-Na concentration (≥ 2 mmol/L) during the same 10-min period that the volumetric fluid balance indicated that irrigating fluid was being absorbed (Table 1). We interpreted this to indicate that irrigating fluid had been absorbed by the intravascular route (2,4). Figure 2 shows the data obtained in one patient with the intravascular pattern of changes in irrigating fluid absorption. Figure 3A shows the relationship between the EB-ethanol concentration recorded at the end of any 10-min period for all 17 operations and the cumulative volumetric balance during the period of intravascular absorption up to that time. A useful regression equation for estimating the volume of irrigating fluid absorbed from a single measurement of EB-ethanol concentration during TURP (ranging between 0.05 and 0.65 mg/mL) can be obtained by switching the x- and y-axes in Figure 3A, which then yields the following equation:

$$\text{Absorption (mL)} = 2900\ \text{EB-ethanol (mg/mL)}, \qquad (r = 0.71;\ P < 0.001), \quad (1)$$

where EB-ethanol is the concentration of ethanol in exhaled breath.

Figure 3B shows that the prediction of the cumulative absorption from the EB test had a higher precision if EB-ethanol concentration was corrected for absorption time (i.e., the time during which ethanol had been detected in the EB up to that particular measurement of EB-ethanol concentration) (2,4). The correction factor was 0.00864 $\text{mg}\cdot\text{mL}^{-1}\cdot\text{min}^{-1}$, which was obtained from a multiple regression equation relating the cumulative absorption, the EB-ethanol concentration, and the absorption time (mean 24 min; range 10–60) at the end of each 10-min period of TURP. By switching the y- and x-axes in Figure 3B, we obtain the following equation:

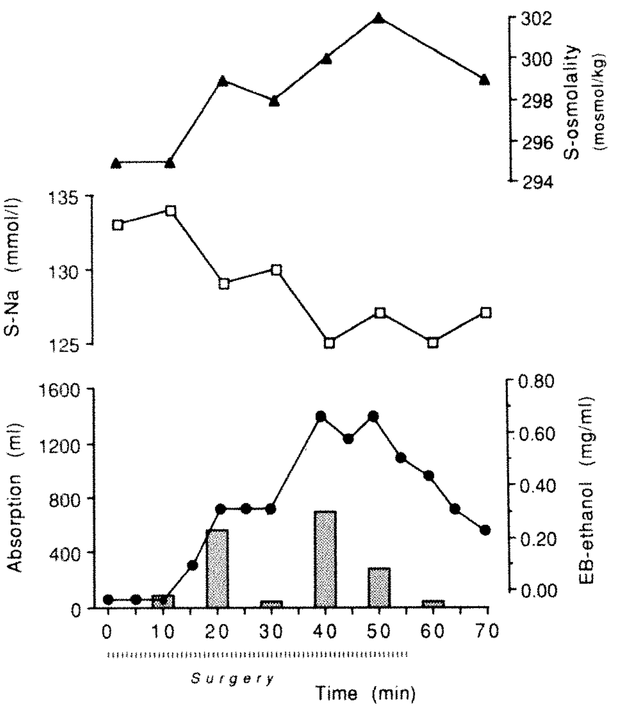

Figure 2. Volume of irrigating fluid absorbed (*bars*), ethanol concentration in expired breath (EB-ethanol), serum osmolality (S-osmolality), and serum sodium concentration (S-Na) measured in one patient with intravascular absorption during transurethral resection of the prostate.

$$\text{Absorption (mL)} = 1828\ \text{EB-ethanol} + 15.8\ t\ (\text{min}) - 81, \qquad (r = 0.89;\ P < 0.001), \quad (2)$$

where t is time. The standard error of an estimate of fluid absorption using Equation (1) was 325 mL; it was 215 mL when using Equation (2) ($P < 0.05$; F-test).

In patients with intravascular absorption, the relationship between the EB-ethanol concentration and the cumulative change in S-Na concentration (maximum −13 mmol/L) up to the end of any 10-min period of TURP was expressed by the following equation:

$$\Delta\text{S-Na (mmol/L)} = 18.1\ \text{EB-ethanol}, \qquad (r = 0.73;\ P < 0.001). \quad (3)$$

The standard error estimate was 2.0 mmol/L. There was an increase in S-osmolality in connection with the largest absorptions (5–10 mOsm/kg when the absorption rate was 50–100 mL/min) (Figure 2).

In five patients, there was only a small increase in EB-ethanol concentration and no significant change in S-Na concentration or S-osmolality in response to irrigating fluid absorption. We interpreted this to indicate that irrigating fluid was absorbed by the extravascular route (2,4). Figure 4 shows the data obtained in one patient with the extravascular pattern of changes in irrigating fluid absorption.

In two patients, our method of analysis suggested that irrigating fluid was absorbed by both the intra-

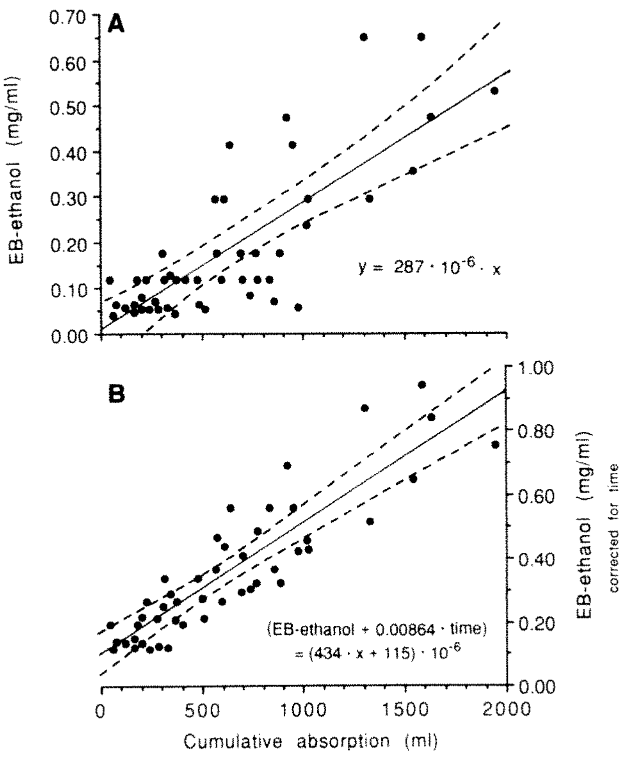

Figure 3. Relationship between the ethanol concentration in the expired breath (EB-ethanol) and the cumulative volumetric fluid balance at the end of all 10-min periods of TURP with intravascular absorption of irrigating fluid (**A**). The same relationship but with EB-ethanol corrected for the time required for absorption to occur (**B**). When absorption time was taken into account, the relationship was strengthened. *Dashed lines* indicate ±1 SD.

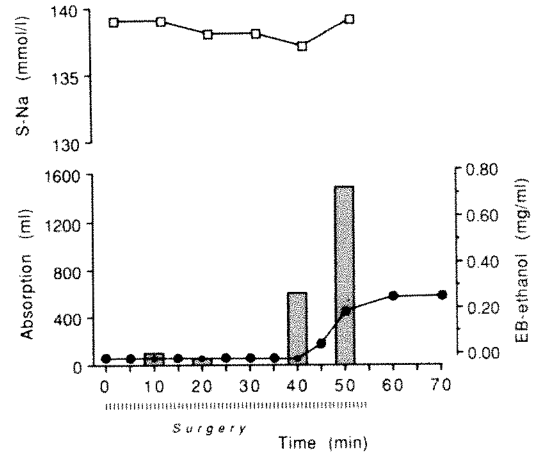

Figure 4. Volume of irrigating fluid absorbed (*bars*), ethanol concentration in the expired breath (EB-ethanol), and serum sodium concentration (S-Na) measured during TURP in one patient with extravascular absorption.

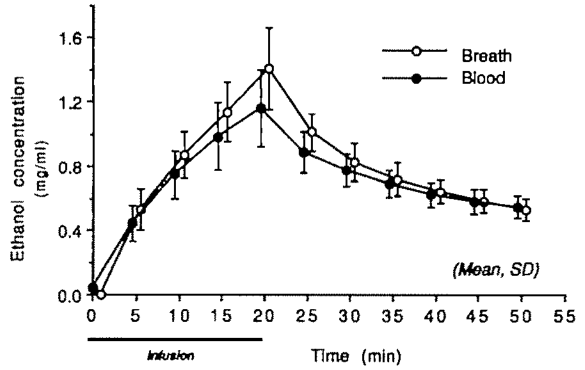

Figure 5. Ethanol concentration in the expired breath and in venous blood during and after an intravenous infusion of 5% glucose and 10% ethanol solution in seven patients.

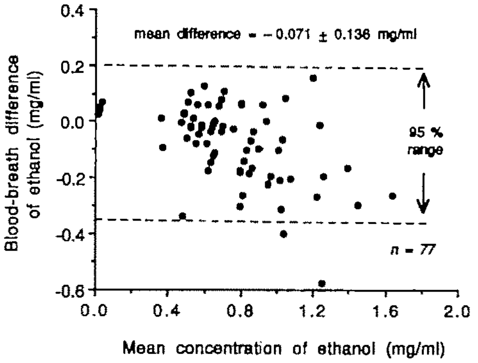

Figure 6. Difference between ethanol concentration in the expired breath and in venous blood in the experiments with intravenous infusion of 5% glucose and 10% ethanol solution in seven patients.

vascular and extravascular routes. However, this occurred during different time periods of each operation.

In 13 patients, the volumetric fluid balance showed that some absorption had taken place without being indicated by the EB test or by a significant decrease in the S-Na concentration ("unclassified absorption") (7). The median absorption rate during the absorption periods was 5 mL/min (range 0.5–18), and the total absorption in these patients was 124 mL (range 43–313). Only one of the 38 patients did not absorb irrigating fluid.

Figure 5 shows the concentration-time profiles of ethanol in venous blood measured both directly and indirectly by analysis of expired air. The average curves are in good agreement (two-factor repeated measures analysis of variance; $P = 0.35$), although the results derived by the analysis of expired air from the endotracheal tube were slightly higher (mean 11%) than the coexisting venous blood level. This difference was significant at 10 ($P < 0.04$), 20 ($P < 0.01$), and 25 min ($P < 0.05$) of the sampling period (paired t-test). The agreement between the blood-ethanol and EB-ethanol concentrations for each paired measurement is displayed in Figure 6.

Discussion

Ethanol monitoring can be used to detect irrigating fluid absorption in TURP surgery. The immediate result obtained from a breath-alcohol test allows early treatment to modify or interrupt absorption by altering the surgical procedure before symptoms ensue (3,8). However, this method was originally developed to monitor fluid absorption in awake patients. In the present study, we examined whether ethanol monitoring is reliable enough for clinical purposes in patients undergoing TURP during general anesthesia. There are two main reasons for suspecting a different accuracy and precision of ethanol monitoring in this situation. The ventilation/perfusion ratio is altered by general anesthesia (9), which may interfere with the blood/breath partition coefficient of ethanol. Moreover, the measurement of EB-ethanol may be influenced by the addition of fresh gas flow in close proximity to the connection between the endotracheal tube and the breathing circuit (Figure 1).

Our results show that the precision of ethanol monitoring in patients undergoing TURP during inhaled anesthesia is almost identical to that for awake patients (2). There was a linear correlation between the EB-ethanol concentration and absorption volumes up to 1950 mL at all times during TURP (Figure 3). The standard error estimate of the volume of irrigating fluid absorbed by the use of a single EB-ethanol concentration value was slightly >300 mL (Equation [1]). This error became significantly smaller by correcting EB-ethanol concentration for absorption time. The absorption time is important, because EB-ethanol concentration is appreciably higher during rapid absorption. This can be understood from the nonequilibrium of ethanol between central and peripheral compartments. Furthermore, the lowering effect of alcohol oxidation on EB-ethanol concentration is greater during prolonged absorption. Whereas Equation (1) reflects the average absorption time in the study, Equation (2) takes into account this variable for each prediction of fluid absorption. The EB-ethanol concentration attains a higher value when the absorption time is longer, according to a constant (correction factor) that carries both distributional and eliminational information for ethanol. The constant can be obtained directly from Equation (2) as 15.8 divided by 1828, which is 0.00864, or 1/116 $\text{mg}\cdot\text{mL}^{-1}\cdot\text{min}^{-1}$. In previous studies in awake patients, this constant was 1/117 (4) and 1/142 (2).

The measurements of ethanol concentration in breath and blood (Figure 5) and a comparison among

Equations (1)–(3) and the corresponding regression equations previously obtained in awake patients (2) suggest that the breath test regularly shows slightly higher values than expected during inhaled anesthesia. This can probably be explained by less reabsorption of alcohol in the oral cavity during expiration, because the endotracheal tube prevents contact between the alcohol and the mucosa.

Hultén et al. (5) have reported reasonably good correlation between EB-ethanol concentration and other methods of measuring absorption, but they did not reach a firm conclusion about the precision of ethanol monitoring in patients undergoing TURP with general anesthesia (5). These workers did not use inhaled anesthetics, which is the most common form of general anesthesia for TURP in our hospital.

The most common pattern of changes in connection with absorption consists of an increase in EB-ethanol concentration and a decrease in S-Na concentration within the same 10-min period that the absorption occurs. Such a rapid response suggests absorption through severed prostatic veins (intravascular absorption). In these patients, the S-Na level remained stable when absorption did not occur and during absorption it could be followed approximately through the EB-ethanol measurement (Equation [3]). A total absorption of 1 L (breath alcohol ≈0.25 mg/mL) should initiate prompt action to reduce further absorption, because this amount may result in mild symptoms of the "TUR syndrome" (2,3). Such actions include reduction of the fluid pressure, thorough hemostasis, or termination of the resection (3,5,8).

There are several other patterns of changes in EB-ethanol and S-Na concentrations after irrigating fluid absorption (Table 1), but only the extravascular type is of importance to the clinician (1). Ethanol monitoring does detect extravascular absorption, but the ethanol levels are lower and increase more slowly than when the same amount of irrigant is absorbed into the circulation. Furthermore, the maximal EB-ethanol level persists when absorption has stopped (Figure 4). The following test can usually determine whether the fluid enters the body by the intravascular or extravascular route. If ethanol is detected in the EB, the operation is stopped for 5 min, and one repeat analysis of the exhaled air is made. If absorption was intravascular, the second result will be less than the first but will remain unchanged or even be higher if absorption was extravascular (10).

In conclusion, we found that ethanol monitoring in tracheally intubated patients undergoing TURP during inhaled anesthesia is precise enough to allow detection of absorption of irrigating fluid in amounts that may be clinically important for the safety of the patient.

Nurse anesthetist Annika Nordin and Dr. Catherine Hannaford assisted in obtaining the data.

Tyraminelike Action of Succinylcholine in the Isolated, Blood-Perfused Canine Atrium

Kimiaki Saegusa, MD, Yasuyuki Furukawa, MD, Masayoshi Takeda, MD, and Shigetoshi Chiba, MD

Department of Pharmacology and the Third Department of Internal Medicine, Shinshu University School of Medicine, Matsumoto, Japan

---

The mechanisms of succinylcholine-induced cardiac effects have not been fully elucidated. Accordingly, we studied the effects of succinylcholine on atrial rate and contractile force in the isolated canine atrium perfused with donor blood. The sinus node artery was perfused with heparinized blood from the common carotid artery of the donor dog at a constant pressure of 100 mm Hg. When succinylcholine in a dose range of 30–1000 μg was injected directly into the sinus node artery of the isolated atrium, increases in atrial rate and contractile force were observed in a dose-related manner. The atrial rate and contractile force were increased to 10.5% ± 1.8% (mean ± SEM) and 56.8% ± 8.5% above the control values after the administration of 1000 μg of succinylcholine, respectively. After treatment with propranolol, the positive chronotropic and inotropic effects of succinylcholine and norepinephrine were significantly suppressed. Hexamethonium or tetrodotoxin pretreatment inhibited the cardiac effects of nicotine but did not modify the succinylcholine-induced cardiac effects. The succinylcholine-induced effects were significantly inhibited by treatment with imipramine, which also suppressed the tyramine-induced effects. We conclude that succinylcholine has cardioexcitatory properties mediated by release of catecholamine due to a tyraminelike action.

(Anesth Analg 1992;75:989–94)

Succinylcholine is a depolarizing muscle relaxant having both rapid onset and very short duration of action; however, there are many conflicting reports with reference to the effects of succinylcholine on the cardiovascular system. Clinically, hypertension and hypotension, tachycardia, and bradycardia are seen during continuous infusion or repeated intravenous injection of succinylcholine (1–3). In experimental studies, succinylcholine produces a dual cardiac action (i.e., a negative chronotropic effect at small doses and a positive one at large doses) in the isolated heart (4). Several mechanisms by which succinylcholine exerts its cardiac effects have been postulated: (a) blockade of cardiac synapses (5); (b) stimulation of the afferent vagal receptors (6); (c) stimulation of autonomic ganglia and mobilization of epinephrine (7); (d) stimulation of nicotinic receptors at the sympathetic nerve terminals (8); and (e) interaction with cholinergic receptors resulting in release of catecholamines (9).

In 1982, Yasuda et al. (10) found that 30–1000 μg of succinylcholine injected into the sinus node artery of the intact dog induced a transient dose-related positive chronotropic effect that was inhibited by pretreatment with reserpine or a β-adrenergic blocker, pindolol. From their findings, we presume that succinylcholine probably liberates a catecholamine by either a nicotinelike or tyraminelike action, because both actions are blocked by treatment with reserpine, which depletes a catecholamine from sympathetic nerve endings (11).

In the present study, we have observed the effects of succinylcholine on pacemaker activity and myocardial contractility in isolated, blood-perfused canine atrial preparations (12,13). Furthermore, to clarify the mechanism underlying succinylcholine-induced catecholamine release, we examined whether the cardiac responses to succinylcholine were modified by sympathetic blocking drugs (i.e., propranolol, hexamethonium [C6], tetrodotoxin [TTX], and imipramine). It is established that a nicotinelike effect is inhibited by C6 (12,14) or TTX (15,16), whereas a tyraminelike effect is suppressed by imipramine (17).

Methods

This study was approved by our institutional Animal Care and Use Committee. Twenty-eight donor dogs weighing 9–19 kg were anesthetized with 30 mg/kg of

intravenous pentobarbital and mechanically ventilated with an inspired O_2 concentration of 0.2. Heparin (500 *USP* U/kg IV) was administered at the beginning of the perfusion, and 200 *USP* U/kg was added at 1-h intervals. The systemic arterial blood pressure of the donor dog was measured from the cannulated right femoral artery with a pressure transducer, and heart rate was measured with a cardiotachograph triggered by the R wave of electrocardiographic lead II.

Isolated right atrial preparations were obtained from 28 other mongrel dogs weighing 7–16 kg and anesthetized with pentobarbital (30 mg/kg IV). After treatment with 200 *USP* U/kg of intravenous sodium heparin, the right atrium was excised and plunged into a cold Tyrode's solution at 4–10°C. The mean wet weight of the atrial preparation was 7.9 g ($n = 28$). The sinus node artery was cannulated via the right coronary artery and perfused with heparinized blood from the common carotid artery of the donor dog by means of a peristaltic pump (Harvard Apparatus, model 1210). A pneumatic resistance was placed in parallel with the perfusion system so that the perfusion pressure could be maintained constant at 100 mm Hg. Blood flow to the isolated atrium was 3–9 mL/min.

The ventricular margin of the isolated atrium was fixed to a stainless steel bar and placed in a cup-shaped glass container maintained at 37°C. The atrium was stretched to a resting tension of 2 g. The isometric tension was recorded on a thermowriting rectigraph (Nihon Kohden, WT 685G). A pair of silver electrodes, with an interelectrode distance of 1.5 mm, were brought into contact with the epicardial surface of the isolated atrium to record the electrogram. The atrial rate was derived from the atrial electrogram with a cardiotachometer. Details of this preparation have been described previously (12,13).

We performed two series of experiments. In the first series, we observed the effects of succinylcholine in doses ranging from 30 to 1000 μg on the sinoatrial pacemaker activity and atrial contractility in six isolated atria. In the second series, we examined whether the cardiac responses to succinylcholine at a dose of 1000 μg were modified by sympathetic blocking drugs: (a) a β-adrenergic blocker, propranolol, in five experiments using five isolated atria; (b) an antagonist of nicotinic receptors, C6, in four experiments using four isolated atria; (c) a fast, inward sodium channel blocker, TTX, in four experiments using four isolated atria; and (d) a neuronal uptake_1 blocker, imipramine, in five experiments using five isolated atrial preparations. Furthermore, we tested whether the cardiac responses to succinylcholine at the smallest dose of 30 μg were inhibited by propranolol or imipramine in two experiments using two isolated atria. To rule out a skew result, the order of drug injection was randomized.

The following drugs were used: succinylcholine chloride (Kyorin Pharmaceutical Co., Tokyo, Japan); *d,l*-norepinephrine hydrochloride (NE) (Sankyo, Tokyo, Japan); *d,l*-propranolol hydrochloride (Sigma Chemical Co., St. Louis, Mo.); nicotine (base) and hexamethonium bromide (C6) (Yamanouchi, Tokyo, Japan); tetrodotoxin (TTX) (Sankyo); tyramine hydrochloride (Wako Purechemical Industries, Osaka, Japan); and imipramine hydrochloride (Fujisawa, Osaka, Japan). Each drug was dissolved in physiologic saline solution before starting the experiment. Drugs were injected into the sinus node artery of the isolated atrium through a rubber tube with a microsyringe (Terumo Co.). The amount of drug solution injected with the microsyringe was 0.01–0.03 mL over a period of 4 s. There were no changes in atrial rate and contractile force when 0.01–0.03 mL of physiologic saline solution was injected into the sinus node artery over a period of 4 s.

Data are given as percentage changes in a maximal positive or negative direction. Data collected before and after treatment with a drug were analyzed by paired *t*-tests; $P < 0.05$ was accepted as indicating a significant difference.

Results

Effects of Succinylcholine on Sinoatrial Nodal Pacemaker Activity and Atrial Contractility

When succinylcholine in doses ranging from 30 to 1000 μg was injected directly into the cannulated sinus node artery of the isolated atrium, positive chronotropic and inotropic responses were induced in a dose-related manner. Figure 1 shows the dose-response curves for the chronotropic and inotropic responses to succinylcholine in six isolated atria. The threshold dose for inducing positive cardiac effects was 10–30 μg in the six preparations. A dose of 30 μg injected into the sinus node artery is considered to be comparable to that achieved at the level of the sinoatrial node after a standard clinical intravenous dose (10). Succinylcholine at a dose of 1000 μg produced conspicuous positive chronotropic and inotropic responses.

Effects of Propranolol on Positive Cardiac Responses to Succinylcholine

These experiments were carried out to confirm that the positive cardiac effects of succinylcholine were mediated through β-adrenergic receptor stimulation by release of norepinephrine from the sympathetic nerve endings. The positive chronotropic and inotro-

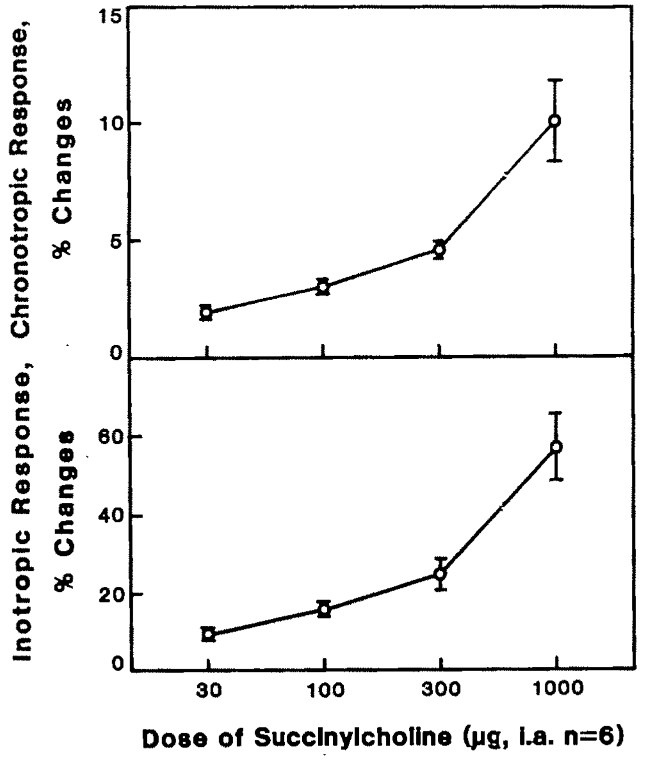

Figure 1. Dose-response curves as percentage changes in the maximal positive chronotropic (*upper panel*) and inotropic (*lower panel*) responses to succinylcholine. *Points* represent means and *vertical lines* show SEM. Baseline levels of atrial rate and contractile force in six isolated atria (i.a.) were 114 ± 6 (mean ± SEM) beats/min and 2.7 ± 0.3 g, respectively.

pic responses to succinylcholine were suppressed by pretreatment with a β-adrenoceptor blocker, propranolol, which markedly blunted norepinephrine-induced positive chronotropic and inotropic responses (Figure 2). Propranolol by itself caused negative cardiac effects. Each agonist was administered after atrial rate and contractility had reached steady state. The blocking effect of propranolol continued over 30 min. Data summarizing five experiments are shown in Figure 3. Propranolol (3 μg) significantly ($P < 0.01$) suppressed the positive chronotropic and inotropic responses to 1000 μg of succinylcholine and 0.03 μg of norepinephrine. The same dose of propranolol completely inhibited the positive chronotropic and inotropic responses to succinylcholine at the lowest dose of 30 μg in two experiments (data not shown).

Effects of Hexamethonium and Tetrodotoxin on Positive Cardiac Responses to Succinylcholine

We tried to elucidate whether succinylcholine-induced norepinephrine release was attributed to a nicotinic action. Nicotine (3 μg) produced negative chronotropic and inotropic responses (13.0% ± 3.1% and 56.7% ± 12.2% decrease, respectively), followed quickly by positive chronotropic and inotropic responses (36.4% ± 10.0% and 157.1% ± 38.3% increase, respectively) in four isolated atria. The duration of action of nicotine was from 1 to 2 min. At a dose of 300 μg, C6 significantly ($P < 0.05$) inhibited the responses to nicotine; that is, after C6 treatment, nicotine (3 μg) induced negative chronotropic and inotropic responses (1.8% ± 0.5% and 4.8% ± 1.7% decrease, respectively), followed by positive chronotropic and inotropic responses (1.9% ± 0.8% and 16.8% ± 8.1% increase, respectively) in the four isolated atria. With the same dose, C6 did not modify the responses to succinylcholine; that is, 1000 μg of succinylcholine produced positive chronotropic and inotropic responses (6.3% ± 1.1% and 61.5% ± 14.1% increase; $n = 4$) before C6 and (6.7% ± 1.2% and 59.7% ± 15.7% increase; $n = 4$) after C6, respectively. After 3 μg of TTX, the responses to nicotine were also significantly ($P < 0.05$) suppressed: nicotine (3 μg) produced negative chronotropic and inotropic responses (31.5% ± 9.6% and 41.6% ± 13.4% decrease; $n = 4$), followed by positive chronotropic and inotropic responses (18.0% ± 3.0% and 143.0% ± 34.3% increase; $n = 4$) before TTX and 4.1% ± 2.8% and 12.1% ± 5.4% decrease ($n = 4$), followed by 1.7% ± 0.4% and 17.5% ± 5.5% increase ($n = 4$) after TTX, respectively. On the other hand, succinylcholine-induced responses were not affected by 3 μg of TTX: 1000 μg of succinylcholine induced positive chronotropic and inotropic responses (5.2% ± 0.9% and 78.4% ± 10.5% increase; $n = 4$) before TTX and (5.2% ± 0.5% and 80.3% ± 12.7% increase; $n = 4$) after TTX, respectively.

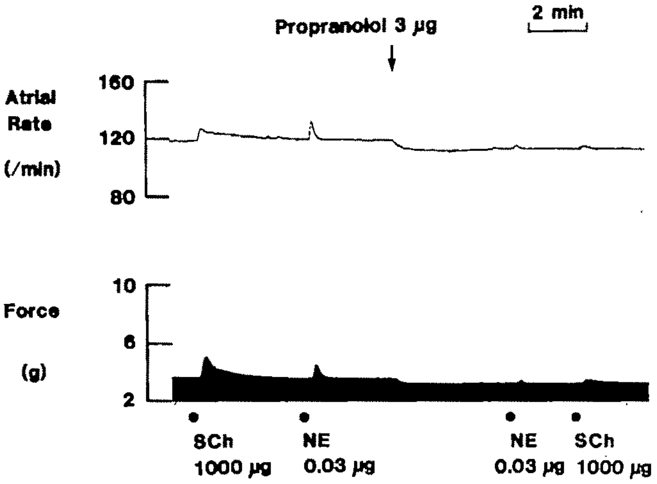

Figure 2. Effects of propranolol on responses of atrial rate and contractile force to succinylcholine (SCh) and norepinephrine (NE) in an isolated, blood-perfused canine atrium.

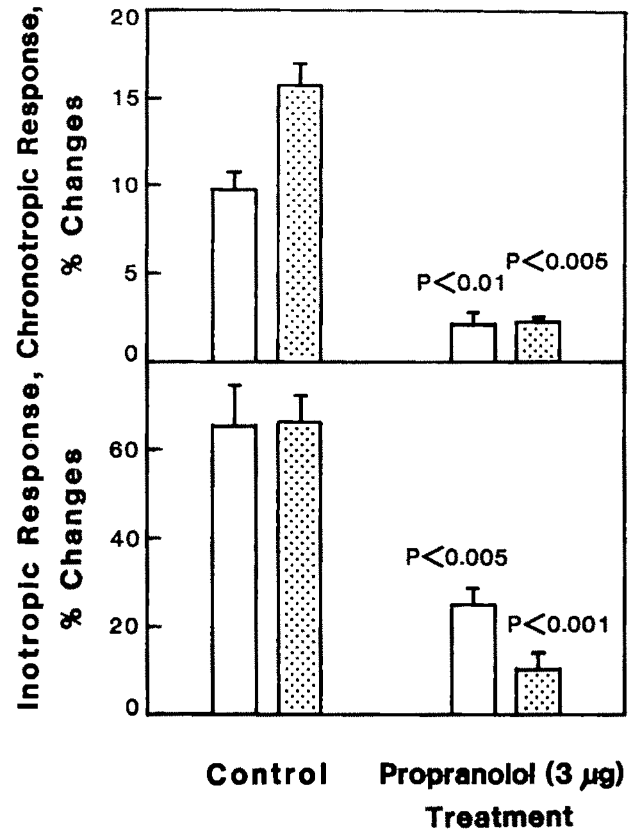

Figure 3. Effects of 3 μg of propranolol on the percentage changes in chronotropic and inotropic responses to 1000 μg of succinylcholine (SCh, *open bars*) and 0.03 μg of norepinephrine (NE, *stippled bars*) in five isolated atria. *Vertical lines* show SEM. Comparisons are with control values (paired *t*-test). Baseline levels of atrial rate and contractile force in five atria were 113 ± 7 beats/min (mean ± SEM) and 2.4 ± 0.4 g, respectively.

Effects of Imipramine on Positive Cardiac Responses to Succinylcholine

We attempted to determine whether succinylcholine-induced norepinephrine release was due to a tyraminelike action. Figure 4 shows typical effects of imipramine, a drug that inhibits the neuronal uptake$_1$ mechanism, on responses to succinylcholine, tyramine, and norepinephrine. Imipramine by itself induced negative chronotropic and inotropic effects followed by positive effects. The effects of each agonist were examined in the subsequent steady state. The positive chronotropic and inotropic responses to succinylcholine and tyramine were suppressed by treatment with imipramine, whereas the positive responses to norepinephrine were enhanced but not significantly. The results of these five experiments are summarized in Figure 5. Imipramine (300 μg) significantly ($P <$ 0.01) suppressed the positive chronotropic and inotropic responses to 1000 μg of succinylcholine and 3 μg of tyramine. Imipramine (300 μg), as well as propranolol, completely inhibited the positive responses to succinylcholine at the lowest dose of 30 μg in two experiments (data not shown).

Discussion

Many conflicting reports still exist concerning the cardiovascular effects of succinylcholine in laboratory animals and in humans. Beretervide (18) reported that intravenous injections of succinylcholine in conscious rabbits caused a decrease in arterial blood pressure and bradycardia at a relatively small dose and a large increase in arterial blood pressure at a large dose (0.4 mg/kg). Williams et al. (3) reported that hypertension and tachycardia after injections of succinylcholine occurred in patients anesthetized with several anesthetics, whereas bradycardia and prolonged asystole were induced by the administration of successive doses of succinylcholine in patients receiving cyclopropane or halothane. One year later, Galindo and Davis (19) described hypertension and tachycardia after administration of a large dose of succinylcholine in rhesus *Macacus* monkeys. More recently, Hannallah et al. (20) stated that intramuscular injections of succinylcholine showed a transient increase followed by a decrease in heart rate in children anesthetized with N_2O/O_2 and halothane. In isolated rabbit heart, succinylcholine produced a dual action (i.e., a negative chronotropic effect at small doses and a positive one at large doses) (4).

In the present study, succinylcholine injected directly into the sinus node artery of the isolated canine atrium had dose-related positive chronotropic and inotropic effects and did not have any negative effects. Schoenstadt and Whitcher (21) suggested that hexaflorenium slowed the hydrolysis of succinylcholine to succinylmonocholine and choline and prevented the succinylcholine-induced bradycardia. Succinylmonocholine causes a negative chronotropic effect attributed to a muscarinic action on the sinoatrial node (10,22). Therefore, bradycardia seen after succinylcholine administration may not be due to the action of succinylcholine itself but, rather, to that of its metabolic products.

Yasuda et al. (10) found that 30–1000 μg of succinylcholine injected into the sinus node artery of the intact dog caused a transient dose-related positive chronotropic effect that was suppressed by pretreatment with reserpine or a β-adrenergic blocker, pindolol. Their findings indicate that succinylcholine probably liberates a catecholamine by either a nicotinelike or tyraminelike action, because both actions are blocked by reserpine, which depletes catecholamine from sympathetic nerve endings (11). Accordingly, we attempted to determine which of these actions is responsible for the liberation of catecholamine after succinylcholine administration.

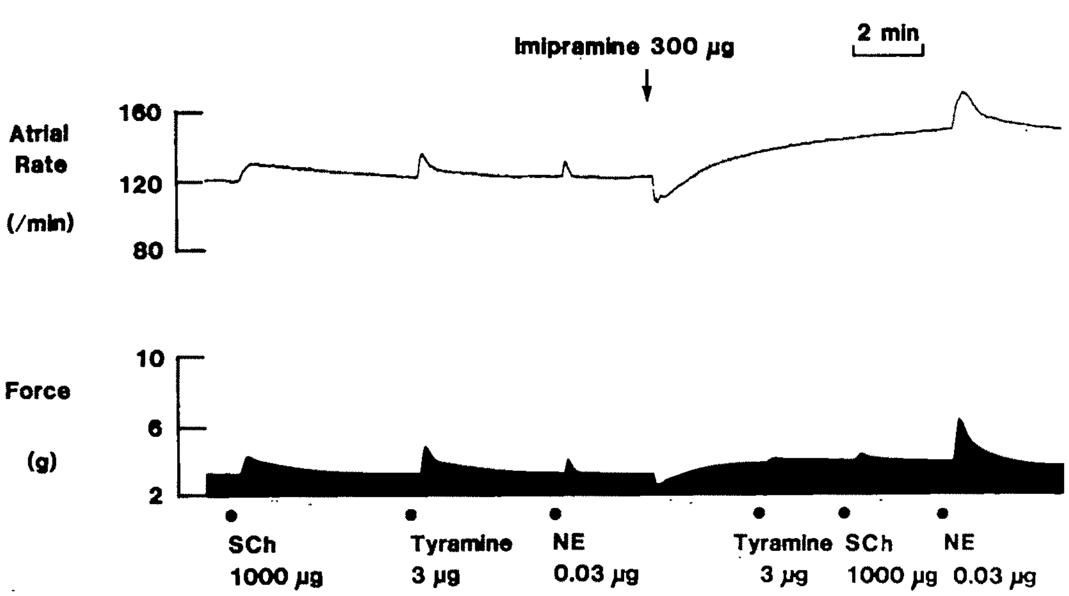

Figure 4. Effects of imipramine on atrial rate and contractile force responses to succinylcholine (SCh), tyramine, and norepinephrine (NE) in an isolated, blood-perfused canine atrium.

In 1983, Nigrovic et al. (8) reported that plasma norepinephrine levels increased significantly 2 min after the injection of succinylcholine in anesthetized and manually ventilated patients. They postulated that succinylcholine might stimulate nicotinic receptors on the postganglionic adrenergic nerve endings. Stimulation of nicotinic receptors in the sympathetic endings results in nerve excitation, which causes the liberation of norepinephrine. It is also an accepted fact that C6 blocks nicotinic receptors not only at parasympathetic ganglia but also at sympathetic nerve terminals (12,14). In our study, the negative chronotropic and inotropic responses followed by positive responses to nicotine were significantly inhibited by treatment with C6, whereas the responses to succinylcholine were not influenced by C6. The succinylcholine-induced responses were also not affected by use of TTX, which blocks nerve excitation in the autonomic nervous system (15,16). On the other hand, the cardiac responses to nicotine were suppressed by TTX. Moreover, we have observed no negative components in the cardiac responses to succinylcholine even after propranolol (Figures 2 and 3). Although a few investigators could not observe the biphasic cardiac responses after exposure of atria to nicotine (23–25), it consistently produces negative chronotropic and inotropic responses as well as positive ones in the isolated, blood-perfused canine atria, as reported previously (26–28). From these findings, the positive cardiac effects of succinylcholine are probably not due to a nicotinic action in the isolated atrium.

In this study, the tyramine-induced positive chronotropic and inotropic responses were significantly inhibited by treatment with imipramine, which po-

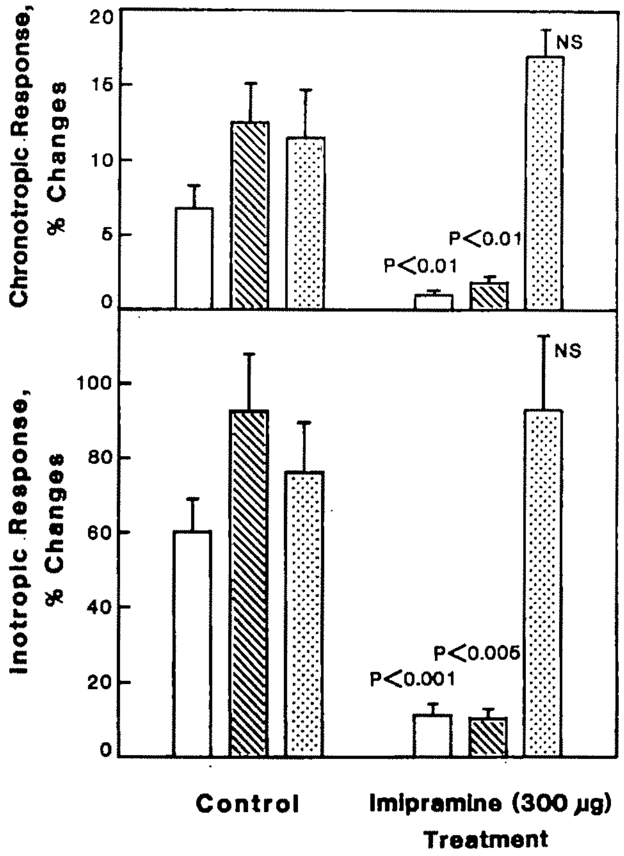

Figure 5. Effects of 300 µg of imipramine on the percentage changes in chronotropic and inotropic responses to 1000 µg of succinylcholine (SCh, *open bars*), 3 µg of tyramine (*hatched bars*), and 0.03 µg of norepinephrine (NE, *stippled bars*) in five isolated atria. *Vertical lines* show SEM. Comparisons are with control values (paired *t*-test); NS, no statistical significance ($P > 0.05$). Baseline levels of atrial rate and contractile force in five atria were 110 ± 7 beats/min (mean ± SEM) and 2.5 ± 0.3 g, respectively.

tently blocks the uptake$_1$ mechanism (17), but not the uptake$_2$ mechanism (29), in the adrenergic nerve terminals. It has been postulated that the norepinephrine efflux evoked by tyramine represents the final result of a number of processes, such as accumulation of tyramine by the uptake$_1$ mechanism, metabolism in the cytoplasm, vesicular uptake, conversion to octopamine and displacement of norepinephrine, outward transport of norepinephrine, and diffusion through the adventitia and media (30–32). Similar to those of tyramine, the succinylcholine-induced positive chronotropic and inotropic responses were significantly suppressed by imipramine. It is recognized that a nicotinelike action is susceptible to TTX but a tyraminelike action is resistant to TTX (33,34). Thus, we conclude that succinylcholine liberates catecholamine by a tyraminelike action.

The nicotinic action of succinylcholine, similar to that of acetylcholine, has been adequately described in previous reports (3,7,8,18,19); however, we demonstrated that the action of succinylcholine on the sympathetic nerve endings is similar to tyramine and different from nicotine in the isolated canine atrium.

We gratefully acknowledge Professor Akira Kotani and Doctor Kaori Sugimoto of the Department of Oral Surgery of Shinshu University for their kind advice, and Kyorin Pharmaceutical Co., Ltd., for their generous supply of succinylcholine.

Direct Measurement of Nitrous Oxide MAC and Neurologic Monitoring in Rats During Anesthesia Under Hyperbaric Conditions

Garfield B. Russell, MD, FRCPC, and John M. Graybeal, CRTT

Department of Anesthesia, Division of Respiratory and Intensive Care, The Milton S. Hershey Medical Center, The Pennsylvania State University College of Medicine, Hershey, Pennsylvania

The minimum alveolar concentration (MAC) of nitrous oxide necessary to prevent purposeful movement in rats has not been directly measured; rather, it has been extrapolated because the required partial pressure exceeds 760 mm Hg, or 1 atm absolute pressure (ATA). Values reported have ranged from 1.36 to 2.20 ATA (136–220 vol%, or 1034–1672 mm Hg). By maintaining general anesthesia at 2.25 ATA (1710 mm Hg), we directly measured the nitrous oxide MAC in 17 Long-Evans rats during mechanical ventilation and monitoring of two-channel electroencephalogram, compressed spectral array and cortical evoked potentials, electrocardiograph, and respiratory and anesthetic gases by mass spectrometry. After a minimal stabilization period of 30 min during ventilation by 1.8 ATA nitrous oxide and 0.45 ATA oxygen, MAC measurements were begun. Each rat was given up to three noxious electrical stimulations of 50 V by 10-ms-duration pulses at 50/s for 45 s. The partial pressure of nitrous oxide was decreased by approximately 10% after each negative response. The MAC was taken as the nitrous oxide concentration midway between that at which there was no response and that at which the rat moved purposefully. The nitrous oxide MAC in Long-Evans rats was determined to be 1.55 ± 0.16 ATA (mean ± SD). Hyperbaric nitrous oxide decreased electroencephalogram wave frequency to a predominantly theta rhythm of increased amplitude. Cortical evoked potentials had decreased wave amplitudes and increased latencies with increasing partial pressures >0.75 ATA. General anesthesia with nitrous oxide at hyperbaric pressures allows direct measurement of the nitrous oxide MAC in rats and demonstrates neurophysiologic depressant effects on the electroencephalogram and somatosensory evoked potentials.

(Anesth Analg 1992;75:995–9)

The minimum alveolar concentration (MAC) of nitrous oxide (N_2O) necessary to prevent repetitive, purposeful movements in rats has not been directly measured. The N_2O MAC is a partial pressure value >760 mm Hg, or 1 atm absolute pressure (ATA); hyperbaric exposure is required for MAC measurement and to enable investigators to ventilate animals with high enough N_2O partial pressures to exceed MAC as well as prevent hypoxemia. Although the MAC of N_2O has been directly measured and reported to be 1.04 ATA in humans (1), the reported values for N_2O MAC in rats have been primarily extrapolated from the presumed linear additivity between N_2O and volatile anesthetics and the correlation of anesthetic potency with lipid solubility (2,3). Values reported have ranged from 1.36 to 2.20 ATA. However, nonlinear additivity of N_2O and other anesthetics has also been reported (3–5). Wardley-Smith and Halsey (6) found N_2O potency to be 1.48 ± 0.076 ATA (mean ± SD) in an unknown number of rats after 10-V electrical stimulation to the tail. Recent theories of anesthetic action have also postulated that there is anesthetic binding to specific membrane proteins (perhaps some degree of anesthetic-specific proteins) rather than disruption of cell membrane lipids (7). Although these theories may be formulative and not fully proved, the extrapolated values assigned to MAC based on lipid solubility or linear additivity because of the same mechanism of action in rats can be questioned. Because of the importance of knowing the true value for N_2O MAC in rats, in particular for experiments in which anesthetic potency and relative dosages of anesthetics are an important part of the protocol, we determined to

directly measure the MAC of N_2O in rats during general anesthesia in a hyperbaric chamber.

Methods

After approval by the Pennsylvania State University College of Medicine Animal Utilization Committee, we studied 17 Long-Evans rats of similar ages (~10 wk) and weights (370 ± 69 g) to directly measure the MAC of N_2O. All rats were fed a similar unrestricted diet of Purina Rat Chow. All studies were performed between 8 AM and 4 PM.

Anesthesia was induced in a 2-L plexiglass box with a total gas flow of 2 L/min of oxygen with 4.0% isoflurane. Each rat was orotracheally intubated and mechanically ventilated with a small-animal volume ventilator (Harvard Apparatus, Cambridge, Mass.) to mild hypocapnea. Each animal was monitored by compressed spectral array with two-channel electroencephalogram (EEG) and somatosensory cortical evoked potentials (Neurotrac, Interspec Medical, Conshohocken, Pa.), electrocardiograph, and respiratory gas measurements, including inspired oxygen, end-tidal carbon dioxide, N_2O, and isoflurane by a calibrated, accurate mass spectrometer (MGA 1100, Marquette Gas Monitoring Corp, St. Louis, Mo.) (8). Each animal was placed on a heating blanket for maintenance of body temperature stability. Temperature did not vary by >1°C during the experiment.

All equipment was positioned inside an animal hyperbaric chamber (Reimers Engineering, Alexandria, Va.). Isoflurane was discontinued from the ventilating gas and flushed from the respiratory circuit. The chamber was sealed and chamber pressure increased to 2.25 ATA (1710 mm Hg). After reaching stable pressure, ventilation was continued with 1.8 ATA N_2O and 0.45 ATA O_2.

The cortically recorded somatosensory evoked potentials (CEPs), two-channel analogue EEG, and compressed spectral array were recorded constantly throughout the experiment. Needle electrode impedance was maintained at <5000 Ω. The evoked-potential stimulator intensity was adjusted to consistently elicit a twitch from the distal paw of the lower limb. A stimulus rate of 5/s with 256 repetitions and an analysis time of 200 ms after each stimulus was utilized. Cortical responses from the peripheral hindlimb stimulation were recorded from contralateral scalp electrodes. The animals were constantly observed by an investigator through a chamber porthole.

After a minimal stabilization period of 30 min and end-tidal isoflurane approaching 0 (maximal detected end-tidal isoflurane was 0.03%), testing for MAC was begun using a supramaximal electrical stimulation technique (9,10). The stimulus used was defined as supramaximal, because electrical stimulation of higher voltage or longer duration has not been shown to result in a response in tested animals (10). Each rat received an electrical stimulation of 50 V by 10-ms-duration pulses at 50/s for 45 s by a Grass SD-5 stimulator. The stimulus was applied subcutaneously to the lower abdomen from a single-needle electrode. The partial pressure of N_2O was decreased by approximately 10% if there was a negative response for three periods of stimulation. A positive response was taken as repetitive, purposeful movement. This did not include tail-wagging activity, back arching, or maintained limb extension. A minimal 15-min equilibration time was taken between each change and stable end-tidal N_2O maintenance documentation. The MAC was taken as the expired N_2O partial pressure in ATA midway between that at which there was no response and that at which the rat moved purposefully.

Although electrical stimulation has often been utilized as a noxious stimulus for MAC measurement, electrical stimulation was compared with the full-ratchet tail-clamp technique in three Sprague-Dawley rats for the measurement of the MAC of isoflurane. Both noxious stimuli were applied after each decrease in end-tidal isoflurane, beginning at 1.6%.

The mean value of the determined MAC values (±SD) was taken as the MAC of N_2O for Long-Evans rats and the MAC of isoflurane for Sprague-Dawley rats.

Results

The directly measured MAC of N_2O in Long-Evans rats was found to be 1.55 ± 0.16 ATA. The range of measured N_2O MAC values was from 1.38 to 1.74 ATA. Positive responses could be elicited repeatedly. The MAC of isoflurane in the three rats tested was the same, 1.31% ± 0.08%, when determined by both electrical stimulation and tail-clamping.

During the study, end-tidal CO_2 was maintained at >25 mm Hg and did not exceed 45 mm Hg in all animals. Normoxic gas mixtures were delivered to all animals throughout the study.

Nitrous oxide was found to be a neurophysiologic depressant both through absence of responses to electrical stimulation and through decreased neuroelectrical activity as monitored by EEG. The analogue EEG output of the computerized EEG showed decreased fast-wave activity with increasing N_2O partial pressure; there was a preponderance of slow-wave activity at >0.90 ATA N_2O (Figure 1). Low-amplitude (<20 μV), beta wave activity was predominant below 0.65 ATA N_2O. Amplitude increased and electrical

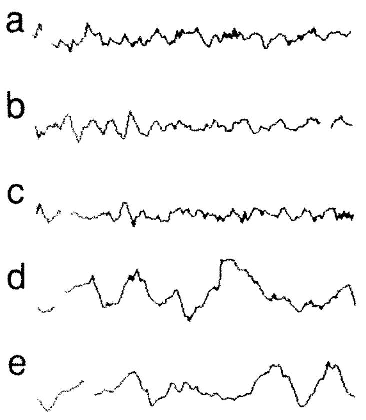

Figure 1. Two-channel EEG was recorded in rats during hyperbaric exposure to N_2O and O_2 at 2.25 ATA (atmospheres absolute pressure). Increased N_2O partial pressures decreased EEG frequency and increased waveform amplitude. End-tidal N_2O measurements correlating with each raw EEG recording were *a*, 0%; *b*, 31% (0.31 ATA); *c*, 68% (0.68 ATA); *d*, 118% (1.18 ATA); *e*, 164% (1.64 ATA).

Table 1. Effects of N_2O on the Electroencephalogram in Rats

N_2O (ATA)	Predominant frequency[a]	Amplitude[b]
0	Beta	Low
0.40–0.65	Beta	Low
0.70–0.80	Alpha	Medium
0.90–1.0	Alpha	High
1.05–1.45	Alpha–theta	Medium–high
1.50–1.60	Theta	Medium–high
1.65–1.90	Theta	Medium–high

ATA, 1 atm absolute pressure.
[a] Alpha, 8–13 Hz; beta, >13 Hz; delta, 0–3 Hz; theta, 4–7 Hz.
[b] Low, <20 μV; medium, 20–50 μV; high, >50 μV.

activity decreased as N_2O partial pressure increased (Table 1).

Neuroelectrical depression was also noted in the CEP recordings. The latency of the CEP was less affected than the amplitude. Although the trends in CEP changes were similar across the population studied, individual examples best exemplify changes at specific N_2O partial pressures (Figure 2). Amplitude decreased with each increase in N_2O partial pressure. Latency was relatively stable until N_2O concentration exceeded approximately 0.75 ATA (Table 2). During ventilation with N_2O >0.9 ATA, the CEP waveform was altered in some animals to the extent that amplitude and latency could not be accurately measured.

No difficulties were encountered with the stimulating electrodes. Tissue burns were not encountered at the stimulating or recording sites.

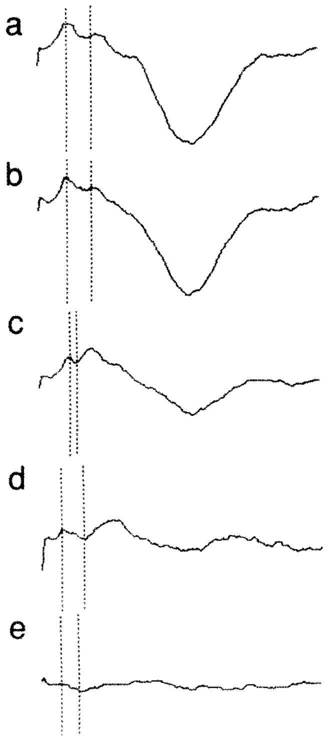

Figure 2. Somatosensory evoked potentials were cortically recorded after hindlimb stimulation in rats during anesthesia with N_2O and O_2 at hyperbaric pressures of 2.25 ATA (atmospheres absolute pressure). Evoked potential amplitude decreases were more sensitive than latency prolongation to the depressant effects of N_2O. The end-tidal N_2O concentrations at which the evoked potentials were recorded were *a*, 0%; *b*, 31% (0.31 ATA); *c*, 68% (0.68 ATA); *d*, 118% (1.18 ATA); *e*, 164% (1.64 ATA). (The *dashed vertical lines* represent the monitor's moveable cursors used to denote the wave points for measurement of amplitude and latency.)

Discussion

For the first time, the MAC of N_2O in rats has been directly measured rather than extrapolated from presumed linear additivity of anesthetics or individual anesthetic lipid solubility. The measured N_2O MAC of 1.55 ± 0.16 ATA is similar to, but exceeds, the value of 1.36 ATA predicted from its lipid solubility and addition to halothane (2) and is less than the 2.20 ATA value assumed if enflurane and N_2O potencies were linearly additive (3). The value is closer to the 1.47 ± 0.076 ATA reported for N_2O MAC by Wardley-Smith and Halsey (6). Although the number of animals tested was not reported, the noxious stimuli were electrical shocks.

The MAC value of an anesthetic can be altered by differences in animal physiology. All animals tested were of similar age and weight. Temperature was maintained and was stable; end-tidal CO_2 was also stable. Although rat brain fatty acid varies with dietary manipulation and can alter volatile anesthetic potency (11), diets were standard and consistent. The

ATA, 1 atm absolute pressure.
[a] Waveform was altered, and analysis could not be performed.

time-course of each experiment was similar, and all were performed during daytime working hours. Isoflurane was administered for initial anesthesic induction and instrumentation. This was discontinued immediately before compression and was absent in expired breath for at least 30 min before testing. Although this should not have influenced MAC values found, perhaps residual isoflurane was present in brain and body tissues. Nitrogen was not present in the ventilating gases, so nitrogen narcosis was not an influencing factor.

The noxious stimulus used for MAC determination was electrical stimulation rather than clamping of the proximal tail. Determination of MAC by supramaximal electrical stimulation has been documented to be accurate and reliable in rats (6,9,12,13), dogs (14,15), and humans (16). The electrical stimulation was applied subdermally to the lower abdomen. This location was thought to decrease the likelihood of the needle electrode becoming disconnected from the animal during movement associated with positive responses while still inside the closed hyperbaric chamber; as well, the likelihood of tissue burns was thought to be less. In previous MAC studies, electrical stimulation has been applied to the base of the tail (12), the cheek, and other membrane surfaces (9). Indeed, 10-V electrical stimuli have been reported to be painful and therefore useful for MAC measurement when applied by needle electrodes to the human forearm (9,16). Electrical stimulation has also been reliably used with stimulating electrodes placed subcutaneously in the lower abdomen (as in the present study) and the perineum (14). The electrical stimulation used was of sufficient intensity, and the needle insertion sites were appropriate for reliable repetition of stimuli. Inside an animal hyperbaric chamber, remotely controlled tail-clamp applications were found to be technically unreliable. Remote control of the electrical stimulation functioned consistently.

To test the electrical stimulator, we compared supramaximal electrical stimulation, as used in the present study, with standard tail cross-clamping for isoflurane MAC measurements in Sprague-Dawley rats and found no difference between values found with each type of noxious stimulus. The isoflurane MAC of 1.31% ± 0.08% found in these comparisons was the same as the isoflurane MAC of 1.38% ± 0.02% reported by White et al. (17) when 58 rats were tested by tail-clamp stimulation.

The question of anesthetic tolerance was not addressed. The MAC values were determined between 90 and 120 min after N_2O anesthesia was initiated; therefore, measurements were performed after a consistent N_2O exposure time. Although performed in only two animals, repeat MAC measurements performed 1 h after the initial determinations were not different from the initial MAC value found. Tolerance has been shown to be present in mice, but it is suggested to occur after the first few minutes of anesthesia (18). The EEG changes from N_2O in humans under halothane anesthesia were demonstrated to be less depressed when N_2O was added a second time after being discontinued for 20–30 min (19). If N_2O tolerance had an effect on the measured MAC, it was not discerned, and avoidance of the effects was not possible.

The monitored neuroelectrical effects of N_2O were similar to those previously reported (20–22). Beta (>13 Hz) and alpha (8–13 Hz) brain wave activity both decreased with increasing N_2O partial pressures. There was a preponderance of higher amplitude, slow brain wave activity with N_2O anesthesia. However, increased delta (0–3 Hz) wave activity was not documented, but theta (4–7 Hz) wave activity commonly occurred at >1.0 ATA N_2O. The EEG activity in the theta range was predominant at ≥1.5 ATA N_2O. Both somatosensory and auditory CEP amplitude and latency have been shown to be decreased and increased, respectively, in humans during inhalation of 33% or 40% N_2O (23,24). The effects of N_2O on CEP may be more graded in humans than those demonstrated in rats (25).

The MAC of N_2O in rats is 1.55 ATA when directly measured with electrical stimulation as a noxious stimulus. During anesthesia with N_2O alone in rats, cortical neuroelectrical activity was progressively depressed as the partial pressure increased, although the EEG fast-wave suppression and amplitude increase may not occur at as low a partial pressure as previously demonstrated in humans.

Departments of Anesthesia and Pharmacology, University of Toronto, Toronto, Ontario, Canada

This study compared systemic hemodynamic and organ blood flow responses to equipotent concentrations of halothane and sevoflurane during spontaneous ventilation in the rat. The MAC values for halothane and sevoflurane were determined. Cardiac output and organ blood flows were measured using radiolabeled microspheres. Measurements were obtained in awake rats (control values) and at 1.0 MAC halothane or sevoflurane. The MAC values (mean ± SEM) for halothane and sevoflurane were 1.10% ± 0.05% and 2.40% ± 0.05%, respectively. The $Paco_2$ increased to a similar extent in both groups compared with control values. During halothane anesthesia, heart rate decreased by 12% ($P < 0.01$), cardiac index by 26% ($P < 0.01$), and mean arterial blood pressure by 18% ($P < 0.01$) compared with control values. Stroke volume index and systemic vascular resistance did not change. During sevoflurane anesthesia, hemodynamic variables remained unchanged compared with control values. Coronary blood flow decreased by 21% ($P < 0.01$) and renal blood flow by 18% ($P < 0.01$) at 1.0 MAC halothane, whereas both remained unchanged at 1.0 MAC sevoflurane. Cerebral blood flow increased to a greater extent with halothane (63%; $P < 0.01$) than with sevoflurane (35%; $P < 0.05$). During halothane anesthesia, hepatic arterial blood flow increased by 48% ($P < 0.01$), whereas portal tributary blood flow decreased by 28% ($P < 0.01$). During sevoflurane anesthesia, hepatic arterial blood flow increased by 70% ($P < 0.01$) without a concomitant reduction in portal tributary blood flow. Total liver blood flow decreased only with halothane (16%; $P < 0.05$). In conclusion, for comparable increases in $Paco_2$, systemic hemodynamic and organ blood flow responses to halothane are significantly greater than the responses to sevoflurane at an equipotent concentration of 1.0 MAC in the spontaneously ventilating rat.

(Anesth Analg 1992;75:1000–6)

The response of the cardiovascular system to inhaled anesthetics includes alterations in systemic hemodynamics and blood flow to a number of vascular beds. These hemodynamic responses differ when ventilation is spontaneous rather than controlled (1–4), owing, in part, to a higher $Paco_2$ and a lower mean intrathoracic pressure during spontaneous ventilation. The inhaled anesthetic sevoflurane is a halogenated methyl isopropyl ether with hemodynamic properties that have been studied in ventilated animals (5–7). Sevoflurane has a low blood-gas partition coefficient and a nonirritating odor (8,9). These properties augur well for the use of sevoflurane to induce anesthesia in children. It is therefore important to have a clear understanding of the hemodynamic alterations produced when sevoflurane is administered during spontaneous ventilation. Of the inhaled anesthetics currently available, halothane is the most common anesthetic used to induce anesthesia in pediatric patients. Halothane would therefore appear to be a suitable reference anesthetic with which to compare the hemodynamic properties of sevoflurane.

The present study was undertaken to compare systemic hemodynamic and organ blood flow responses to 1.0 MAC halothane with those to an equipotent concentration of sevoflurane during spontaneous ventilation in the rat.

Methods

After the protocol was approved by our Animal Care Committee, Sprague-Dawley rats (weight 260–320 g) were housed in a temperature- and humidity-controlled environment with a 12-h light/dark cycle. Before the experiments, the rats fasted overnight, with water available ad libitum.

The MAC values for halothane ($n = 8$) and sevoflurane ($n = 8$) were determined in 16 fasted rats using a tail-clamp technique (10,11). Rectal temperature was monitored, and normothermia was maintained using radiant heating lamps.

During ether anesthesia of 15–20-min duration, polyethylene catheters (Tygon; PE 50) were inserted in the left femoral artery for blood pressure monitoring, blood sampling, and reference sample withdrawal, and the left ventricle via the right common carotid artery for injection of radioactive microspheres, as previously described (12). Placement of the catheter in the left ventricle was verified by monitoring the blood pressure waveform. Incisions were infiltrated with 1% lidocaine, and the cannulas were capped with rubber injection ports and tunneled subcutaneously to the midback of the rat, where they were brought to the skin surface. After the operative procedure, the rats were allowed to recover in a temperature-controlled environment for 4 h. There was no obvious evidence of stress or pain during recovery. In previous studies, we showed that indices of stress, such as blood glucagon level, mean arterial pressure, and heart rate, remain unchanged after these operative procedures (12).

After recovery, the rats ($n = 45$) appeared comfortable and resumed their usual behavior. They were placed in cylindrical plexiglass chambers through which oxygen (5 L/min) was administered. After 20 min of stable hemodynamics, heart rate, mean arterial pressure, and arterial blood gases were recorded, and cardiac output and organ blood flows were determined using ^{57}Co-labeled microspheres. The rats were then randomly assigned to receive either 1.0 MAC halothane or sevoflurane. Thirty minutes after the start of anesthetic administration, heart rate, mean arterial pressure, and arterial blood gases were measured, and ^{46}Sc-labeled microspheres were injected to determine cardiac output and organ blood flows. In previous control studies, values for cardiac output and organ blood flows obtained with ^{46}Sc-labeled microspheres were similar to those obtained 30 min earlier with ^{57}Co-labeled microspheres in awake rats (F. J. Carmichael et al., unpublished observations). In the present study, all measurements were performed during periods of stable hemodynamics. Throughout the study period, ventilation was spontaneous, and normothermia was maintained using radiant heating lamps. Inspired anesthetic concentration was monitored continuously using a calibrated infrared medical gas analyzer (SensorMedics LB 2, Anaheim, Calif.). Rectal temperatures taken at the end of the experiments were 37.3° ± 0.3°C (mean ± SEM).

Arterial blood pressure was monitored using a physiograph (Narco Biosystems, Houston, Tex.). Heart rate was determined from the blood pressure waveform. Cardiac output and organ blood flows were measured using 16.5 ± 0.1-μm-diameter radiolabeled microspheres (New England Nuclear, Boston, Mass.). The microspheres, prepared as previously described (13), were suspended in 10% dextran containing 1 drop of Tween-80, agitated for 10 min using a Vortex mixer, and aspirated into polyethylene tubing for gamma-scintillation counting (Nuclear Chicago counter, model 1185, Chicago, Ill.) just before injection. Approximately 40,000–50,000 microspheres were then infused into the left ventricle over 20 s using an infusion pump. A 0.6-mL reference sample that contained 300–400 microspheres was obtained from the femoral artery using a withdrawal pump that began to aspirate blood 10 s before the infusion of microspheres and continued for 60 s. The presence of this number of microspheres in the reference sample has been shown to yield valid cardiac output measurements (14). An equal volume of ficoll (0.6 mL, 13% wt/vol) (Sigma Chemical Co., St. Louis, Mo.), a nonionic synthetic polymer of sucrose, was flushed through the microsphere infusion tubing to replace the volume of blood sampled. The infusion of microspheres and the withdrawal of the reference sample had no demonstrable effect on monitored hemodynamic variables. The net counts infused were the difference between the counts obtained before injection into the left ventricle and those remaining in the polyethylene tubing. At the termination of the study, the rats were killed with intravenous KCl, and the following organs were removed and placed in saline-containing vials for analysis of radioactivity: brain, lungs, heart, liver, kidneys, spleen, stomach, omentum, pancreas, and small and large intestines. All organs were analyzed intact, with the exception of the liver and small intestine, which were each divided into five sections. The mixing of microspheres in the circulation was considered to be adequate if the difference between the right and left renal blood flows was <15% (12). Three rats were eliminated from the study on the basis of this criterion.

Mean arterial pressure was calculated as diastolic pressure plus one-third the pulse pressure. Corrections for overlap during counting of the radioisotopes were made. Cardiac index (Qt) ($\mathrm{mL \cdot min^{-1} \cdot kg\ body\ wt^{-1}}$) was calculated by the equation

Table 1. Systemic Hemodynamics and Arterial Blood Gases in the Spontaneously Ventilating Rat, Awake (Control) and During 1.0 MAC Halothane or Sevoflurane

	Halothane (n = 22)		Sevoflurane (n = 20)	
Physiologic variable	Awake	1.0 MAC	Awake	1.0 MAC

Pao_2 (mm Hg)	385 ± 11	410 ± 14	391 ± 16	414 ± 12

HR, heart rate; SVI, stroke volume index; Qt, cardiac index; MAP, mean arterial pressure; SVR, systemic vascular resistance; pHa, arterial pH.
Values are mean ± SEM.
[a] $P < 0.01$, compared with respective control.
[b] $P < 0.01$, compared with halothane.
[c] $P < 0.05$, compared with halothane.

$$Qt = \frac{Ci \cdot R}{Cr \cdot w},$$

where Ci is net counts injected, R the reference sample withdrawal rate, Cr the net counts in the reference sample, and w the body weight (kg). Organ blood flow (Qo) ($mL \cdot min^{-1} \cdot kg$ body wt^{-1}) was calculated by the equation

$$Qo = \frac{Qt \cdot Co}{Ci},$$

where Co is net counts in the organ. Systemic vascular resistance ($mm\ Hg \cdot mL^{-1} \cdot min \cdot kg$) was calculated as the quotient of the mean arterial pressure and cardiac index. Central venous pressure was assumed to approximate zero. Stroke volume index (mL/kg) was calculated as the quotient of cardiac index and heart rate. Organ vascular resistances ($mm\ Hg \cdot mL^{-1} \cdot min \cdot kg$) were calculated as the quotient of the mean arterial pressure and organ blood flow.

Portal tributary blood flow (PTBF) was calculated as the sum of the blood flow to the spleen, stomach, omentum, pancreas, and small and large intestines. The contribution of blood flows from the pancreas and omentum, which cannot be readily isolated in the rat, is included in the flows to the small and large intestines. The accuracy of this method as an estimate of PTBF is well validated (15,16). Hepatic arterial blood flow (HABF) was determined from the net counts within the liver. Total hepatic blood flow was calculated as the sum of the PTBF and HABF.

Cardiac output, stroke volume, organ blood flows, and vascular resistances were indexed to body weight (kg). Because the relationship of organ weight to body weight did not change throughout the study period, there are no differences in the conclusions derived when this form of expression is used as opposed to blood flows expressed per gram organ.

Data are presented as mean ± SEM. Statistical significance ($P < 0.05$) was determined using one-way analysis of variance. Intergroup differences were determined by the least-significant difference method (17).

Results

The MAC values (mean ± SEM) for halothane and sevoflurane were 1.10% ± 0.05% and 2.40% ± 0.05%, respectively. The $Paco_2$ increased from a control value of 37 ± 3 to 50 ± 2 mm Hg with halothane ($P < 0.01$) and from 39 ± 4 to 48 ± 3 mm Hg with sevoflurane ($P < 0.01$) (Table 1). The differences in $Paco_2$ at 1.0 MAC were not significant. The pHa and Pao_2 did not differ between groups either as control values or at 1.0 MAC (Table 1).

Control (awake) hemodynamic measurements were similar in the two groups (Table 1). Compared with control measurements, heart rate decreased by 12% ($P < 0.01$), cardiac index by 26% ($P < 0.01$), and mean arterial pressure by 18% ($P < 0.01$) during halothane anesthesia (Figure 1). These variables remained unchanged during sevoflurane anesthesia compared with control values (Figure 1). Stroke volume index and systemic vascular resistance did not change during administration of either anesthetic (Table 1).

Control organ blood flow measurements were similar in the two groups (Table 2). Compared with control measurements, coronary blood flow decreased by 21% ($P < 0.01$) (Figure 2) without a significant change in coronary vascular resistance (Table 3) during halothane anesthesia. In contrast, neither coronary blood flow (Figure 2) nor coronary vascular resistance (Table 3) changed during sevoflurane administration. Cerebral blood flow increased

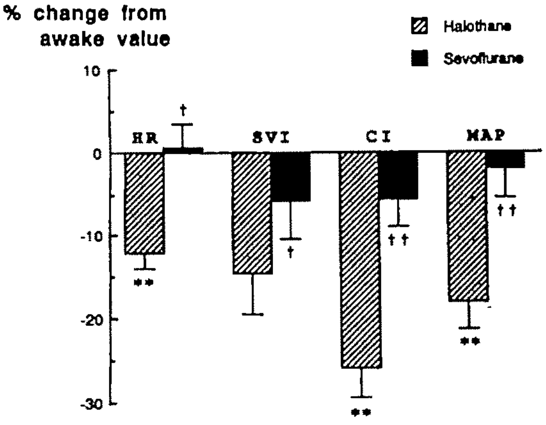

Figure 1. Systemic hemodynamic responses to 1.0 MAC halothane or sevoflurane anesthesia in the spontaneously ventilating rat. Data are presented as percent change from the control (awake) values shown in Table 1. HR, heart rate; SVI, stroke volume index; CI, cardiac index; MAP, mean arterial pressure. $^{**}P < 0.01$, compared with control (awake) value. $^{\dagger}P < 0.05$, compared with halothane. $^{\dagger\dagger}P < 0.01$, compared with halothane.

by 63% ($P < 0.01$) (Figure 2), whereas cerebral vascular resistance decreased by 50% ($P < 0.01$) (Table 3) during halothane anesthesia. During sevoflurane anesthesia, the changes in cerebral blood flow and vascular resistance were less marked, 35% ($P < 0.05$) (Figure 2) and 27% ($P < 0.05$) (Table 3), respectively. Renal blood flow decreased by 18% ($P < 0.01$) (Figure 2) without a change in renal vascular resistance during halothane anesthesia. Neither renal blood flow (Figure 2) nor renal vascular resistance (Table 3) changed during sevoflurane administration. Blood flow to the lungs was similar in awake and anesthetized rats, suggesting that arteriovenous shunting of microspheres did not occur during anesthesia.

The HABF increased by 48% ($P < 0.01$) (Figure 3) in association with a 44% ($P < 0.01$) decrease in hepatic arterial vascular resistance during halothane anesthesia (Table 3). Similarly, HABF increased by 70% ($P < 0.01$) (Figure 3), and hepatic arterial vascular resistance decreased by 42% ($P < 0.01$) during sevoflurane anesthesia (Table 3). The increase in HABF was associated with a reduction in PTBF during halothane (28%; $P < 0.01$) but not during sevoflurane anesthesia. Portal tributary vascular resistance did not change during administration of either halothane or sevoflurane (Table 3). Total hepatic blood flow decreased only with halothane (16%; $P < 0.05$) (Figure 3).

Splenic blood flow decreased by 38% ($P < 0.01$) during halothane anesthesia and by 24% ($P < 0.05$) during sevoflurane anesthesia (Table 2), with corresponding increases in splenic vascular resistance of 38% ($P < 0.05$) and 28% (NS), respectively (Table 3). Gastric blood flow decreased by 32% ($P < 0.01$) after halothane and by 29% ($P < 0.01$) after sevoflurane (Table 2), with corresponding increases in gastric vascular resistance of 21% (NS) and 42% ($P < 0.05$), respectively (Table 3). Small and large intestinal blood flows decreased by 27% ($P < 0.01$) and 14% ($P < 0.01$), respectively, after halothane (Table 2), with no change in vascular resistances (Table 3).

Discussion

The present study compared systemic hemodynamic and organ blood flow responses to 1.0 MAC halothane with those to an equipotent concentration of sevoflurane in the spontaneously ventilating rat. It is important to study the hemodynamic effects of inhaled anesthetics during spontaneous ventilation, because this anesthetic technique is commonly used in both pediatric and adult anesthesia, particularly for

Table 2. Organ Blood Flow Responses in the Spontaneously Ventilating Rat, Awake (Control) and During 1.0 MAC Halothane or Sevoflurane

Organ blood flow ($mL \cdot min^{-1} \cdot kg^{-1}$)	Halothane ($n = 22$)		Sevoflurane ($n = 20$)	
	Awake	1.0 MAC	Awake	1.0 MAC

outpatients. Hemodynamic alterations that occur during inhaled anesthesia may be attributed not only to direct pharmacologic effects of the anesthetic, but also to an increase in Pa_{CO_2}. Other factors, including alterations in autonomic outflow, cardiac output, mean arterial pressure, and oxygen requirements, may alter organ blood flow. To help ensure that the conditions of the present study were parallel to those of clinical inhaled anesthesia, no attempt was made to regulate these factors. In agreement with a previous study (18), the increase in Pa_{CO_2} observed in the present study with 1.0 MAC halothane was similar to that with 1.0 MAC sevoflurane. An increase in Pa_{CO_2} of this magnitude might have attenuated the hemodynamic depression induced by the inhaled anesthetics (1,3,19). Nevertheless, the present data demonstrate that for comparable increases in Pa_{CO_2} during spontaneous ventilation, sevoflurane produces minimal hemodynamic alterations compared with halothane.

Inspired rather than end-tidal anesthetic concentrations were measured in the present study. An estimation of anesthetic requirement based on inspired anesthetic concentration assumes the equilibration of inspired, alveolar, and brain anesthetic tensions. The time to attain equilibrium is influenced by the solubility of the anesthetic and its effect on minute ventilation (10). In the present study, the effect of sevoflurane on minute ventilation was similar to that of halothane, which negates a differential effect of this variable on equilibration. However, the solubilities of the two anesthetics differ (8,9). For an anesthetic with a blood-gas partition coefficient similar to that of sevoflurane, the ratio of end-tidal to inspired anesthetic concentration has been shown to approach unity within 30 min in the rat (20). In the present study, therefore, it is likely that the inspired concentration of sevoflurane closely reflected the alveolar or end-tidal value when hemodynamic and organ blood flow values were determined. It is probable that the greater solubility of halothane may have delayed equilibration beyond 30 min. However, previous studies in rats report that the end-tidal to inspired ratio of halothane was within 10% of unity after 25–35 min (10). In addition, the use of end-tidal measurements of halothane concentration yielded a MAC value for halothane in the rat similar to that found in the present study (10). Furthermore, had a longer time been allowed for equilibration in the present study, it is probable that even greater differential effects on systemic hemodynamics and organ blood flows would have been observed.

Awake values are in agreement with those of previous dose-response studies from this laboratory on the hemodynamic effects of MAC multiples of

sevoflurane (11) and halothane (21). For comparable increases in Pa_{CO_2} in the present study, systemic hemodynamics were affected to a greater extent by halothane than by an equipotent concentration of sevoflurane. Consistent with these findings, sevoflurane decreased hemodynamic variables to only a small extent in newborn swine (22). Greater reductions in stroke volume, cardiac output, and mean arterial pressure were reported to occur during sevoflurane anesthesia in mature swine (5) and in rats (7). The difference between the results of the present study and those in mature swine (5) may be attributed in part either to the hyperdynamic state of the spontaneously breathing awake swine or to the introduction of controlled ventilation during sevoflurane anesthesia. The discrepancy in the study in rats (7) may also be due to an effect of controlled ventilation or, more likely, to the simultaneous presence of two other anesthetics, chloral hydrate and chloralose, in that study.

The microsphere technique yields an accurate estimate of organ blood flows, provided that several important criteria are satisfied (12,13,23). The validity of the awake blood flow measurements in the present study is substantiated by previous work from this laboratory (11,12) and from a number of other investigators (13,14,24).

The response of the coronary circulation to halothane in the present study is consistent with the reports of other investigators (25). The lack of an effect of sevoflurane on coronary blood flow is of interest, because both a decrease (5) and an increase (6) in coronary blood flow have been reported during sevoflurane anesthesia. The decrease in coronary blood flow may be attributed to the administration of a general anesthetic in swine with elevated hemodynamic variables in the awake state, whereas the increase in coronary blood flow observed in dogs was associated with a 60% increase in heart rate and thus might have reflected an increase in myocardial oxygen requirement.

For comparable increases in Pa_{CO_2}, cerebral blood flow increased, and cerebral vascular resistance decreased to a greater extent during halothane than during sevoflurane anesthesia. This finding suggests that the cerebrovascular effects of halothane exceed those of sevoflurane. In support of this observation, the effects of sevoflurane on cerebral blood flow, cerebral oxygen requirement, and intracranial pressure were recently shown to compare favorably with those of isoflurane (26).

During hypercarbia, HABF has been reported to either remain unchanged (27) or to decrease transiently, followed by a return to control values (28). It is unlikely therefore that the increase in HABF observed in the present study with both halothane and sevoflurane is due to an effect of hypercarbia. Indeed, this increase in flow is consistent with the reports of other investigators (5,11,21,29–31) and may represent either a reciprocal change associated with reduced PTBF, in the case of halothane (21), or, a direct pharmacologic action of the inhaled anesthetics on hepatic arterial vasculature.

In the present study, the changes in PTBF were not associated with alterations in portal tributary vascular resistance but, rather, paralleled the changes in cardiac output. Although hypercarbia has been associated with portal tributary vasodilation and an increase in flow (27,28), PTBF did not increase under the conditions of the present study. In fact, PTBF decreased with halothane. These observations are consistent with previous reports that inhaled anesthetics may attenuate the response of the portal circulation to hypercarbia (32) and suggest that PTBF depends to a greater extent on changes in cardiac output than on changes in Pa_{CO_2} in the presence of potent anesthetics.

In summary, systemic hemodynamics and organ blood flows are disturbed to a greater extent by 1.0 MAC halothane than by an equipotent concentration of sevoflurane during spontaneous ventilation. These results have clinical implications and suggest that sevoflurane may be advantageous when hemodynamic stability is required during an inhaled induction of anesthesia.

The authors thank Dr. Robert Creighton for his helpful suggestions in the preparation of this manuscript.

Halothane Enhances Pulmonary Artery Endothelial Eicosanoid Release

Steve D. Barnes, MD, Lynn D. Martin, MD, and Randall C. Wetzel, MB, BS, FCCM

Departments of Anesthesiology/Critical Care Medicine and Pediatrics, The Johns Hopkins Medical Institutions, Baltimore, Maryland

To determine whether anesthetics alter endothelial eicosanoid release, cultured bovine pulmonary artery endothelial cells were studied during constant flow and pressure perfusion at two oxygen tensions (hypoxia, 50 ± 2 mm Hg; normoxia, 144 ± 5 mm Hg; mean ± SEM) with and without 1% halothane. Endothelialized microcarriers containing ~5 × 10^6 cells were loaded into cartridges and perfused (3 mL/min) with Krebs' solution (pH 7.4, at 37°C) equilibrated with each gas mixture. Eicosanoids (6-keto prostaglandin $F_{1\alpha}$, thromboxane B_2, and total peptidoleukotrienes [C_4, D_4, E_4, F_4]) were measured by radioimmunoassay and quantified per gram of cellular protein per minute. Eicosanoid release did not vary over time. The 6-keto prostaglandin $F_{1\alpha}$ release increased during hypoxia (normoxia 291 ± 27 vs hypoxia 395 ± 35 $ng \cdot min^{-1} \cdot g$ $protein^{-1}$; $P < 0.01$). Halothane (H) increased release of each eicosanoid during both normoxia and hypoxia: 6-keto prostaglandin $F_{1\alpha}$—normoxia 291 ± 27 versus normoxia + H 356 ± 32 $ng \cdot min^{-1} \cdot g$ $protein^{-1}$, hypoxia 395 ± 35 versus hypoxia + H 464 ± 40 $ng \cdot min^{-1} \cdot g$ $protein^{-1}$, $P < 0.05$; thromboxane B_2—normoxia 19 ± 2 versus normoxia + H 26 ± 2 $ng \cdot min^{-1} \cdot g$ $protein^{-1}$, hypoxia 20 ± 2 versus hypoxia + H 38 ± 5 $ng \cdot min^{-1} \cdot g$ $protein^{-1}$, $P < 0.001$; leukotriene—normoxia 363 ± 35 versus normoxia + H 489 ± 52 $ng \cdot min^{-1} \cdot g$ $protein^{-1}$, hypoxia 329 ± 29 versus hypoxia + H 455 ± 39 $ng \cdot min^{-1} \cdot g$ $protein^{-1}$, $P = 0.001$. We conclude that alteration of endothelial eicosanoid release by halothane and hypoxia could modulate pulmonary vascular tone.

(Anesth Analg 1992;75:1007–13)

Anesthetics alter vascular tone and inhibit hypoxic pulmonary vasoconstriction (HPV) (1,2). This has been attributed to many factors, including alterations in autonomic activity and direct anesthetic effects on vascular smooth muscle. Because the endothelium is intimately involved in the regulation of both systemic and pulmonary vascular resistance (PVR), a further explanation for the effect of anesthetics could be either the potentiation or inhibition of the release of endothelial-derived vasodilators, such as prostacyclin or nitric oxide, or both, or endothelial-derived vasoconstrictors, such as thromboxane, leukotrienes, or endothelin, or all of these (3–5). Modulation of endothelial function by inhaled anesthetics could, in part, mediate their vascular effects (1,2,6–10). Although the anesthetic modulation of endothelial-derived relaxing factor has recently been studied (10), the effect of anesthetics on endothelial eicosanoid release has received little attention. A relationship between endothelial eicosanoid release and inhaled anesthetics-mediated vasodilation was suggested by Stone and Johns (10), but whether volatile anesthetics directly affect endothelial eicosanoid release is not known.

Pulmonary vascular resistance and its relation to oxygen tension is influenced by many factors, including volatile and intravenous anesthetics (1,2,11,12). Despite numerous investigations to define how anesthetics and oxygen interact to influence PVR, unanswered questions remain. Pulmonary artery endothelium produces numerous eicosanoids, some potent vasoconstrictors (thromboxane, prostaglandin $F_{2\alpha}$ [$PGF_{2\alpha}$]), and other potent vasodilators (prostacyclin, prostaglandin E_1 [PGE_1]) (13,14). Studies in intact animals and isolated lungs have demonstrated eicosanoid involvement in the pulmonary vascular response to hypoxia (11). In vitro studies in static endothelial cells have failed to clearly demonstrate altered eicosanoid release by hypoxia (15–17). These studies, however, did not include the important physiologic factor, shear stress, which is ever present in perfused, in vivo endothelium (18,19).

This study was designed to determine whether halothane alters the release of prostacyclin, thromboxane, and total peptidoleukotriene (C_4, D_4, E_4, F_4)

Accepted for publication July 28, 1992.

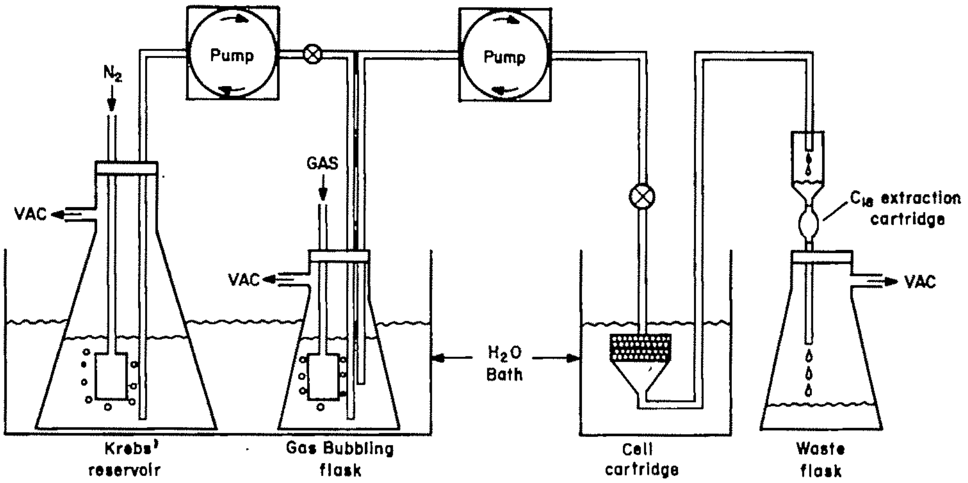

Figure 1. The perfusion circuit. Krebs' solution bubbled with 100% N_2 was pumped via a multichannel variable-speed roller-head pump to the gas-bubbling flask. Krebs' perfusate oxygen tension and halothane concentration was controlled by bubbling gas (1 L/min) of known oxygen tension (normoxia, 21% O_2; hypoxia, 4% O_2; normoxia + 1% halothane; hypoxia + 1% halothane) through the perfusate. The perfusate was pumped through the cell cartridge containing 5 × 10^6 pulmonary artery endothelial cells on microcarrier beads to the C_{18} Sep-Pak extraction cartridge and into a vacuum (VAC)-evacuated waste flask. Temperature was maintained at 37°C by immersion of the perfusion circuit components in a servoregulated water bath.

by perfused bovine pulmonary artery endothelial cells during normoxia and hypoxia.

Methods

Cell Culture

Bovine pulmonary artery endothelial cells (CCL-209 CPAE; American Type Culture Collection, Rockville, Md.) >95% pure, as determined by morphology, the presence of factor VIII antigen, angiotensin-converting enzyme activity, and diacyl low-density lipoprotein uptake, were cultured according to the method of Ryan et al. (20). Endothelial cells were suspended in M-199 containing 20% fetal bovine serum, penicillin (50 U/mL), streptomycin (50 μg/mL), and amphotericin (0.25 μg/mL) and initially seeded in 75-cm^2 flasks (Fisher, Orangeburg, N.Y.). Culture flasks were incubated at 37°C in 95% air–5% CO_2 and the medium changed at 24 h and then every 3 days until confluence was reached (5–8 days). The cells were scraped from the flask with a sterile rubber policeman, resuspended, and seeded onto 2 × 10^5 microcarrier beads (Cytodex-3, Sigma Chemical Co., St. Louis, Mo.) hydrated in Dulbecco's phosphate-buffered saline (PBS) and placed in a 100-mL siliconized roller bottle (Gibco, Grand Island, N.Y.). The roller bottle was gassed with 95% air–5% CO_2, sealed, and rotated at 2 rpm for 2 min every 30 min for 3 h and then continuously rotated at 1.5 rpm at 37°C. When cells were confluent on the microcarrier beads, as seen on phase-contrast microscopy, additional microcarrier beads (1 × 10^5) were added to the roller bottle (every 2–3 days) until 5 × 10^5 confluent microcarrier beads were obtained (approximately 3–4 wk). The medium was changed approximately every 2 days and roller bottles were gassed with 95% air–5% CO_2. Twenty-four hours before the experiment, the cell medium in the roller bottles was changed to standard medium enriched with 20 μM arachidonic acid to ensure adequate substrate for eicosanoid release. This supplementation with arachidonate does not alter either prostacyclin release or the proportions of eicosanoids released (15,21,22).

Perfusion System

The perfusion system was designed to perfuse four identical circuits simultaneously with the same pressure and flow characteristics (Figure 1). Each circuit contained a similar number of cells from a single roller bottle. For each experiment (n = 8), cells from a single population were exposed to four conditions (normoxia, normoxia + halothane, hypoxia, hypoxia + halothane) while being identically perfused. Perfusate oxygen tension was controlled by bubbling gas (1 L/min) of known oxygen concentration (normoxia—21% O_2, 5% CO_2, 74% N_2; hypoxia—4% O_2, 5% CO_2, 91% N_2) through the perfusate in a closed, 250-mL vacuum-evacuated Erlenmeyer flask until equilibration occurred (<5 min). Perfusate Po_2, Pco_2, and pH were analyzed (Radiometer ABL 30) in each circuit. Halothane 1% was added to one hypoxic and one normoxic gas mixture by diverting 1 L/min of the respective gases through a calibrated halothane vaporizer (Fraser-Harlake, Orchard Park, N.Y.). Halothane concentration was monitored by a calibrated Servo Gas Monitor 120 (Siemens, Schaumburg, Ill.) before, during, and after each experiment and was constant at 1%.

The perfusion rate (3 mL/min) of the cells was controlled in each circuit by using a single, multichannel, variable-speed, roller-head pump (Masterflex 7553-60; Cole-Parmer Instrument Co., Chicago, Ill.). Perfusate was pumped from the reservoir through the gassing flask to the cell cartridges (25-mm air monitoring cassette; Gelman Sciences, Ann Arbor, Mich.) and then onto a vacuum-extracted C_{18} Sep-Pak cartridge. At this perfusion rate, <4 min was required for oxygen tension in the cell cartridge perfusate to equilibrate with the gassing flask perfusate. Pressure measurements at locations proximal and distal to the cell cartridge showed that perfusate pressure increased linearly with increasing flow and was not measurably different across the cell cartridge. Perfusate pulsatile pressure at the experimental flow rate (3 mL/min) was 9/6 mm Hg (mean 7 mm Hg). The temperature of the perfusate was maintained at 37°C by immersing the reservoir, bubble chamber, and cell cartridges in servoregulated water baths (220 A; Fisher). Filter paper (0.8 μm; Gelman Sciences) was placed in the distal end of the cell cartridge to prevent loss of microcarrier beads and cells. Inspection under a phase-contrast microscope revealed no beads or cells. After perfusion, microcarriers inspected by phase-contrast microscopy demonstrated adherent cells that remained confluent and unchanged in physical appearance.

Experimental Protocol

For each experiment, four circuits were primed with Krebs' solution. The medium was aspirated from the roller bottle, and the microcarrier beads were washed three times with PBS (pH 7.4) and resuspended in 10 mL of Krebs' solution. Two-milliliter samples of this microcarrier bead suspension ($\sim 5 \times 10^6$ cells) were placed into each cell cartridge. A fifth sample was used as a nonperfusion control for protein quantitation. Ten minutes after initiating perfusion, nine successive 20-min aliquots of perfusate lipids were extracted with C_{18} Sep-Pak extraction cartridges (Waters Associates, Milford, Mass.) over the next 3 h.

The lipid portion of the filtrate was eluted from the C_{18} cartridges with methanol. The methanol was vacuum evaporated (Speed Vac Concentrator; Savant, Farmingdale, N.Y.) at 1700 rpm at 4°C and the sample stored at −20°C until assay. During each experiment, perfusate was collected from each circuit just proximal to the cell cartridge for oxygen, carbon dioxide, and pH measurement, as previously described.

Protein Assay

At the end of each experiment, each cell cartridge was washed with distilled water to remove the microcarrier beads and cells. The microcarriers were vortexed, and the quantity of cellular protein from the lysed cells was determined by the method of Bradford (23) (Bio-Rad, Protein Assay; Bio-Rad Laboratories, Richmond, Calif.) using bovine serum albumin as the standard.

Radioimmunoassay of Eicosanoid Release

The assays of 6-keto $PGF_{1\alpha}$, the stable metabolite of prostacyclin; thromboxane B_2 (TXB_2), the stable metabolite of thromboxane A_2 (TXA_2); and total peptidoleukotriene (LT) (C_4, D_4, E_4, F_4) were performed by standard radioimmunoassay techniques, as previously described (24). All assays were performed in duplicate and at room temperature, unless otherwise indicated. The dried lipid extracts were resuspended in 3 mL of 0.1% gelatin (PBS) with 0.02% sodium azide and 50 μL of antiserum (Advanced Magnetics, Cambridge, Mass.), 50 μL of tritiated eicosanoid (6-keto $PGF_{1\alpha}$, TXB_2, LT) (New England Nuclear, Boston, Mass.), and 100-μL samples in duplicate or 100 μL of standards (Advanced Magnetics) in triplicate were incubated in plastic test tubes (2 h for 6-keto $PGF_{1\alpha}$ and TXB_2; 2.5 h for LT at 4°C).

After incubation, 50 μL of 0.5% gelatin PBS was added to each assay tube for 10 min, followed by the addition of 1 mL of dextran-coated charcoal. After incubation in dextran-coated charcoal (10 min for $PGF_{1\alpha}$; 11 min for TXB_2; 15 min for LT), the samples were centerfuged at 2000 rpm for 15 min, and the supernatant, containing antibody-bound radiolabel, was decanted directly into scintillation vials (Beckman, Fullerton, Calif.) with 8 mL of scintillation cocktail added for liquid scintillation counting (Liquid Scintillation Counter; LKB Wallace, Washington, D.C.). The standard curve obtained was logit transformed, and sample potency estimates were calculated by least-square regression of the log dose logit transformation. Antisera used for 6-keto $PGF_{1\alpha}$ and TXB_2 had a cross-reactivity of <0.1% for all other antisera tested. Antisera used for LT had a reactivity for LTC_4 (55%), LTD_4 (100%), LTE_4 (57%), and LTF_4 (67%), and a cross-reactivity for LTB_4 (0.25%), 5-HETE (0.19%), and <0.01% for other prostaglandin products. In other experiments, recovery rates for known amounts of eicosanoid were >90%. The concentrations of 6-keto $PGF_{1\alpha}$ and LT were 10–100 times greater than the lower limit of detection (1.95 pg/0.1 mL) in >95% of the assays. For TXB_2, levels <1.95 pg/0.1 mL were counted as zero.

Table 1. Mean Oxygen, Carbon Dioxide, Hydrogen Ion, and Protein Concentrations of Each Circuit

	Po_2 (mm Hg)	Pco_2 (mm Hg)	pH (U)	Cellular protein (mg)
Normoxia	144 ± 5	30 ± 2	7.30 ± 0.03	0.25 ± 0.05
Normoxia + halothane	143 ± 5	30 ± 2	7.30 ± 0.03	0.26 ± 0.05
Hypoxia	50 ± 2*	28 ± 2	7.34 ± 0.03	0.27 ± 0.08
Hypoxia + halothane	51 ± 3*	28 ± 2	7.32 ± 0.03	0.21 ± 0.04

Mean ± SEM, $n = 8$.
$^*P < 0.001$ versus normoxia.

Statistics

Data are presented as mean ± SEM. Analysis of variance comparing eicosanoid release rates at different oxygen tensions, with and without halothane, over time was performed by a standard computerized statistical program (Crunch Software Corp., Oakland, Calif.). A significant difference among means was determined by the Newman-Keuls method (25). Paired t-tests were used to compare normoxic and hypoxic perfusate system data, with and without halothane. A P value <0.05 was considered significant.

Results

The oxygen tension of the perfusate was significantly lower during hypoxia compared with normoxia (Table 1). There were no differences in perfusate carbon dioxide tension or pH. The quantity of cellular protein recovered was similar from the normoxic and hypoxic circuits (Table 1) and did not differ from the nonperfusion (control) samples.

Because timed aliquots were collected, eicosanoid release (total eicosanoid eluted or released from the cell cartridges) could be quantitated per minute. The amount of eicosanoid released was indexed to the amount of cellular protein measured from each cell cartridge. Therefore, all eicosanoid release rates are expressed in nanograms per minutes per gram of cellular protein ($ng \cdot min^{-1} \cdot g\ protein^{-1}$). The means of the measured concentration of each eicosanoid determined were significantly greater than the lower limit of detection of the assay.

Release of 6-keto $PGF_{1\alpha}$, TXB_2, and LT did not vary over time during each of the four conditions tested. For example, 6-keto $PGF_{1\alpha}$ release over time is demonstrated in Figures 2 and 3. Because the mean release rates of the three different eicosanoids did not vary over time during all conditions tested, the release rates for each condition were combined and are summarized in Table 2. Hypoxia resulted in a significant increase in mean 6-keto $PGF_{1\alpha}$ release. Hypoxia did not alter TXB_2 ($P = 0.5$) or total LT ($P = 0.25$) release. Halothane caused a significant increase in

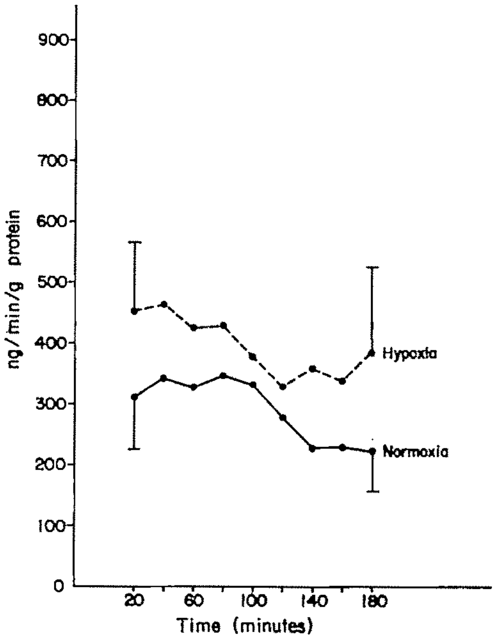

Figure 2. Mean 6-keto $PGF_{1\alpha}$ release ($ng \cdot min^{-1} \cdot g\ protein^{-1}$) over time during normoxia and hypoxia; $n = 8$, mean ± SEM. The 6-keto $PGF_{1\alpha}$ release did not significantly vary over time and was greater during hypoxia ($P \leq 0.01$).

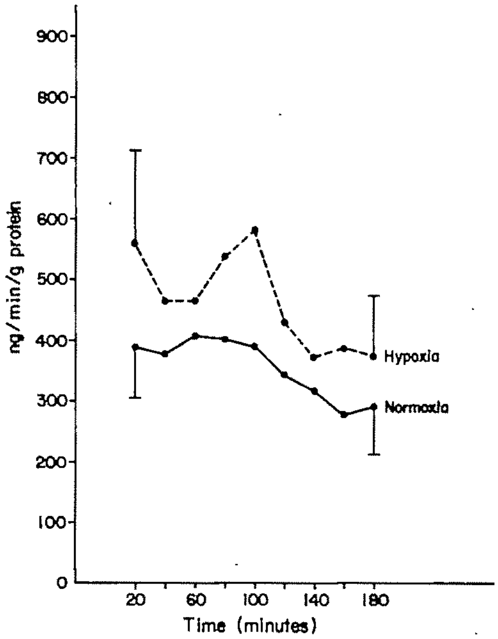

Figure 3. Mean 6-keto $PGF_{1\alpha}$ release ($ng \cdot min^{-1} \cdot g\ protein^{-1}$) over time during normoxia and hypoxia with halothane; $n = 8$, mean ± SEM. The 6-keto $PGF_{1\alpha}$ release did not vary over time and was greater during hypoxia.

Table 2. Mean 6-keto $PGF_{1\alpha}$, Thromboxane B_2 (TXB_2) and Leukotriene (LT) Release

	$PGF_{1\alpha}$ ($ng \cdot min^{-1} \cdot g$ $protein^{-1}$)	TXB_2 ($ng \cdot min^{-1} \cdot g$ $protein^{-1}$)	LT ($ng \cdot min^{-1} \cdot g$ $protein^{-1}$)
Normoxia	291 ± 27	19 ± 2	363 ± 35

[e] $P = 0.015$ versus normoxia with halothane.

mean 6-keto $PGF_{1\alpha}$, TXB_2, and LT release during both normoxia and hypoxia.

Discussion

Eicosanoid metabolites play a critical role in the regulation of vascular resistance, particularly in the pulmonary circulation (3–5,13,14). Numerous studies in a wide variety of experimental preparations have demonstrated the role of eicosanoids but have not directly demonstrated whether the endothelium plays a central role. These preparations, which include intact anesthetized animals, isolated perfused lungs, pulmonary vascular strips, and vessel loops, did not directly provide information concerning endothelial function. For example, hypoxia changes pulmonary vascular pressure and flow, and these changes could be responsible for secondary alterations in endothelial eicosanoid release (26–28). On the other hand, in static endothelial cell systems, important physiologic stimuli, flow, and pulsatile pressure are absent.

Perfusion-associated pressure and shear stress critically affect endothelial cell function, including cyclooxygenase activity (29,30). The use of endothelialized microcarriers, in addition to providing a large surface area, permitted the ubiquitous in vivo physiologic environmental factor, flow, to be incorporated into an isolated cell system (26–28). Indeed, in this preparation, flow is the primary stimulus to eicosanoid release (net eicosanoid eluted from the cell cartridges), which is then modulated by halothane and oxygen tension. Thus, it was possible to determine the effects of acute hypoxia and halothane on endothelium exposed to constant flow and pulsatile pressure, analogous to the in vivo situation but without the variability inherent in intact preparations. Therefore the response of perfused endothelium (eicosanoid release) during normoxia and hypoxia, with and without halothane, could be defined while controlling many of the above factors.

Inhaled anesthetics alter vascular tone and inhibit HPV (1,2). Several studies support the idea that inhaled anesthetics alter the release of eicosanoids by the pulmonary circulation in response to various stimuli, including hypoxia (6,8,10). These studies used organ systems and demonstrated prostanoid involvement by cyclooxygenase blockade; however, the source of these prostanoids could not be identified. The present study supports and extends these results by demonstrating that halothane increased eicosanoid release by perfused pulmonary endothelium. These data are consistent with modulation of endothelial eicosanoid release as a mechanism by which anesthetics could affect vessel tone and blunt HPV. Eicosanoids other than 6-keto $PGF_{1\alpha}$ were assayed to elucidate the spectrum of eicosanoid metabolism rather than only cyclooxygenase-dependent activity. The increase in all eicosanoids suggests an anesthetic effect proximal to cyclooxygenase in arachidonate metabolism. Inhaled anesthetics are known to interact with cell membranes (31). Potentially, anesthetics could alter endothelial arachidonate metabolism, which occurs in the lipid bilayer of cell membranes. Both prostaglandin and LT release were increased by halothane, indicating increased activity in both cyclooxygenase and lipoxygenase, and may cause arachidonate release from the cell membrane phospholipids, perhaps by increased phospholipase A_2 activity (13).

In this study, the endothelial release of eicosanoids was determined at two oxygen tensions that resulted from equilibrating perfusate with a normoxic (fraction of inspired O_2 [FIO_2] 0.21) and hypoxic (FIO_2 0.04) gas mixture. Although a PO_2 of 50 mm Hg is physiologic in the main pulmonary artery, a perfusate PO_2 of 50 mm Hg was selected because at this oxygen tension, the pulmonary vascular response to hypoxia is maximal (11). Prostacyclin release by perfused endothelial cells was acutely increased by hypoxia, and this response was sustained over 3 h (Table 2). These results are consistent with intact animal and isolated perfused lung studies (32–34) but differ from previous results in static cell populations exposed to acute and chronic hypoxia (15,16,35). These results underline the importance of perfusion as a factor in endothelial cell function. Halothane increased prostacyclin release similarly during both normoxia and hypoxia.

Several studies have reported conflicting conclusions concerning the role of thromboxane in HPV (17,36,37). Inhibitors of thromboxane synthetase did not prevent HPV in isolated, perfused rat lungs (37).

However, thromboxane was implicated in pulmonary venous constriction during hypoxia in isolated, perfused lamb lungs (36). Farber et al. (17) showed a transient elevation in thromboxane release during acute hypoxia using a static endothelial cell culture model. In our study, hypoxia did not alter thromboxane release, which implies that endothelial thromboxane release is unlikely to be involved in the pulmonary vascular response to hypoxia. Halothane increased TXB_2 release, but the release rate was quite low.

Numerous studies have reached conflicting conclusions concerning LT involvement in HPV (36,38–42). Leukotriene antagonists, as well as LT synthesis and receptor blockers, have been reported to inhibit HPV (38,39). In contrast, other studies have shown no role for LTs in HPV (40–42). These studies are complicated by the presence of multiple cell types (mast cells, leukocytes, platelets) that all potentially produce LTs in response to hypoxia. Leukotriene assays are problematic, due in part to the presence of protein in serum-containing media. In this study, the perfusate was a protein-free, buffered crystalloid solution. Although endothelium is not recognized as a significant source of LTs, isolated endothelial cells have been shown to possess lipoxygenase activity (43,44). The present study investigated total peptidoleukotriene release in isolated, perfused endothelial cells, which has not previously been (specifically) investigated. By assaying for total peptidoleukotriene production, as opposed to each peptidoleukotriene individually, the amount released may have been sufficient to be measurable. In addition, perfusion may have provided the shear stress to the lipid cell membrane that is necessary for measurable peptidoleukotriene production. Nevertheless, this release was not altered by hypoxia. Therefore, endothelial peptidoleukotriene release seems unlikely to mediate HPV.

Halothane increased the release of all assayed eicosanoids during both normoxia and hypoxia. In vivo, the local concentrations of endothelial eicosanoids and the response of the subjacent vascular smooth muscle determine the physiologic response. Because the relationship of the release rates in this system to in vivo eicosanoid concentrations is unknown, application of these data is largely qualitative. Prostacyclin is a potent pulmonary vasodilator and inhibits HPV (13). The effect of peptidoleukotrienes is less clear. Although in some species peptidoleukotrienes are pulmonary vasoconstrictors, in others, including cows, primates, and humans, they have little effect (45,46). In these species, the increased endothelial peptidoleukotriene release with halothane is unlikely to have any significant vascular effect. The release of TXB_2 is an order of magnitude less than that of prostacyclin and the LTs, and therefore its effect would be much less significant. For these reasons, it seems likely that the net vascular effect of increased endothelial eicosanoid release by halothane seen in this study would be decreased PVR, especially when PVR is elevated, as, for example, by hypoxia.

In conclusion, hypoxia stimulated endothelial prostacyclin release, consistent with endothelial attenuation of HPV by altered eicosanoid release. Halothane increased pulmonary endothelial eicosanoid release during both normoxia and hypoxia. Altered endothelial eicosanoid release may be an important mechanism by which halothane modulates vascular tone.

Acute Toxic Delirium in a Patient Using Transdermal Fentanyl

Robert B. Steinberg, PhD, MD, Deborah E. Gilman, MD, and Fielding Johnson III, MD

Departments of Anesthesiology, Psychiatry, and Medicine, Baystate Medical Center, Springfield, and Tufts University School of Medicine, Boston, Massachusetts

Recent advances in transdermal drug systems permit continuous delivery of medications to patients for a variety of indications. The development of such a system for fentanyl (Duragesic, Janssen Pharmaceutica) has greatly expanded the use of systemic fentanyl for patients with chronic pain. Using this device, serum concentrations of fentanyl reach a plateau after approximately 18 h and tend to remain stable thereafter (1). Few complications have been reported, of which nausea and somnolence are the most common (1,2). We report a case of acute toxic delirium in a patient who used transdermal fentanyl patches for 24 days.

Case Report

A 71-year-old woman with squamous cell carcinoma had undergone a hemimandibulectomy followed by maximal radiation therapy. She lived alone and was stable until 2 wk before admission, when she sought relief of increasing jaw pain. She was given a Duragesic 25-μg/h patch. When her pain persisted the next day, she was switched to a 50-μg/h patch and told to increase her dose by 25 μg/h once daily until pain control was achieved. Four days before admission, she again complained of pain despite the use of 125 μg/h of transdermal fentanyl. The next day, she began to hallucinate, and her family described her as having become delusional. Admission was arranged.

On the day of admission, the patient was using two 50-μg/h Duragesic patches and one 25-μg/h patch. The next day, she was given one tablet of 60-mg sustained-release morphine sulfate. On the third day, she said, "This is some kind of trick." She was confused during the evening, asking for breakfast and trying to get up to go home. Lorazepam (0.5 mg orally) was given at bedtime. On the fourth day, the transdermal fentanyl patches were replaced, and she was also given three doses of 60-mg sustained-release morphine sulfate during the day and an evening dose of lorazepam (0.5 mg). She appeared restless and spent the entire night pacing her room, confused and agitated. On the fifth day, she remained confused, agitated, and paranoid despite four doses of lorazepam (0.5 mg) and two 60-mg morphine tablets during the day. On the sixth day, the same pattern continued, despite the addition of haloperidol (0.5 mg) given by mouth. Serum concentrations of sodium, potassium, magnesium, calcium, vitamin B_{12}, and folate were normal; the urea nitrogen and creatinine concentrations were 44 and 2.2 mg/dL, respectively. A computed tomography scan of the head was essentially normal. She remained confused and agitated on hospital days 7–9. On the ninth day, psychiatric consultation was requested after full-time sitters were required, despite daily doses of haloperidol (up to 9 mg on day 9). The transdermal fentanyl patches, 100 and 25 μg/h, had been replaced on day 7.

Psychiatric assessment on day 9 revealed an elderly, cachectic woman standing beside her bed, picking aimlessly at the bedclothes. She had been incontinent of stool. Pupils were pinpoint. She was able to give only one- or two-word responses. She was oriented to the year but not to month, date, or place. She was able to name her daughter and sister (they were present in the room) but could not describe their relationships correctly. She was uncooperative with further mental status examination. Her affect was flat, and she was in no obvious pain. The psychiatrist diagnosed toxic delirium.

On the tenth hospital day, the transdermal fentanyl patches were removed, and intravenous morphine at 4 mg/h was begun. The next day the patient was dozing comfortably, able to ambulate with assistance to the toilet, and began to take fluids by mouth. She was no longer combative and denied experiencing pain. Her mental state improved so that sitters and antipsychotic medications were discontinued. She was maintained on modest doses of intravenous and oral morphine and required only general supportive care until her discharge to an extended care facility on hospital day 28. During this time, she was alert and oriented, reading books, listening to the radio, and visiting with family members.

Discussion

Fentanyl is a phenylpiperidine derivative, structurally related to meperidine. Like meperidine, it can be

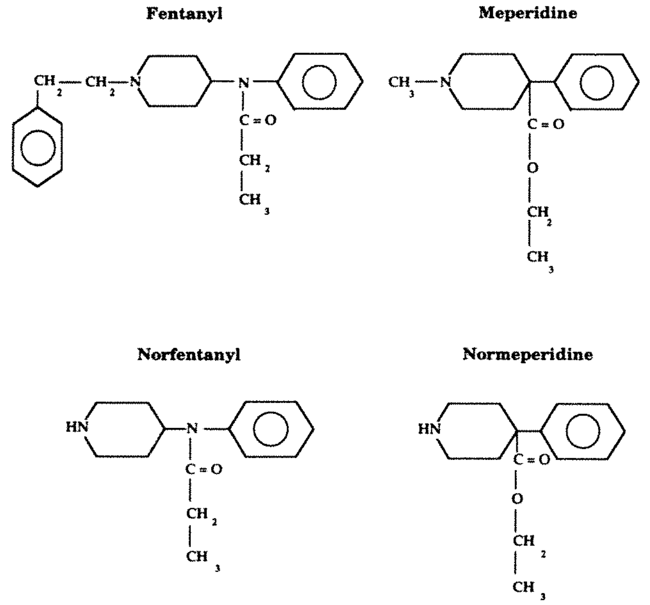

Figure 1. Chemical structures of fentanyl, norfentanyl, meperidine, and normeperidine. The structural similarity of norfentanyl to normeperidine is easily seen.

metabolized by *N*-demethylation, producing norfentanyl, which is structurally similar to normeperidine (Figure 1). Norfentanyl may be the principal metabolic degradation product of fentanyl in humans (3–5). It is excreted by the kidney and can be detected in the urine 72 h after a single intravenous dose of fentanyl (3). Animal studies suggest that norfentanyl has less analgesic potency than fentanyl (4). No detailed pharmacokinetic data or information concerning its physiologic effects in humans appears in the literature.

Normeperidine can accumulate in the serum and cause a variety of adverse effects in patients taking repeated doses of meperidine (6–8). Its serum half-life of 15–30 h is prolonged in patients with diminished renal function (6,7). Normeperidine appears to have antianalgesic properties and has been associated with negative mood alterations. It can cause a variety of central nervous system excitation effects, including tremors, myoclonus, and grand mal seizures (6,8). These adverse effects cannot be reversed with naloxone (6).

We suspect that norfentanyl began to accumulate in this patient's serum, perhaps accelerated by her advanced age, general debility, and renal insufficiency. The effects of age on fentanyl pharmacokinetics remain unclear. Singleton et al. (9) found that the clearance and elimination half-life of intravenous fentanyl in healthy elderly persons was the same as in a younger group. Two reports suggest that the elimination half-life of fentanyl in healthy adults after transcutaneous administration for 1 day is 16–21 h (10,11). Esteve et al. (12) confirmed this result in a group aged 30–65 yr but found that older patients (78–88 yr; $n = 6$) had an elimination half-life of 43 h. The effect of age, if any, on the clearance of norfentanyl is unknown. The potential actions of norfentanyl, toxic or otherwise, remain speculative; however, its structural similarity to normeperidine raises the possibility that it has similar physiologic effects. If so, it may have been responsible for the excitation and narcotic resistance demonstrated by our patient.

There are a number of other potential causes for this patient's delirium. Persons receiving potent opiates may experience a variety of subjective effects, including hallucinations and delirium. Such paradoxical reactions usually occur shortly after the opiate is administered and can be reversed with naloxone. A literature search revealed a single case report of acute delirium that occurred after intravenous administration of fentanyl (100 μg) (13). This patient's mental status returned to normal shortly after she received naloxone. Another report describes a case in which acute delirium followed general anesthesia during which the patient also received droperidol and epidural fentanyl. In this instance, no naloxone was administered, and the patient recovered gradually over 2 days (14). We also cannot exclude with certainty the possibility of an adverse reaction to one of her other medicines as a cause of her altered sensorium. However, all of these, except the transdermal fentanyl patch, were continued after the resolution of her delirium. The list of potential side effects of Duragesic noted in the package insert includes hallucinations, agitation, abnormal thinking, and paranoid reaction. However, the manufacturer was unable to provide any specific case histories to support this information (I.H. White, personal communication), and no published reports link transdermally administered fentanyl to these side effects.

Large doses of opiates may cause hypoventilation and hypoxemia, although this usually coincides with clinically obvious sedation. Hypoxemia occasionally presents as confusion. Neither arterial blood gases nor hemoglobin saturation was measured directly in this case, but the patient had normal pulmonary function and remained alert and active, even agitated, throughout the period of her confusion. She continued to complain of pain before her admission, despite the use of transdermal fentanyl (125 μg/h). The addition of up to 120 mg/day of oral morphine did not fully relieve her discomfort. This represents an opiate dose equivalent to more than 14 mg/h of morphine. In the subsequent absence of fentanyl, she remained comfortable while receiving only intravenous morphine at 4–5 mg/h. The absence of effective pain control and the clinical picture of an active patient suggest that opiate overdose with respiratory depression was not the major issue. It is unfortunate that this impression was not confirmed by a blood gas measurement.

In summary, we present a patient with renal insufficiency who experienced poor pain control and developed an acute toxic delirium while receiving transdermal fentanyl in doses of up to 125 μg/h. One day after the fentanyl patch was removed, her pain could be controlled with intravenous morphine at 4–5 mg/h, and her mental status abnormalities resolved without specific treatment. We suspect that accumulation of norfentanyl in her serum caused her narcotic resistance and delirium.

Prolonged Hypotension by Enalaprilat in a Case of Renal Artery Stenosis

Joseph Mirenda, MD, and Cowan Edwards, RPH

Departments of Anesthesiology and Pharmacy, Roanoke Memorial Hospital, Roanoke, Virginia

The use of angiotensin-converting enzyme (ACE) inhibitors has been a major advance for the treatment of both hypertension and congestive heart failure. Moreover, the introduction of the intravenous preparation enalaprilat has expanded the use of these drugs to the intraoperative and perioperative periods (1–3). As with outpatient use, however, intraoperative complications, such as severe hypotension or acute renal insufficiency, or both, may be seen when these drugs are used in the setting of high renin states such as renal artery stenosis (4,5). We describe a case of significant and prolonged hypotension associated with the intraoperative use of intravenous enalaprilat in a patient with undiagnosed renal artery stenosis. In retrospect, the severity of the complication confirms the dangers associated with ACE inhibitor use in conditions that constitute contraindications.

Case Report

The patient was a 36-yr-old, 98-kg, 155-cm woman admitted for lumbosacral vertebral decompression with Steffe instrumentation due to degenerative spine disease and segmental instability of segments L1–S1. Her past medical history was significant for a recent 4-mo history of diastolic hypertension (95–110 mm Hg) treated with alterations in diet and with diuretic therapy. The patient also admitted to cigarette smoking and a strong family history of hypertension. Preoperative physical examination was unremarkable except for moderate obesity. Arterial blood pressure was measured at 134/95 mm Hg (mean arterial pressure [MAP] 108 mm Hg) and heart rate at 90 beats/min. Serum potassium concentration was 3.6 mEq/L, and hematocrit was 36% (after predonation of two autologous whole units of blood).

The patient was first seen the morning of surgery, at which time she was given her diuretic (chlorothiazide, 500 mg by mouth) and midazolam (0.05 mg/kg intramuscularly). Before induction of anesthesia, electrocardiogram (leads II and V_5), digital pulse oximeter, radial artery, and central venous pressure monitoring were established. Anesthesia was induced with thiopental (5 mg/kg IV), droperidol (0.625 mg IV), and sufentanil (0.5 $\mu g/kg$ IV), and tracheal intubation was facilitated by administration of doxacurium (0.08 mg/kg IV). Radial artery blood pressure increased to 190/120 mm Hg (heart rate 122 beats/min) after tracheal intubation and was treated successfully with isoflurane, 2.0% inspired in oxygen, and an additional dose of sufentanil (0.25 $\mu g/kg$ IV). After insertion of an indwelling urinary catheter, the patient was positioned prone for surgery, ensuring an uncompressed abdomen and proper limb support. Anesthesia was maintained with sufentanil (0.25 $\mu g \cdot kg^{-1} \cdot h^{-1}$ IV) and 0.5% isoflurane inspired in a 70%/30% mixture of N_2O/O_2, with additional bolus doses of doxacurium (0.01 mg/kg) as needed for surgical relaxation. Ventilation was controlled mechanically and monitored capnographically.

On incision, the radial artery pressure was measured at 160/105 mm Hg (MAP 123 mm Hg), heart rate at 82 beats/min, and central venous pressure (CVP) at 6 mm Hg. In an attempt to minimize blood loss and facilitate surgical exposure, a MAP of 75–80 mm Hg was chosen to be achieved by a combination of increasing concentrations of isoflurane and sodium nitroprusside (SNP). Approximately 45 min after incision, and immediately before osteotomy, arterial blood pressure remained at 155/92 mm Hg (MAP 113 mm Hg), with a heart rate of 99 beats/min despite an isoflurane concentration of 3.0% and an infusion of SNP of 2.0 $\mu g \cdot kg^{-1} \cdot min^{-1}$. The CVP was 9 mm Hg, and urine flow was >1.0 $mL \cdot kg^{-1} \cdot h^{-1}$. As progressively higher infusion rates of SNP failed to significantly affect the MAP (to a dosage of 6.1 $\mu g \cdot kg^{-1} \cdot min^{-1}$), 0.625 mg of intravenous enalaprilat was administered as a third antihypertensive drug. Commencing approximately 10 min after administration, radial artery blood pressure diminished gradually. Within 20 min after enalaprilat administration, however, arterial blood pressure decreased to 65/32 mm Hg (MAP 43 mm Hg), with a heart rate of 79 beats/min despite withdrawal of the SNP and sufentanil infusions and isoflurane, as well as irrigation and packing of the wound by our surgical colleagues. Ventilation was controlled with 100% inspired oxygen. End-tidal CO_2 concentrations decreased from 36 to 25 mm Hg, and CVP diminished to 2 mm Hg. No air could be aspirated from the central venous catheter nor were murmurs heard through an esophageal stethoscope. The position of the abdomen

was examined for unusual compression or rotation from the initial prone position, although without comment. Radial artery pressure was increased with significant difficulty to 112/64 mm Hg (MAP 80 mm Hg) and CVP to 11 mm Hg with aggressive intravenous crystalloid and hetastarch resuscitation (3 and 1 L, respectively) and increment boluses of ephedrine (5 mg IV) and phenylephrine (50 μg IV), thus allowing reinstitution of the anesthetic and resumption of surgery. Urine output remained >1.0 mL·kg^{-1}·h^{-1}, and arterial blood gases revealed a lowest base deficit of -1.2 mEq. Surgery and anesthesia were completed without incident thereafter, with an estimated total blood loss of 650 mL.

Within the first 5 days postoperatively, the patient remained stable, except for consistent diastolic hypertension (110 mm Hg) and a slight increase in the serum creatine level (0.8 to 1.1 mg/dL). Within 1 mo of surgery, owing to her history of hypertension along with recent intraoperative events, the patient underwent an intravenous pyelogram and technetium DTPA (renal) scan that revealed a small, atrophic right kidney with poor uptake (respectively) as opposed to a slightly larger than normal left one with good isotope uptake. Differential renal vein renin determinations revealed a wide disparity between the opposing kidneys (16.2 ng·mL^{-1}·h^{-1} right; 2.8 ng·mL^{-1}·h^{-1} left). Eventual arteriography demonstrated a 95% luminal narrowing of the right renal artery, consistent with fibromuscular dysplasia. The patient underwent successful transluminal balloon dilation of the stenosis shortly thereafter, with resolution of her diastolic hypertension within the following 48 h.

Discussion

Renovascular hypertension resulting from renal artery stenosis accounts for up to 5% of the hypertension seen in the general population (6). Fibromuscular dysplasia of the renal arteries accounts for about one-fourth of all cases of renovascular hypertension, most commonly affecting young women (7). Atheromatous disease, on the other hand, constitutes the bulk of the remaining majority, although it most often afflicts older individuals with risk factors for (or known) atheromatous disease elsewhere.

The diagnosis of renal artery stenosis, and in particular fibromuscular dysplasia, requires a high index of suspicion and is often considered in the young, otherwise healthy, woman with severe diastolic hypertension (>110 mm Hg) (8). It can be argued that such a diagnosis should have been entertained preoperatively in our patient, although the combination of documented moderate diastolic hypertension (95–110 mm Hg) and a host of risk factors for essential hypertension (obesity, smoking, family history) incorrectly led to that diagnosis. This, unfortunately, is not uncommon. In fact, large series using arteriography in patients with risk factors for essential hypertension have detected some degree of renal artery stenosis in 32% of the normotensive patients and in 62% of the hypertensive patients in such series, which may or may not have contributed to the hypertension in the latter group (9).

It is interesting to note that arterial blood pressure responses to ACE inhibitors, and in particular captopril, have been used to diagnose renovascular disease despite evidence of poor sensitivity and specificity. Better established, though, is the good correlation between the hypertension control from long-term use of ACE inhibitor therapy and predictions of the surgical curability of renovascular hypertension (10,11). This "hypotensive" response is largely due to blunting of angiotensin II production from the stenotic kidney (secreting the majority of renin), with significant reductions in vascular resistance and, subsequently, arterial blood pressure. Our patient exhibited profound, refractory hypotension in conjunction with enalaprilat use, most likely due to the dangerous combination of high doses of two vasodilators and (relative) hypovolemia, the latter being unmasked by the inhibition of the chronic production of the vasoconstrictor angiotensin II. That the renin-angiotensin system, in addition, plays a role in the maintenance of blood pressure during anesthesia, including isoflurane anesthesia, may have contributed to the hypotension seen with use of the ACE inhibitor as well (12).

The hypertensive responses seen in our patient during anesthesia and surgery, despite what was judged to be an adequate depth of anesthesia, are entirely consistent with secondary forms of hypertension such as renal artery stenosis. Our attempt to decrease MAP, to facilitate surgical exposure and minimize blood loss, by the administration of an ACE inhibitor (as opposed to a β-adrenergic blocker or other antihypertensive drug) is entirely consistent with previous work (13,14). Administration of ACE inhibitors has been associated with significantly lower doses of SNP used to achieve deliberate hypotension as well as diminished plasma cyanide levels during SNP use. Although we did not suspect cyanide toxicity in our patient nor determine cyanide levels, the maximal dosage used (6.1 μg·kg^{-1}·min^{-1}) did approach recommended safe guidelines for administration (8.0 μg·kg^{-1}·min^{-1}).

We should note that at present, enalaprilat lacks Food and Drug Administration approval for use in deliberate hypotension, although its use is appropriate in cases of resistant hypertension seen perioperatively or otherwise.

It is certainly possible that etiologies other than enalaprilat administration, such as unrecognized hemorrhage, positioning errors, or air embolism, were responsible for the rather precipitous hypotension seen in this case. We believed, as did our surgical colleagues, however, that the former two reasons were satisfactorily ruled out. Although we could not definitely rule out the presence of air embolism as a cause of the hemodynamic collapse because our end-tidal CO_2 levels did decrease and we had not used end-tidal nitrogen or Doppler techniques in this case, our suspicions were minimized because of the lack of aspiration of air through the central venous catheter, the low CVP reading itself, and the modest accumulation of blood in the wound before the event. We eventually attributed the lowered end-tidal CO_2 measurements to poor pulmonary blood flow associated with the hypotension.

Of importance, the time frame involved from administration of intravenous enalaprilat to the hypotension is entirely consistent with the pharmacokinetics of the drug given its onset of approximately 15 min and peak effect of 30 min (15). In addition, enalaprilat, in doses as low as 0.5 mg IV, completely inhibits ACE activity for ≥60 min (3) and may explain the difficulty we experienced when attempting to increase our patient's blood pressure. The heart rate of 79 beats/min during the event, which was less than expected or previously recorded, especially in the absence of β-adrenergic blockade, is also consistent with the effects of the ACE inhibitor (16). This lack of reflex tachycardia, unlike the increases in heart rate seen with other afterload reducers, has yet to be adequately explained, although enhancement of parasympathetic activity (or disinhibition) (17) and a drug-induced venodilatory action have been suggested (18).

Although this case should serve to heighten our suspicion of renovascular disease in our patient's subgroup, it most importantly demonstrates the potential dangers of ACE inhibitor use, especially in conjunction with other potent vasodilators also used during anesthesia. Profound hypotension, associated with the use of these drugs, has also been reported intraoperatively as well as postoperatively, although often for reasons unknown at the time (19,20). Moreover, as our patient had unilateral renal artery stenosis with a normal contralateral kidney, the likelihood of acute renal failure precipitated by enalaprilat use was small. However, in patients likely to benefit from use of ACE inhibitors, specifically those with hypertension and concomitant peripheral vascular disease, the incidence of undetected, bilateral renal artery stenosis may be as high as 12% (21). Such patients may have a dramatic decrease in glomerular filtration rate and renal function as a result of ACE inhibitor therapy (4). This decrease in glomerular filtration rate is attributed to blunting of angiotensin II-mediated efferent arteriole constriction necessary to maintain glomerular capillary perfusion in patients with bilateral renal artery stenosis or stenosis in a solitary kidney (22). These conditions, as well as those of low intravascular volume, abnormal electrolyte status (i.e., hyponatremia), and effects of other vasoactive drugs, should be very familiar to the clinician before the consideration of administration of any ACE inhibitor.

In summary, we report a case in which unexpected and severe hypotension from intravenous enalaprilat use occurred in a patient with undiagnosed renal artery stenosis. It is hoped that this discussion will help more clearly define the appropriate guidelines for use of ACE inhibitors in the intraoperative and perioperative periods.

Electroencephalographic Monitoring of Cerebral Function During Asystole and Successful Cardiopulmonary Resuscitation

Thomas J. Losasso, MD, Donald A. Muzzi, MD, Frederic B. Meyer, MD, and
Frank W. Sharbrough, MD

Departments of Anesthesiology, Neurology, and Neurosurgery, Mayo Clinic, Rochester, Minnesota

Previous studies have documented changes in the electroencephalogram (EEG) that occur secondary to cerebral ischemia (1–3). During periods of complete global ischemia, such as occur after cardiac arrest, cerebral blood flow ceases. The functional (electrical) activity of the cerebral cortex, as monitored by the EEG, is abolished as a result of compromised cerebral oxygenation. Initially, there is a reduction in the high-frequency component of the EEG with an apparent increase in the low-frequency component; soon thereafter, the EEG becomes isoelectric. In a patient with generalized EEG suppression that occurs secondary to cardiac arrest, it is appropriate to assume that cerebral oxygenation due to cardiopulmonary resuscitation (CPR) is adequate in the setting of EEG recovery. In this setting, EEG changes associated with cardiac arrest and CPR are of significance.

Using seven-channel EEG monitoring in a patient undergoing carotid endarterectomy, Moss and Rockoff (4) described the changes in EEG activity that occurred during a brief period (27 s) of ventricular asystole and the prompt return of EEG activity with restoration of intrinsic cardiac rhythm and blood pressure. Using compressed spectral-array EEG monitoring in a patient undergoing carotid endarterectomy, Young and Ornstein (5) described the changes in spectral edge frequency during cardiac arrest and CPR. As pointed out by these authors, because they lacked a concurrent display of the raw EEG, they could not separate artifact from EEG activity during the time of resuscitation.

Neither of these cases describe changes in the raw EEG during manual chest compressions. We describe here a case of intraoperative cardiac arrest (of approximately 2-min duration) and the resulting changes in the raw EEG signal after initiating manual chest compressions and CPR in a patient undergoing carotid endarterectomy. This case demonstrates the time-course for EEG activity to return when effective manual chest compressions are initiated soon after cardiac arrest occurs. Additionally, this case suggests that EEG monitoring of cerebral function can provide useful information with regard to the adequacy of cerebral oxygenation during manual chest compressions and CPR in anesthetized patients experiencing cardiac arrest.

Case Report

A 72-yr-old man experienced several episodes of left hemispheric transient ischemic attacks. Carotid angiography revealed >95% stenosis of the left internal carotid artery, <15% stenosis of the right internal carotid artery, and filling of the left middle cerebral artery distribution during injection of the right carotid artery. The patient was scheduled to undergo a left carotid endarterectomy.

Past medical history was remarkable for chronic atrial fibrillation and non-insulin-dependent diabetes mellitus. The patient denied a history of angina or previous myocardial infarction. Preoperative echocardiography revealed an ejection fraction of 58% without regional wall motion abnormalities. Medications included digoxin and micronase. Preoperative electrocardiogram (ECG) was remarkable for atrial fibrillation with a ventricular rate of 78 beats/min and nonspecific ST-T wave abnormalities. The ECG was unchanged compared with an ECG obtained 3 yr earlier. Preoperative laboratory values revealed hemoglobin 14.8 g/dL, serum potassium 4.1 mEq/L, glucose 157 mg/dL, and digoxin 1.2 ng/mL (normal 0.5–2.0 ng/mL). Preoperative arterial blood pressure and heart rate ranged from 110/60 to 120/80 mm Hg and from 65 to 85 beats/min, respectively. The patient did not experience symptoms of cerebral ischemia within this blood pressure range during his 4 days of hospitalization before surgery.

On physical examination, there was no detectable neurologic deficit on the morning of surgery. Intraoperative monitoring included a blood pressure cuff, five-lead ECG, pulse oximeter, indwelling radial artery catheter, esopha-

geal stethoscope, esophageal temperature probe, peripheral nerve stimulator, mass spectrometer, and continuously monitored 16-channel EEG. Before the administration of any anesthetics, a baseline EEG was obtained. The baseline EEG was symmetric and without focal abnormalities suggestive of cerebral ischemia or infarction. After preoxygenation, anesthesia was induced with intravenous propofol (1.3 mg/kg) and fentanyl (2.7 μg/kg). Vecuronium (0.2 mg/kg IV) was administered to facilitate laryngoscopy and tracheal intubation. Anesthesia was maintained with a continuous infusion of propofol (30–70 $\mu g \cdot kg^{-1} \cdot min^{-1}$) and 50% N_2O in O_2. Blood pressure was maintained between 110/60 and 140/80 mm Hg, with a phenylephrine infusion as needed.

During surgical manipulation of the carotid artery, but before the endarterectomy, the patient's heart rate, which had ranged between 50 and 60 beats/min suddenly decreased and progressed to asystole <10 s later. The surgeons immediately discontinued manipulation of the carotid artery, but cardiac rhythm failed to return. Administration of propofol and N_2O was discontinued, the lungs were ventilated with 100% O_2, atropine (0.8 mg IV) was administered, and manual chest compressions were begun simultaneously. Epinephrine (1.0 mg IV) was administered soon thereafter, because no intrinsic cardiac rhythm could be detected when chest compressions were temporarily suspended.

Continuous recordings of the 16-channel EEG (longitudinal bipolar montage) were obtained immediately before, during, and after the period of asystole (Figure 1). Approximately 10 s after the onset of asystole, there was generalized suppression on the EEG that progressed to near isoelectricity soon thereafter. With institution of manual chest compressions, low-voltage high-frequency activity began to return approximately 15–20 s later. During pauses in CPR to assess the presence or absence of cardiac rhythm, low-voltage high-frequency activity was evident in most channels without gross asymmetry in EEG activity between corresponding channels of the left and right cerebral hemispheres. After the return of cardiac rhythm and termination of CPR, the EEG appeared similar to the recording obtained immediately before cardiac arrest.

Cardiac rhythm was not detected until approximately 2 min after the onset of asystole, at which time sinus tachycardia (heart rate increased to 180 beats/min) and systemic hypertension (arterial blood pressure increased to 220/120 mm Hg) developed. Intravenous esmolol, in 0.5-mg/kg increments, and a continuous infusion of nitroprusside were temporarily used to control heart rate and arterial blood pressure until the hemodynamic effects of the epinephrine subsided.

Hemodynamics stabilized, and the decision was made to proceed with the endarterectomy after infiltrating the carotid sinus with 2 mL of 2% lidocaine to prevent further episodes of bradycardia and asystole during carotid manipulation. Anesthesia was maintained with propofol and N_2O, and the endarterectomy was performed without further incident. The patient emerged from general anesthesia without a neurologic deficit and remained neurologically and hemodynamically stable throughout the perioperative period. The patient was discharged to home on the eighth postoperative day with normal neurologic function.

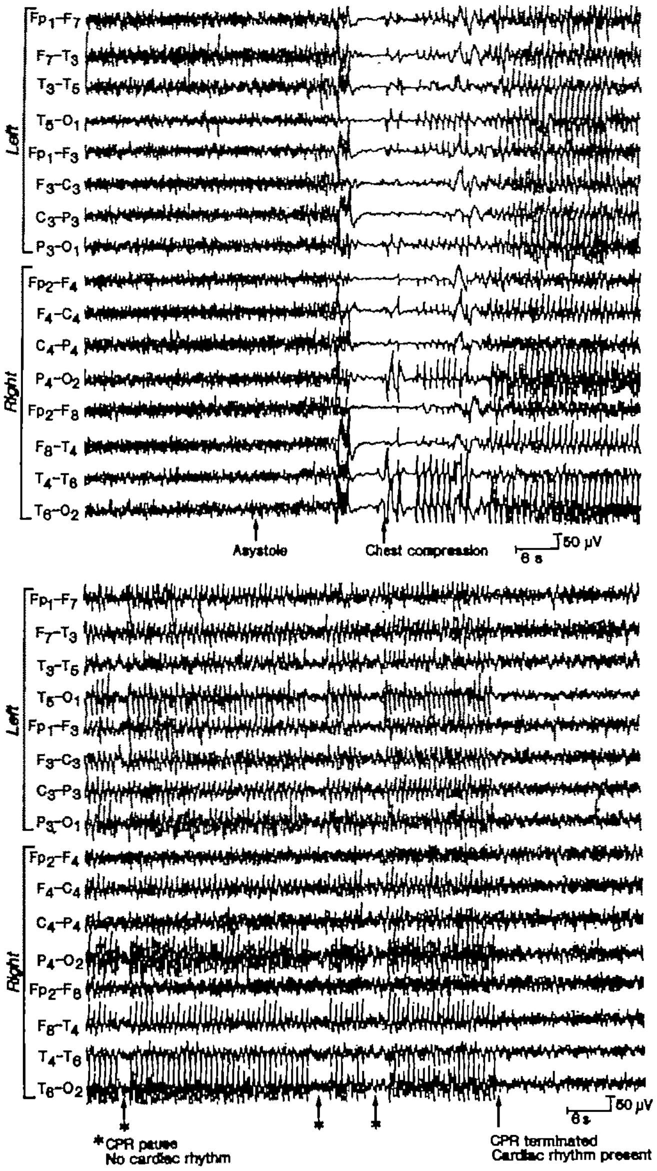

Figure 1. Continuous recordings of the 16-channel EEG obtained immediately before, during, and after the period of asystole. **Top.** Approximately 10 s after the onset of asystole, there was generalized suppression on the EEG, progressing to near isoelectricity soon thereafter. Manual chest compressions are responsible for the EEG artifact (biphasic spikelike activity) that is evident in most channels of the EEG. Amid this artifact, low-voltage high-frequency activity began to return approximately 15–20 s after initiating manual chest compressions. **Bottom.** Chest compressions were temporarily suspended to assess cardiac rhythm. In the absence of EEG artifact during these periods, low-voltage high-frequency activity is evident in most channels without gross asymmetry in EEG activity between corresponding channels of the left and right hemispheres. After the return of cardiac rhythm and the termination of chest compressions, the EEG appears similar to that observed immediately before the onset of asystole. CPR, cardiopulmonary resuscitation.

Discussion

We describe a patient who developed diffuse EEG slowing and suppression within 10–20 s after asystole occurred. This is consistent with experimental data in primates and humans. In a primate study of complete cerebral ischemia, the mean time to development of an isoelectric EEG was approximately 10–15 s (6). Similarly, after brief cardiac arrest in humans, the mean time to onset of EEG changes was approximately 10 s (7).

In the absence of specific measurements, such as regional cerebral blood flow, cerebral metabolites, or cerebral tissue acid-base status, it is not possible to eliminate the possibility that some degree of cerebral ischemia occurred during CPR. However, despite the amount of EEG artifact produced by chest compressions as well as the brief duration of CPR pauses during which time this artifact was absent, it is clear that low-voltage high-frequency activity was present in most, if not all, channels of the EEG during CPR. In addition, no channel demonstrated predominant slow-wave activity or complete absence of electrical activity, as would be expected to occur in the setting of severe cerebral ischemia. After the return of cardiac rhythm and arterial blood pressure, there was no evidence of gross cerebral cortical dysfunction on the EEG, because it appeared similar to the recording obtained immediately before the cardiac arrest.

Using a compressed spectral array, Young and Ornstein (5) observed a transient reduction in spectral edge frequency immediately after successful CPR in a patient undergoing carotid endarterectomy. With time, spectral edge frequency gradually increased toward the prearrest value. The authors speculated that transient cerebral ischemia may have been responsible for this observation, although the period of cerebral ischemia should have been brief. When CPR was terminated in our patient, there were no changes indicative of cerebral ischemia on the EEG. This suggests that cerebral oxygenation was adequate at this time and that if some degree of cerebral ischemia did occur during CPR, it must have been brief or mild, or both.

In our patient, high-frequency activity began to return to the EEG approximately 15–20 s after CPR was initiated. The return of this activity signaled the return of cerebral perfusion and oxygenation. The speed with which EEG activity returned was similar to that with which EEG activity was lost after the onset of asystole. It is likely that several factors are responsible for the rapid return of EEG activity after CPR was initiated. First, CPR was initiated soon after asystole occurred, thus preventing a prolonged episode of cerebral ischemia. Second, it is likely that well-oxygenated blood was essentially "standing by" in the arterial circulation and that restoration of cerebral blood flow with manual chest compressions quickly restored cerebral oxygenation, as evidenced by the rapid return of EEG activity.

Although it is appropriate to assume that cerebral oxygenation is adequate in the setting of EEG recovery, one cannot assume that the absence of EEG recovery would indicate poor CPR and cerebral oxygenation. Recovery of EEG activity depends on both the magnitude and duration of the ischemic episode as well as on the efficacy of CPR. Thus, it would have been possible to have a much longer period of ischemia before initiating CPR, with equivalently effective CPR during the resuscitation period, and have minimal or no recovery of EEG activity owing to the magnitude of the ischemic insult.

It is interesting that in this patient with a critical carotid stenosis there was no gross asymmetry evident on the EEG during manual chest compressions and CPR. As demonstrated on the preoperative angiogram, the patient had a hemodynamically insignificant atherosclerotic lesion (15% stenosis) of the right internal carotid artery with filling of the left middle cerebral artery distribution during injection of the right carotid artery. Therefore, although the patient had a >95% stenosis of the left internal carotid artery, blood was being supplied to the left cerebral hemisphere in the distribution of the left middle cerebral artery from the right internal carotid artery through the circle of Willis. Similar to the description of cerebral blood flow evident on the preoperative angiogram, during manual chest compressions and CPR, blood flow and oxygen supply to the cerebral hemisphere ipsilateral to the carotid stenosis were probably via the contralateral internal carotid artery and circle of Willis. The observation that asymmetric EEG changes of cerebral ischemia were notably absent during CPR probably relates to the fact that the right internal carotid artery and circle of Willis provided an essentially disease-free route for blood flow and oxygen delivery to the left cerebral hemisphere during manual chest compressions and CPR.

In conclusion, the 16-channel EEG can be a useful monitor of cerebral perfusion and oxygenation during CPR, because it provides a functional assessment of the cerebral cortex. Use of EEG monitoring during CPR, although not allowing us to rule out the presence of a small ischemic insult, did provide us with reassurance that manual chest compressions were effective and that there were sufficient cerebral perfusion and oxygenation to restore the electrical activity of the cerebral cortex after a brief period of EEG suppression.

Chiari I Malformation Presenting as Recurrent Spinal Headache

R. Michael Hullander, MD, Terrence D. Bogard, MD, David Leivers, FRCAnaes,
Deborah Moran, MD, and David M. Dewan, MD

Departments of Anesthesiology and Clinical Investigation, Naval Hospital, San Diego, California and the Department of Anesthesiology, Wake Forest University, Bowman Gray School of Medicine, Winston-Salem, North Carolina

Postdural puncture headache (PDPH) is a well-recognized complication after spinal anesthesia (1). When conservative treatment or epidural blood patch (EBP) fail, alternative causes of the headache need to be reconsidered. We present a previously unreported association of recurrent PDPH with a Chiari I malformation.

Case Report

A 31-yr-old woman (gravida 1, para 0), with an unremarkable medical history, received analgesia for labor via a lumbar epidural catheter. Subsequently, when she required cesarean section for failure of the labor to progress, satisfactory lumbar epidural anesthesia could not be established. Good surgical anesthesia was provided by subarachnoid block, although spinal needle placement proved technically difficult and required several attempts before successful dural puncture with a 22-gauge needle. The surgery and immediate postoperative period were uneventful. Although she reported a mild positional headache, her surgeon discharged her on the third postoperative day. However, over the following several days, the patient's headache became progressively more severe. The headache was associated with mild neck pain, which worsened when the patient was sitting or standing. Moderate relief was obtained by caffeine ingestion. On the sixth postoperative day, although afebrile, she developed hearing changes (echoing), visual disturbances (blurring and color distortion), and nausea. The diagnosis of PDPH was made. An EBP using 15 mL of autologous blood was administered, with marked improvement of all symptoms.

The patient had a recurrence of the headache 4 days later. The headache was similar in character to the original, but the severity had increased, causing her to awaken at night. In view of these symptoms, neurologic consultation was obtained before consideration was given to a repeat EBP. Although the physical examination was normal, a magnetic resonance imaging scan was ordered, which revealed a Chiari I malformation. During the recommended treatment of a 6-wk course of prednisone, her symptoms progressively improved, and she remains symptom free.

Discussion

The Chiari I malformation consists of displacement of the tonsils of the cerebellum through the foramen magnum and, possibly, into the cervical spinal canal (2). Banerji and Millar (3) state that the presenting features of the anomaly in adults are variable and may be deceptive, with the diagnosis only being made after radiologic investigation. The prognosis in such patients is good with conservative therapy, but when objective neurologic deficits develop, surgical decompression to establish free-flow cerebrospinal fluid (CSF) from the fourth ventricle may be required (4).

The prevailing opinion is that the herniation is secondary to congenital hydrocephalus (5). However, on the basis of several patients becoming symptomatic after placement of subarachnoid-peritoneal shunts, Welch et al. (6) postulated that it may be an acquired disorder. The common feature of both theories is that an increased gradient of CSF pressure develops between the brain and the spinal canal. A similar pressure differential, caused by CSF leakage, is also believed to account for the PDPH (7).

In this case, the presenting features were typical of PDPH. After conservative measures failed, an EBP was performed with initial success, supporting this diagnosis. Persistent PDPH is effectively treated by an EBP in approximately 95% of cases (8). Persistence or recurrence of a PDPH in obstetric patients neces-

sitates reviewing alternative causes for headaches, such as cortical vein thrombosis (9,10). Prolonged headache with neurologic signs may indicate a subdural hematoma (11,12) requiring specific investigation. The finding of a Chiari I malformation on magnetic resonance imaging scan in this case led to the possibility that the headache was secondary to the Chiari I malformation. Whether the spinal puncture unmasked a preexisting malformation or created the anomaly is unknown. In either case, the Chiari I malformation should be considered in the differential diagnosis of persistent PDPH. Although there are no reported cases of the administration of spinal anesthesia in patients with a symptomatic Chiari I malformation, we believe that the choice of anesthesia should take into account the risk of increasing the CSF pressure gradient between the brain and the spinal canal when the diagnosis is known.

Acute Respiratory Failure in a Patient With Acute Leukemia Undergoing Minor Surgery

Harald Groeben, Michael Thomas, MD, and Bernhard Grote, MD

Departments of Anesthesiology and of Hematology and Oncology, Heinrich-Heine-University, Düsseldorf, Germany

Advances in oncology therapy and interdisciplinary cooperation have improved the rate of remission and its duration in patients with leukemia. Interdisciplinary treatment includes the application of general anesthesia in patients (especially children) undergoing diagnostic procedures, implantation of long-term central venous catheters (Hickman, Broviac, Port-A-Cath), and surgical emergencies. We report a case of acute respiratory failure in a patient with acute leukemia and a white blood cell count $>100{,}000/mm^3$ (hyperleukocytosis).

Case Report

A 49-yr-old woman (67 kg, 166 cm) with acute myelogenous leukemia underwent general anesthesia for implantation of a Hickman catheter for continuation of chemotherapy. The patient had had slight chronic bronchitis that was treated with fenoterol. Preoperative lung function tests revealed only a slight reduction of the forced expiratory vital capacity in the first second (80% of predicted). Induction chemotherapy should have followed a schedule of thioguanine, cytosine arabinoside, and daunorubicin. Because of a high leukocyte count (white blood cell count before therapy of $279{,}000/mm^3$), a prephase of chemotherapy with low-dose continuously infused cytosine arabinoside ($50 mg/m^2$ daily) preceded implantation of the Hickman catheter by 3 days. This slight cytoreductive regime was completed with allopurinol, potassium hydrogencitrate, and controlled hydration to prevent tumor lysis syndrome. Leukopheresis was canceled because of low platelet and red blood cell count. Norfloxacin and amphotericin B solution were administered orally for prophylactic gut decontamination. Because of fever of unknown origin, empiric antibiotic treatment (ampicillin, ceftazidine, penicillin) was performed.

A chest radiograph and electrocardiogram 2 days before the intervention showed no abnormal findings. Routine laboratory findings included a white blood cell count of $234{,}000/mm^3$, hemoglobin 7.8 g/dL, platelet count $68{,}000/mm^3$, and prothrombin time 65% of control. Serum sodium and potassium and liver and kidney tests were within the normal range.

The patient was completely conscious and complained of slight dyspnea and moderate expectoration. Physical examination showed normal heart and lung status. Heart rate was approximately 110 beats/min, and arterial blood pressure was 140/80 mm Hg. Body temperature of 38.5°C was believed to be due to the tumor. The patient insisted on general anesthesia and therefore fasted overnight.

Anesthesia was induced with thiopental (400 mg IV), vecuronium (6 mg IV), and inhaled enflurane. The trachea was intubated, and anesthesia was maintained with enflurane, N_2O in O_2, and fentanyl (0.075 mg IV). Ventilation was controlled to maintain normocarbia. Oxygen saturation was 97%, and approximately 700 mL of lactated Ringer's solution was administered.

When surgery was completed, approximately 60 min after induction of anesthesia, the trachea was extubated. The patient showed spontaneous ventilation of 8.5 L/min at a rate of 16 breaths/min. She was orientated and complained of dyspnea, with an arterial O_2 saturation of 83% (on room air) measured by pulse oximetry. Application of O_2 via face mask (6 L/min) led to an arterial O_2 saturation of 91%. On auscultation, the lungs were clear. Arterial blood gas analysis showed Pao_2 54 mm Hg, $Paco_2$ 38.1 mm Hg, arterial pHa 7.40, and a calculated arterial O_2 saturation 87%. A chest radiograph (Figure 1) revealed an interstitial/alveolar pulmonary edema and a normal heart.

The trachea was reintubated, and controlled mechanical ventilation was established with a positive end-expiratory pressure of 8 cm H_2O. Blood gas analysis taken from an arterial catheter showed Pao_2 values between 160 and 250 mm Hg, with a fraction of inspired O_2 of 0.98. Pulse oximetry measured 99% arterial O_2 saturation. Serum calcium, potassium, and phosphorus were normal. Central venous pressure obtained through the Hickman catheter was approximately 4–6 mm Hg. An urethral catheter was inserted.

The patient was then transferred to the intensive care unit. Her status improved after mechanical ventilation and high-dose corticosteroid therapy. Her electrocardiogram was normal. Microbiologic specimens were negative. The cytoreductive prephase chemotherapy was continued, and the trachea was extubated on the third day postoperatively. Thioguanine, cytosine arabinoside, and daunorubicin therapy was then started. On the fifth day postoperatively, the

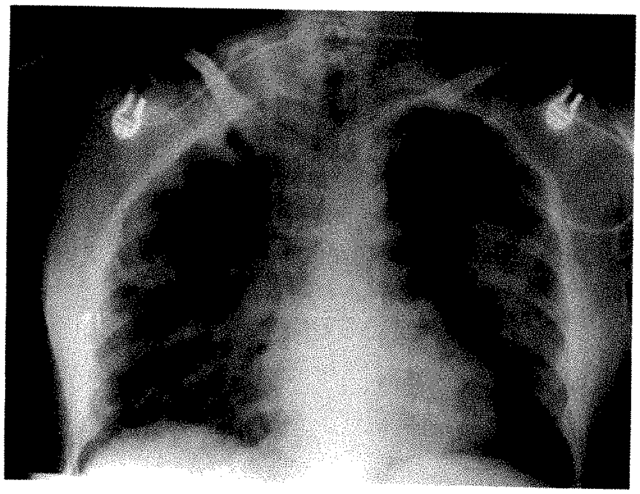

Figure 1. Anteroposterior radiograph of the chest obtained with portable apparatus in the supine position, taken in the immediate postoperative phase, revealing pulmonary edema of interstitial and alveolar pattern. The heart is of normal size, and a Hickman catheter is placed through the right internal jugular vein.

patient was admitted to the hematology ward. Two months later, she was discharged from hospital in complete remission.

Discussion

Because the patient had no history of cardiac disease, a normal electrocardiogram, central venous pressure of 4–6 mm Hg, and pulmonary edema with an interstitial/alveolar pattern, we concluded that she had developed a noncardiogenic pulmonary edema. Because aspiration of gastric contents and excessive intervascular volume could also be excluded, some particular features of leukemia and its therapy had to be considered to explain the acute respiratory failure. Acute dyspnea can be induced by the leukostasis syndrome as a symptom of the tumor lysis syndrome, or as a side effect of cytotoxic drugs.

Leukostasis syndrome describes the acute onset of pulmonary failure and, often, neurologic deficits in patients with hyperleukocytosis (1). Because leukocytes are less deformable than red blood cells, and blast cells are less deformable than mature cells, microvascular blood flow can be seriously affected (2,3). Moreover, the diameter of leukemic blast cells exceeds the internal diameter of capillaries and small vessels, leading to a mechanical obstruction of vessels by leukemic cells (1).

Activated by complement, leukocytes are capable of aggregating and marginating (i.e., sticking to the endothelium) (4,5), leading to parenchymal damage (1) by an exaggerated leukocytic oxygen consumption and the release of toxic respiratory "burst" products by the leukocytes (e.g., superoxide and proteases [elastase, collagenase]). Histologically, leukocyte thrombus, vessel occlusions, infiltration of the perivascular tissue, and parenchymal bleeding could be found (6).

The frequency of the syndrome is determined by the size, maturity, and number of leukocytes, so that approximately 15% of patients with chronic myelogenous leukemia, and only approximately 1% of those with chronic lymphocytic leukemia, develop leukostasis syndrome (7). This syndrome appears in the form of acute dyspnea and is often accompanied by confusion or disorientation and focal deficits due to cerebral perfusion impairment. Tinnitus, hearing loss, digital necrosis, priapism, retinal hemorrhage, and retinal vein distention sometimes occur (8). Neither hematocrit nor plasma viscosity is a predictor of leukostasis syndrome. Hematocrit does not change in these patients, because the increase in leukocyte count is compensated by a decrease in erythrocyte count, and plasma viscosity is not altered (3).

A typical sign for hyperleukocytosis is an alteration in arterial blood gas analysis. Chillar et al. (9) demonstrated in an in vitro study that Pa_{O_2} is significantly reduced within 30 s owing to exaggerated leukocytic oxygen consumption. With regard to the time necessary for drawing, cooling, and rewarming of the samples, cooling on ice can only prevent subsequent oxygen consumption during transport. Moreover, Loke and Duffy (10) showed a difference between the arterial oxygen saturation calculated from arterial blood gas analysis and that obtained by ear oximetry in patients with hyperleukocytosis. The authors observed a difference of 8% arterial oxygen saturation before cytoreductive therapy, which decreased to 2% after therapy. Thus, arterial blood gas analysis in patients with hyperleukocytosis is of questionable value, and the use of ear oximetry is recommended.

Leukostasis syndrome can be triggered by the application of red packed cells (11), deteriorating viscosity, or by surgery through complement activation (4). Leukostasis syndrome must be treated by cytoreduction via leukapheresis or cytotoxic drugs.

Patients with a large tumor cell mass (i.e., hyperleukocytosis) can develop tumor lysis syndrome in the first 2 days of chemotherapy (12). Lysis of a large number of tumor cells leads to hyperphosphatemia, hyperkalemia, hyperuricemia, and hypocalcemia. This syndrome is complicated by the precipitation of uric acid, xanthine, and phosphate in the renal tubules. This can impair renal excretory function, which in turn can lead to further elevation of these metabolites and even result in acute renal failure (3,12). In some cases of tumor lysis syndrome, acute respiratory failure occurs, induced by metabolites and cytolytic enzymes released from necrotic leukemic cells (1). Chest radiographs show a noncardiogenic pulmonary edema (1). Therapy requires, on the one hand, diuresis of $>3.0\ \mathrm{L{\cdot}m^{-2}{\cdot}24\ h^{-1}}$ to support renal function and, on the other, a negative fluid balance to treat pulmonary edema. Mechanical ventilation may be necessary, and high-dose corticosteroid therapy has been reported to be helpful (12).

Several chemotherapeutic drugs are responsible for acute or chronic respiratory failure. The only cytotoxic drug that was administered in our patient was cytosine arabinoside, which can cause a noncardiogenic pulmonary edema. This edema appears within the first 8 days of therapy and has a rapid onset within 1 or 2 h (13,14). This side effect was observed during cytosine arabinoside monotherapy of 300 $\mathrm{mg/m^2}$ to 1 $\mathrm{g/m^2}$ and more (13) and during therapy with low-dose cytosine arabinoside (100 $\mathrm{mg/m^2}$) in combination with other drugs (lomostine and daunorubicin) in up to 20% of treated patients (14). How the edema is initiated is not known, and no causal therapy has yet been established. Symptomatic therapy with oxygen applied via face mask, mechanical ventilation in severe cases, and high-dose corticosteroid therapy have been recommended (13).

In our patient, the discrepancy between the photometrically measured arterial oxygen saturation and that obtained by ear oximetry, the classification of a FAB M4/5 leukemia with hyperleukocytosis, the onset and development of dyspnea, the response to cell reduction, and the lack of tumor lysis signs (hyperphosphatemia, hyperkalemia, hyperuricemia, and hypocalcemia) led us to conclude that the patient had leukostasis syndrome that was associated with a noncardiogenic pulmonary edema.

Because of these particular features of leukemia and leukemia therapy, we conclude that the first days of chemotherapeutic therapy and hyperleukocytosis should be considered relative contraindications for general anesthesia and surgery. Anesthesiologists and surgeons who are responsible for the emergency care of these patients should be aware of the possible development of acute respiratory failure.

Change of Ectopic Supraventricular Tachycardia to Sinus Rhythm During Administration of Propofol

Robert Hermann, MD, and Jörg Vettermann, MD

Department of Anesthesiology and Resuscitation, Johann Wolfgang Goethe-University Clinic, Frankfurt, Germany

Paroxysmal supraventricular tachycardia is one of the most common dysrhythmias in infants and children. It is caused by altered normal automaticity of the sinus node or by abnormal automaticity of atrial cell compounds other than those responsible for normal pacemaker function (1,2). Perioperative provocation of such paroxysms by surgical stress or by anesthetic drugs should be avoided because persistent tachycardia may lead to congestive heart failure. Propofol anesthesia was administered to a child who had severe supraventricular tachycardia with paroxysms since birth. The child had been under close cardiologic monitoring, demonstrating that periods of regular sinus rhythm had been brief and extremely rare. Repetitive administration of propofol was associated with conversion to sinus rhythm, which remained stable for the entire surgical procedure.

Case Report

A 3.5-yr-old, 15-kg boy was scheduled for adenoidectomy and tympanic membrane incision because of recurrent otitis media. Such an infection had previously caused pneumococcus sepsis. The child suffered from supraventricular tachycardia based on ectopic monofocal atrial automaticity, suggesting a chronic ectopic atrial tachycardia (3). The surface electrocardiogram (ECG) showed narrow complex supraventricular tachycardia with marked changes in P-wave morphology during tachycardic episodes. The dysrhythmia had been diagnosed previously in utero and had to be treated with methyl-digoxin and verapamil. A therapeutic trial with propafenon and sotalol had been ineffective. Symptoms consisted of daily paroxysmal tachycardic episodes lasting 1–2 h, with heart rates of 200–250 beats/min. His prevailing "normal" heart rate was found to vary between 140 and 175 beats/min (ECG: ectopic atrial pacemaker) with brief periods at 75 beats/min (ECG: sinus rhythm with normal P-wave morphology). Paroxysms lasting longer than 60 min had previously caused clinical signs of congestive heart failure. The boy had therefore been under ECG monitoring at home. Although the tachycardic paroxysms occurred predominantly in the morning, no additional correlation with either physical activity or excitement or anxiety could be observed. No detailed invasive electrophysiologic procedures for focus localization had been performed, and the boy was scheduled for subsequent presentation in a cardiosurgical department to consider surgical excision of the ectopic focus.

On hospital admission, he was otherwise healthy and in good condition. In view of this, it was decided to dispense with a preoperative assessment with regard to left ventricular function. All laboratory findings were normal and serum potassium was 4.7 mmol/L. He was premedicated with a rectal instillation of 15 mg of midazolam, and he had received his regular oral morning dose of 40 mg of verapamil and one of his two daily doses of 0.05 mg of methyl-digoxin.

In the operating room, he appeared sedated and cooperative. A standard ECG lead II showed his heart rate to be 165 beats/min, arterial pressure 95/60 mm Hg, Sa_{O_2} 98% (pulse oximeter, Ohmeda, Biox 3700e). After well-tolerated preoxygenation, the child was anesthetized by injections of 2.7 mg/kg of propofol and 0.35 mg/kg of nalbuphine. On laryngoscopy, the glottis was wide open, and the trachea was intubated without using succinylcholine; neither bucking nor an increase in heart rate (still 165 beats/min) nor blood pressure occurred during intubation. An additional 20 mg of propofol was injected after intubation.

A few seconds later, his heart rate converted to a normal sinus rhythm at 75 beats/min (Figure 1). Anesthesia was maintained with repetitive injections of 10–20-mg doses of propofol approximately every 10 min while the boy's lungs were ventilated with an inspired fraction of O_2 of 0.3 and an inspired fraction of N_2O of 0.7. The surgical procedure was uneventful, and the child's sinus rhythm varied between 75 and 110 beats/min with an apparently normal P wave and was never interrupted by ectopic atrial or ectopic ventricular beats. Thirty-five minutes after tracheal extubation, his heart rate suddenly increased to 215 beats/min (ECG: ectopic atrial pacemaker) and did not return to the intraoperatively observed normal sinus rhythm (Figure 1). On arrival in the recovery room he was awake and cooperative, his heart rate subsequently declined to 160 beats/min, and his ECG was not different from that seen preoperatively. The child was discharged from the hospital in good condition,

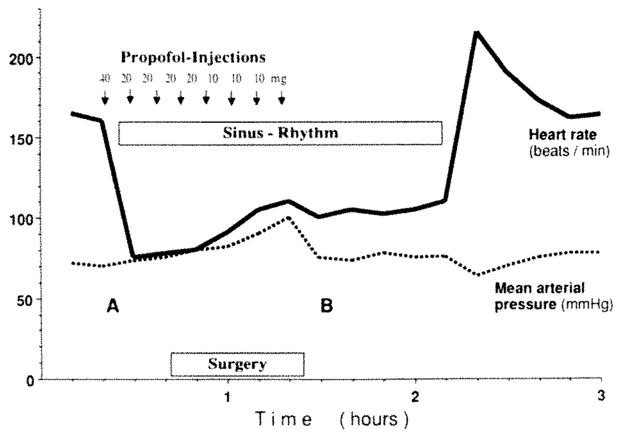

Figure 1. Diagram of heart rate and mean arterial blood pressure before, during, and after propofol anesthesia. On induction (**A**), supraventricular tachycardia converted to sinus rhythm, which converted back to supraventricular tachycardia 25 min after tracheal extubation (**B**).

and his dysrhythmias were not different from those observed before admittance.

Discussion

When considering all supraventricular tachycardias, the incidence of automatic atrial tachycardia is approximately 10% in children (4). Depending on the site of automaticity, these tachycardias can be subcategorized as inappropriate sinus tachycardia or chronic ectopic atrial tachycardia. The changing P-wave morphology suggests that our patient most likely had chronic ectopic atrial tachycardia (3). Paroxysmal tachycardia is characterized by sudden increases in heart rate to up to 250 beats/min. They may occur several times per day and may last from a few minutes up to 1 h, rarely longer (1).

The mechanisms thought to be responsible for these arrhythmias are disturbance of ionic membrane potentials, leading to an altered automaticity, extra sinoatrial focus sites, or AV node reentrant tachycardia (2,3). Among the external mechanisms triggering such supraventricular tachycardias are stress, drugs, ischemia, organ system disease, or electrolyte imbalance (2). Congestive heart failure and pulmonary edema may occur if the duration or the extent of the increase in heart rate decreases ventricular performance or ventricular filling, respectively. In addition, sustained automatic atrial tachycardia may lead to tachycardia-induced cardiomyopathy. Therefore, any surgical trigger stimulus should be suppressed, a concern of the anesthesiologist when choosing the anesthetic technique (5,6).

The rapidly acting hypnotic agent propofol (2,6-diisopropylphenol) has a short duration of action and is suitable for both induction and maintenance of anesthesia, either by continuous or by intermittent intravenous application (7).

Administration of propofol was found to have minimal effects on heart rate and rhythm, with even a tendency to lower heart rate (7). Propofol anesthesia is associated with a resetting of the tachycardiogenic baroreceptor reflex such that heart rate remains stable despite the drug's dose-related property to lower blood pressure (8). The comparably small sympathetic hemodynamic responses to endotracheal intubation during propofol induction, especially in combination with a narcotic agent (9), determined our choice of drugs. It seems unlikely that the observed change from supraventricular tachycardia to sinus rhythm in our patient was caused by nalbuphine because it has been found to leave myocardial function unaltered (10). We are unaware that nitrous oxide may affect myocardial conduction or sinus node automaticity.

Propofol, however, suppresses pacemaker automaticity and causes slowing of atrial conduction times in atrial preparations of rabbits and guinea pigs. This action of propofol was similar to the action of a local anesthetic. From another study in dogs it was concluded that the decreased activity of the sinus node after administration of propofol resembled an anion antagonistlike action, such as seen with alinidine (11).

In search of propofol's molecular site of action, a voltage-clamp study in human cell preparations found propofol to significantly prolong action potential-associated sodium channel conductance (12). Even though clinical relevance of such experimental findings remains to be proved, these results suggest a possible mechanism by which propofol may have converted tachycardic ectopic atrial pacemaker activity to sinus rhythm in our patient.

We cannot rule out that a decrease in sympathetic tone or an increase in vagal activity as a mere result of inducing general anesthesia may have contributed to the conversion to normal sinus rhythm. However, the observation that previous general anesthesia with halothane/nitrous oxide, which had been administered to our patient 3 yr earlier, left his ectopic supraventricular tachycardia almost unaltered suggests that the beneficial action of propofol was not simply caused by a nonspecific effect on the autonomic nervous system.

If propofol does possess a protective action against abnormal myocardial automaticity, further studies are needed to compare propofol with volatile anesthetics that may have both dysrhythmic and antidysrhythmic actions (2).

In summary, we report conversion of prevalent supraventricular tachycardia to normal sinus rhythm in a patient receiving propofol anesthesia. Previous administration of a volatile anesthetic to the child had not resulted in such normalization of the heart rate. Our observation indicates that propofol may be an appropriate anesthetic drug for patients with supraventricular tachycardia.

Epidural Anesthesia in a Parturient Patient With Congenital Absence of the Inferior Vena Cava

Nicholas J. Marsh, DO, and Robert S. Dorian, MD

Department of Anesthesiology, Saint Barnabas Medical Center, Livingston, New Jersey

The congenital absence of the inferior vena cava (IVC) is uncommon (1,2). In these persons, venous drainage from structures below the diaphragm is diverted to collateral channels, including the azygous system, vertebral vessels (3), and superficial vessels in the abdominal wall (4). Although anomalous IVC occurs in 0.6% of patients with heart disease (5) and 1.0% of patients undergoing cardiac catheterization (6), the incidence of absent IVC is unknown. Pregnancy may adversely affect vascular malformations, resulting in serious complications (7).

Formation of the IVC (8) coincides with organization of the heart (9,10), liver (1,10), spleen (11), and lung (12,13) and rotation of the bowel (1) and formation of the pleuropericardial membrane (14). Coexisting abnormalities influence management of patients with anomalous or absent IVC. Pulmonary anomalies, such as arteriovenous malformations and dysgenesis of the bronchi (13), may disrupt oxygenation during positive pressure ventilation. Circulatory changes in the vertebral column (15) may profoundly affect subarachnoid and epidural techniques of regional anesthesia. We report the use of epidural regional anesthesia in a parturient patient with congenital absence of the IVC.

Case Report

A 34-yr-old woman (72 kg, 160 cm) was admitted for elective induction of labor at 41-wk gestation. Her history included hospital admission 1 yr previously for ruptured esophageal varices. During an exploratory laparotomy under general anesthesia, multiple vascular abnormalities were found, including congenital absence of the IVC and left renal vein. Devascularization of the stomach, splenectomy, and cholecystectomy were performed. Hemoglobin oxygen desaturation complicated the anesthetic course, the cause of which was not clearly understood. Postoperative respiratory insufficiency and hypoxia required mechanical ventilation for several weeks, but eventually the patient stabilized. Additional medical history included vascular insufficiency of the lower extremities, left renal insufficiency, and mitral valve prolapse. Physical examination on current admission was remarkable for stasis ulcerations, venous congestion and severe edema of the lower extremities, and numerous dilated superficial abdominal vessels. Laboratory studies were all normal.

Lactated Ringer's solution was administered through a peripheral venous line, and labor was induced by administration of oxytocin. Arterial blood pressure was measured by noninvasive oscillometric blood pressure machine. The patient requested epidural analgesia. In the sitting position, numerous dilated superficial veins were noted in the posterior lumbar region. A 17-gauge Tuohy needle was introduced into an area of skin devoid of superficial vessels and, using air loss-of-resistance technique, gently advanced to the epidural space via midline approach. Sterile saline solution (10 mL) was injected and the epidural catheter advanced into the space with no resistance. The catheter was tested with 2% lidocaine (2 mL) with 1:200,000 epinephrine. The patient was monitored closely for evidence of intrathecal or intravascular injection over a 5-min period; 0.25% bupivacaine (5 mL) was then administered in fractionated doses. After good onset of analgesia to a T-10 level, a continuous epidural infusion of 0.0625% bupivacaine and fentanyl (2.7 μg/mL) was started at 10 mL/h while the patient was positioned with left pelvic tilt.

Labor progressed well for 2.5 h, when fetal bradycardia occurred and persisted despite increased left lateral position and administration of supplemental oxygen. Maternal vital signs remained normal. Fetal heart rate was improved by Trendelenburg's position and appeared stable in this position for 45 min. However, serial fetal scalp samples revealed deteriorating acid-base status. When bradycardia recurred, the decision was made to deliver by cesarean section.

After the placement of pulse oximetry and an electrocardiogram, 2% lidocaine (10 mL) with 1:400,000 epinephrine was incrementally administered. Intense analgesia to a T-2 level was obtained within 7 min and cesarean section was performed uneventfully, delivering a normal male infant. The placenta was normal. Estimated blood loss was 450 mL. The epidural catheter was easily removed. Conva-

lescence was uneventful, and on the fifth postoperative day mother and baby were discharged.

Discussion

During her previous experience with general anesthesia, our patient had encountered complications that may have been related to coexisting anomalies. Pulmonary abnormalities in similar patients include pulmonary dysgenesis (13), consisting of multiple branched, redundant bronchi with bronchial atresia, and arteriovenous malformations (12). Resultant intrapulmonary shunting may worsen during pregnancy (16). Positive pressure ventilation may further impede oxygenation by increasing dead-space ventilation (17) and may promote the rupture of pulmonary vascular anomalies with life-threatening consequences (18). Although aspiration of blood or respiratory distress syndrome from multiple transfusions may have contributed to the prolonged hypoxia during her first general anesthesia, coexisting pulmonary abnormalities had not been excluded. Repeating general anesthesia was considered undesirable. Regional anesthesia imparted several advantages: it allowed spontaneous ventilation to continue during surgical delivery, may have limited intraoperative blood loss (19), and improved uteroplacental blood flow during labor (20).

Patients with anomalous IVC have an increased epidural venous blood flow (2) that may be enhanced during pregnancy. Compression of the azygous-hemiazygous vessels may promote epidural blood flow changes analogous to caval compression. In some patients, however, predominance of venous return through superficial abdominal vessels may result in minimal epidural changes.

Management of regional anesthesia in these patients should include testing the position of the catheter with epinephrine-containing solutions (21) and slow, fractionated delivery of anesthetic, because accidental venous cannulation is more likely (22). Positioning the epidural needle with loss-of-resistance to air avoids confusing the clinical indices of accidental dural puncture in the presence of abnormal vertebral anatomy (23). Lubricating the epidural space with saline solution may facilitate passage of the catheter and minimize the chance of vessel injury (24) and epidural hematoma formation (25,26). Smaller doses of anesthetic are needed, because the enlarged venous compartment limits the epidural space and enhances the spread of anesthetic (27). Highly lipid-soluble local anesthetics or additional epinephrine may also minimize systemic uptake (28).

In patients with significant clinical deterioration during pregnancy or coexisting cardiac abnormalities, invasive monitoring should be considered during labor. In those without compromise, however, noninvasive monitoring may be adequate, eliminating the risk of placing catheters into potentially anomalous vessels.

Alleviation of maternal hypotension and uteroplacental insufficiency by left lateral position (29,30) may be ineffective in these patients. Left lateral tilt had no significant impact on fetal heart rate decelerations in our case, but Trendelenburg's position improved the fetal condition without compromising the mother's vital signs.

This case demonstrates epidural regional anesthesia for labor and cesarean section in a patient with congenital absence of the IVC. Associated systemic abnormalities must be considered during the management of such patients, with particular attention to the increased blood flow in the epidural space and its implications.

We thank Dr. David Hollander, Department of Obstetrics and Gynecology, Saint Barnabas Medical Center, for his assistance in the preparation of this manuscript.

Glossopharyngeal Nerve Block for Carotid Sinus Syndrome

Kazuhisa Kodama, MD, Norimasa Seo, MD, Takanori Murayama, MD,
Yuriko Yoshizawa, MD, Kiyoshi Terasako, MD, and Toshio Yaginuma, MD

Departments of General Medicine and Anesthesia and Critical Medicine, Omiya Medical Center, Jichi Medical School, Omiya, Japan

---

Carotid sinus syndrome (CSS) is caused by hyperactivity of the carotid sinus reflex and is categorized as type 1, cardioinhibitory; type 2, vasodepressor; and type 3, mixed. Syncope and dizziness are common symptoms (1,2). Several therapeutic measures have been recommended for CSS, including cardiac pacemaker implantation, radiation, surgical denervation of the carotid sinus, and various drug therapies. However, an optimal treatment for CSS has not yet been established (3). We report a case of mixed-type CSS secondary to a malignant lymphoma of the pharynx, the symptoms of which were completely ameliorated by a glossopharyngeal nerve block.

Case Report

A 76-yr-old man with a left cervical mass was admitted to the coronary care unit with repetitive syncopal episodes. During this admission, he developed a sinus bradycardia of 36 beats/min, followed by severe hypotension (56/36 mm Hg). Left carotid sinus massage reliably reproduced his symptoms. Computed tomography of the neck and biopsy of the cervical mass revealed a malignant lymphoma of the pharynx involving the left carotid sinus. We diagnosed a mixed-type CSS due to a malignant lymphoma of the pharynx. His symptoms were refractory to temporary cardiac pacing and combined drug therapy with atropine sulfate (1.5 mg/day), midodrine hydrochloride (6 mg/day), and fludrocortisone acetate (1 mg/day). A left selective glossopharyngeal nerve block was performed to reduce the afferent impulse from the left carotid sinus. A 5-cm insulated needle was inserted at the midpoint between the angle of the mandible and the tip of the mastoid process. The needle was advanced to the styloid process and then drawn back to the skin and reinserted anterior to the styloid process with intermittent electrical stimulation and continuous aspiration through the needle. The needle was advanced until the patient felt a vague, oppressive sensation radiating to his left external ear canal and epipharynx. No evidence of cranial nerve stimulation was noted, and no blood was aspirated during insertion of the needle. Three milliliters of 1% mepivacaine was injected through the needle. Five minutes later, the left and right carotid sinus reflexes were compared with each other. Left carotid sinus massage induced less bradycardia than that on the right (Figure 1). Correct needle position was confirmed by plain roentgenography of the basal skull and computed tomography of the neck (Figure 2). The glossopharyngeal nerve block was effective until the anesthetic action of the injected mepivacaine disappeared. Two days later, 1 mL of pure ethanol was injected to obliterate the left glossopharyngeal nerve. Since then, the patient has had a complete remission of symptoms.

Discussion

Cardiac pacemaker implantation is the preferred treatment for type 1 CSS. However, it is less effective for types 2 and 3 CSS because the restoration of a normal heart rate does not result in normotension (3). In these patients, treatment options include the administration of vasoconstrictive agents or procedures to reduce the afferent outflow from the carotid sinus. A permanent glossopharyngeal nerve block may relieve a patient with a mixed-type CSS from recurrent syncope and circulatory collapse.

Selective glossopharyngeal nerve block is a relatively difficult procedure and is associated with a number of potential complications (4,5). Nerve block may be more difficult in a patient with a neck tumor, owing to displacement of the glossopharyngeal nerve. To avoid injury to nearby nerves and vessels, we used an insulated needle with intermittent electrical stimulation and continuous aspiration. Correct needle position was determined by the patient's reporting a vague sensation radiating to the area supplied by the glossopharyngeal nerve. A decreased heart rate response to the carotid sinus massage compared with that on the unblocked side after infiltration of a local anesthetic provided further evidence of correct placement. Finally, the position of the needle was confirmed by plain roentgenography of the basal skull and computed tomography of the neck.

In conclusion, we report the effectiveness of a

Dorsal Primary Ramus Nerve Block for Treatment of Low Back Pain After Epidural Analgesia

Michael R. Trindle, MD, and Warren R. McKay, MD

Department of Anesthesia, University of California, San Francisco, California

New low back pain due to intrathecal or epidural injection is a puzzling and often frustrating problem for the anesthesiologist. This is especially confounding when the back pain is associated with radicular symptoms indicating, at least to the patient, that the injection may have resulted in nerve damage. Most anesthesiologists attribute postepidural back pain to local trauma and reassure patients that this will resolve in a few days. Other causes of back pain after epidural or spinal anesthesia might include needle puncture of an intervertebral disk or flattening of the normal lumbar lordosis owing to muscle relaxation, thus allowing stretching of the joint capsules and ligaments beyond their physiologic range (1). However, the problem becomes more complicated when the back pain either persists or radicular symptoms become evident.

Back pain after intraspinal injection may be similar to that in facet syndrome. Pain is of an aching quality in the lower lumbar region, with or without radiation to the buttock or posterior thigh. Tenderness is elicited with palpation over the paraspinal muscles or facet joints, or both (2). In our experience, the so-called facet syndrome responds well to blockade of the dorsal primary ramus, which innervates the facet joint. Dorsal primary ramus nerve block achieves the same goal as facet joint injection but with more complete analgesia of the posterior midline structures. In this report, we discuss two patients who presented to the Pain Management Center at the University of California, San Francisco, with prolonged midline back pain after epidural anesthesia. Their pain was completely relieved with dorsal primary ramus nerve blocks at the levels indicated by local back pain symptoms. This is the first report of such treatment for postepidural back pain.

Case Reports

Case 1

A 36-yr-old woman (58 kg) had a peroneal nerve injury with foot drop after a total hip replacement, under general anesthesia, for degenerative arthritis. In the immediate postoperative period, she noted pain in the foot; her foot was also cool and moist. One month later, she was referred to the Pain Management Center, where a diagnosis of reflex sympathetic dystrophy was made. Of note, the patient did not complain of back pain on her initial presentation to the Pain Management Center. After a lumbar sympathetic block with a single bolus injection of 0.5% bupivacaine (6 mL), the patient expressed moderate-to-good pain relief, and increased skin temperature and blood flow were noted; however, analgesia lasted for only 2 days. Administration of a second sympathetic block (0.25% bupivacaine, 10 mL) produced adequate sympathectomy but no pain relief.

Considering the failed sympathetic block and the probability of a primarily neuropathic pain syndrome, we elected to pursue a course of epidural analgesia. An initial, single bolus epidural injection of 0.125% bupivacaine (10 mL) with fentanyl (50 μg) at the L3-4 level resulted in good pain relief. Subsequently, the patient was admitted to the hospital for a continuous epidural infusion of 0.0625% bupivacaine (12 mL/h) and fentanyl (50 μg/h) via a catheter placed at the L2-3 level. The patient experienced good pain relief during the epidural infusion; however, the patient's pain recurred whenever the infusion rate was reduced. Because of this breakthrough pain, it was elected to continue the patient's treatment with epidural infusion, at initial rates, as an outpatient. This was facilitated by the home therapy service, which arranged a home infusion pump and follow-up management. Before discharge, a third epidural puncture (L3-4) for catheter replacement was performed. An inadvertent dural puncture at this time necessitated a fourth epidural injection (L2-3) for blood patch.

We elected to terminate treatment with epidural infusion and manage the patient's pain medically with a regimen of tricyclic antidepressants and prazosin. However, she developed persistent midline low back pain at the L3-4 level, with radiation to the lateral right leg. In addition, examination revealed tender right paraspinous muscle spasm but no neurologic deficits other than the foot drop, which preexisted the epidural punctures. We elected to

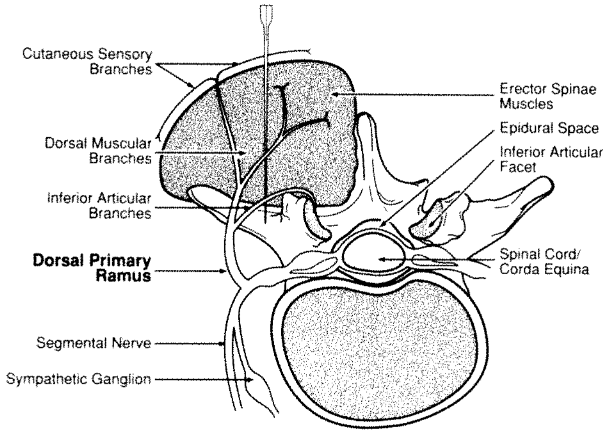

Figure 1. Segmental innervation of the dorsal spinal structures. Posterior elements are innervated by the dorsal primary ramus. The needle rests at the junction of the transverse process (medial one-third) with the dorsal lumbar process of the vertebral body, as in administration of a dorsal primary ramus nerve block. (Adapted from Boas [Reference 2], page 200, with permission.)

treat the patient using dorsal primary ramus nerve blocks at the L3 and L4 levels.

Dorsal primary ramus nerve blocks were performed according to the technique described previously by Boas (2) (Figure 1). Twenty-two-gauge spinal needles were advanced under fluoroscopy to the junction of the transverse process with the dorsal lumbar process of the vertebral body bilaterally at the L3 and L4 levels. Two milliliters of 0.5% bupivacaine was injected at each of the four sites. Within 30 min, her back pain was completely relieved (pain score 6/10 before injection; 0/10 after injection) and has not recurred 12 mo later.

Case 2

A 36-yr-old woman (52 kg) complained of 1.5 yr of localized midline back pain after epidural analgesia (via a catheter placed at the L3-4 level) for vaginal delivery. Her pain was constant, midline, and without radiation. It was worse in the prone position, while flexing at the waist, or while carrying her child. Her back pain was refractory to physical therapy and a single intraligamentous steroid injection (L2-3 level) performed in the orthopedic clinic. Her physical examination was significant for a decrease in muscle strength in the right leg secondary to a childhood history of polio and local tenderness at the L2 and L3 interspace in the midline, as well as over the adjacent facet joints. She underwent bilateral L2 and L3 dorsal primary ramus nerve blocks (2) with 0.5% bupivacaine (2 mL per injection at each of four sites) with complete relief of her pain. Two months later, pain recurred, and she again underwent dorsal primary ramus nerve blocks, this time with a mixture of 0.5% bupivacaine (1.5 mL) and triamcinolone (15 mg) at each injection site. Steroid was added to the treatment regimen in an attempt to achieve longer lasting pain relief. Her pain was completely relieved and has not recurred approximately 22 mo later.

Discussion

Epidurally administered local anesthetics or narcotics, or both, are often used for treatment of various pain syndromes. When the epidural injection itself causes an additional persistent pain problem, frustration and disappointment can result. Although effective therapy for persistent back pain induced by intraspinal injection has not been described, our success in two patients with a dorsal primary ramus nerve block is encouraging.

That a dorsal primary ramus nerve block may be successful has some anatomic and scientific basis. As early as the mid-1930s, it was recognized that as much as 80% of back pain with sciatic radiation was due to referred pain and not direct nerve irritation (3). In 1933, Ghormley (4) used the term "facet syndrome" to describe the syndrome of back pain with sciatic radiation presumed secondary to disorders of the vertebral facet joint, not to direct nerve root compression. In 1985, Peng and colleagues (5) reported a reduction of prolonged backache after lumbar puncture from 3% to 0% using a field block technique to anesthetize posterior midline structures before intraspinal injection.

Posterior midline structures, including the facet joint, are richly innervated with somatic and autonomic nerves. Yet, despite the attention placed on the anatomy of dorsal structures in the performance of epidural and spinal anesthesia, many anesthesiologists may be unfamiliar with the innervation of these structures. In 1956, Stillwell (6) described the innervation of the vertebral column and associated structures in primates. His findings were confirmed in humans by Pedersen et al. (7). The posterior midline structures are innervated mainly by the dorsal primary ramus of each spinal segmental nerve. Rami communicantes connect spinal and sympathetic ganglia and allow autonomic fibers to refer to the dorsal primary ramus. Somatic axons from the dorsal primary ramus are similarly communicated back to the autonomic plexus that surrounds the vertebral artery. Branches from the dorsal primary ramus, carrying somatic and autonomic fibers, innervate the posterior longitudinal ligament, interspinous and flaval ligaments, sacrospinalis muscle, lumbodorsal fascia, and facet joints. Branches of the paravertebral plexus supply the anterior longitudinal ligament, dura mater, annulus fibrosis, periosteum, and bone (6–8) (Figure 1). Because axons from the segmental nerves enter the paravertebral plexus before distribution, there is some overlap of innervation. Also, facet joints receive dual innervation, with the inferior articular surface being innervated by the segmental nerve at its level and the superior articular surface being innervated by the segmental nerve one level cephalad (2). This may explain why the patient in case 2 experienced pain one level below her initial epidural injection.

The performance of a routine epidural anesthetic encroaches on many of the posterior midline structures. Ligaments are initially penetrated, periosteum may be contacted, and the dura may be encroached on during the passage of the epidural catheter. A misdirected needle can trespass on muscle, fascia, periosteum, dura, and even facet joints. Local trauma may be increased in the patient who requires multiple epidural anesthetics or multiple attempts at localizing the epidural space. Although direct trauma may cause localized pain, persistent or radiating pain requires further explanation.

In 1939, Kellgren (9) demonstrated that local trauma caused by injection of hypertonic saline into interspinous ligament resulted in patterns of local and referred pain in a segmental distribution. Similar referral patterns were found after injection of muscle, fascia, tendons, and periosteum. Basically, local pain caused by injection of hypertonic saline was referred to other areas with the same spinal segmental innervation (9,10).

Persistent or radiating back pain after epidural anesthesia can be explained on the basis of the innervation of dorsal structures as well as knowledge of pain referral patterns. The rich innervation of posterior structures with somatic and autonomic fibers can explain pain as a result of trauma to tissues innervated by the posterior segmental nerves. Pain is referred, as proposed by Kellgren (9), to more distal areas innervated by the same segmental nerve and maintained either sympathetically or somatically owing to muscle spasm.

In summary, we present two cases of persistent back pain after epidural analgesia successfully treated with dorsal primary ramus nerve blocks. To our knowledge, this is the first report of this therapy for back pain after intraspinal injection. We propose that this back pain is caused by local trauma to nerves innervating structures trespassed during the injection. It remains to be determined whether repeated injections or multiple attempts to identify the "difficult" epidural space may more commonly precipitate this pain. Pain is referred in a spinal segmental pattern. Pain is relieved with a dorsal primary ramus nerve block by interrupting the sympathetic or somatic cycle that maintains the pain. We suggest that early consideration be given to dorsal primary ramus nerve block as a potential treatment for persistent back pain after intraspinal anesthesia.

The editorial assistance of Winifred Von Ehrenburg in the review and preparation of this manuscript is greatly appreciated.

Continuous Stellate Ganglion Blockade for Reflex Sympathetic Dystrophy

Alan Owen-Falkenberg, MB, BCh, DEAA, and Karsten Skovgaard Olsen, MD

Department of Anaesthesia and Intensive Care, Glostrup Hospital, University of Copenhagen, Denmark

Reflex sympathetic dystrophy (RSD) is a syndrome comprising burning pain, hyperalgesia, and allodynia alone or in combination with vasomotor and dystrophic changes and may be related to peripheral nerve injury (1). Sympathetic blockades are often performed to relieve the symptoms of RSD. Both central sympathetic ganglion blockade using a local anesthetic and Bier block with guanethidine or reserpine have been employed with varying success (2). Such treatments are often performed as a series of sympathetic nerve blocks. The following case describes a new method for the continuous blockade of the cervical sympathetic ganglia in a patient resistant to other forms of treatment.

Case Report

A 31-yr-old woman presented with several months' history of piercing pain in her right shoulder, with occasional radiation to the right hand. Symptoms of RSD were present in the right hand in the form of color change, hyperhidrosis, and allodynia. A diagnosis of brachial plexus neuritis after minor trauma 2 yr earlier had been made based on the clinical picture and an electromyographic examination that showed evidence of denervation plus delayed polyphasic potentials. Previous therapy with simple analgesics, oral steroids, massage, trigger point injections, and transcutaneous nerve stimulation plus a series of Bier blocks with guanethidine had failed to relieve the shoulder pain or reduce the sympathetic overactivity. The patient presented with severe pain, a score of 9 using a visual analogue scale (VAS 0–10), and she had about 10 episodes of sympathetic overactivity daily. She was taking no medication.

A sympathetic blockade of the stellate ganglion provided pain relief, after which it was decided to perform a continuous blockade of the ganglion. After locating the transverse process of C7 using an intravenous cannula (gauge 17 Venflon), an epidural catheter was threaded into position on the suface of the same transverse process. The catheter was sutured to the skin and covered with a sterile translucent plaster. A test dose of 1% lidocaine (8 mL) resulted in Horner's syndrome, and the catheter was then attached to a transportable infusion pump with a 100-mL cassette (Figure 1). A mixture of 0.25% bupivicaine with 4 mg morphine/100 mL was infused at a rate of 6–8 mL/h. During this treatment, the patient became symptom free. At the end of 7 days, the treatment was stopped, and the patient was asked to score shoulder pain and the number of episodes of sympathetic overactivity. Pain score (VAS) had decreased from 9 to 5 and sympathetic overactivity from 10 to 2 episodes daily.

During the following weeks, a series of four continuous blockades using a new catheter and each lasting 3 days was performed, during which the patient was symptom free and after which the pain score (VAS) and sympathetic episodes had been further reduced to 2 and 0, respectively. The improvement is still present several months later, although a tendency for relapse of the shoulder pain during exertion (e.g., badminton) is an irritation to the patient.

Discussion

Although the pathophysiology of RSD is poorly understood, it is well known that increased sympathetic activity reduces the threshold of nociceptors. The fact that many of the symptoms of RSD are relieved by sympathetic blockade is supportive of the theory that the pain in RSD is sympathetically maintained (3).

Single injection of the stellate ganglion has provided pain relief of longer duration than the action of the local anesthetic would suggest. In cases in which central sympathetic blockade provides relief of symptoms, it would seem logical to give a continuous blockade instead of single shots. This approach will result in a prolonged absence of sympathetic overactivity, at the same time reducing the input of painful afferent stimuli to the central nervous system, thus reversing the process of central hyperexcitability and increasing the likelihood of a return to a more normal discrimination of pain information (4).

Morphine was added to the infusion to maintain the maximal level of sensory analgesia (5). This morphine may in fact have had an effect on sensory perception via intrinsic local anesthetic properties (6)

Accepted for publication July 1, 1992.

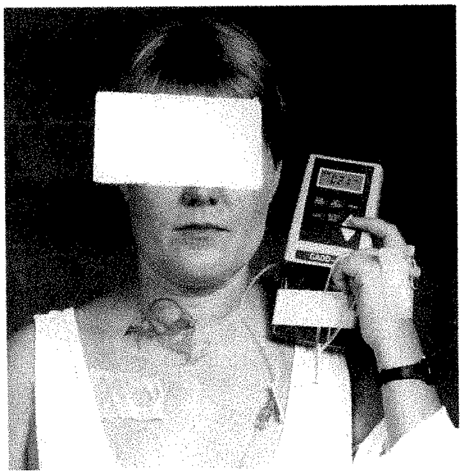

Figure 1. The patient with an epidural catheter connected to a portable infusion pump.

and on centrally placed morphine receptors via diffusion to the dorsal column of the spinal cord.

Although there is no anatomic space that can be located in the same way as the epidural space, an epidural catheter could be placed in close relation to the sympathetic ganglia on five successive occasions and a continuous sympathetic blockade achieved. There were no signs of toxicity to the local anesthetic, and infusion rates of the same order of magnitude are used to treat postoperative pain in our hospital.

The technique is thus an alternative to the established method consisting of a series of "single-shot" injections in RSD. The technique is only suitable for patients who can be admitted to the hospital for observation during the period of infusion.

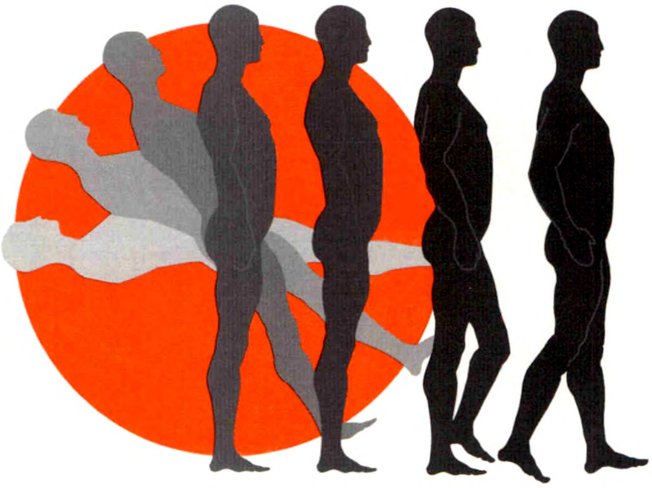
Only one nondepolarizer provides



complete, spontaneous **recovery*** **in less than 20 minutes**

Now for longer cases...

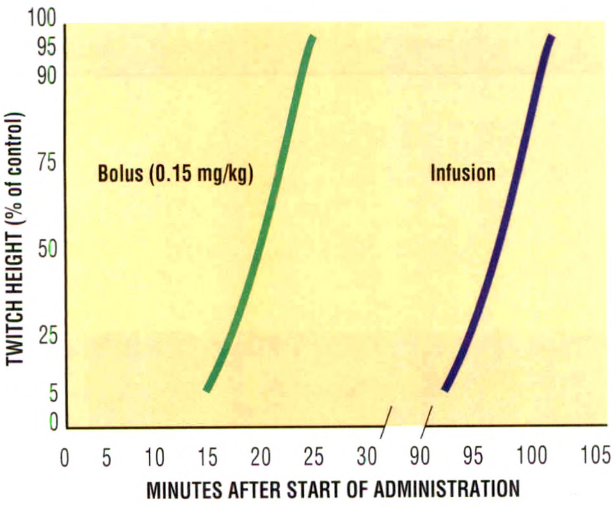
---

* from discontinuation of infusion

MIVACRON®
(mivacurium chloride)

Complete spontaneous recovery in less than 20 minutes*

Fast recovery following bolus or infusion



Adapted fom Savarese et al, p. 727.[1]

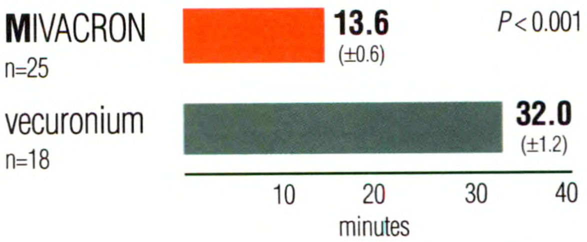
Noncumulative—minimal rate adjustments needed

Continuous infusion for up to 2.5 hours is not associated with tachyphylaxis or cumulative neuromuscular block in ASA Physical Status I-II patients (data for infusions > 2.5 hours are limited).

> "Steady-state levels of block may be produced rapidly with minimal adjustment of the infusion rate and a consistent rate of recovery occurs...."

Ali et al, p.544.[2]

Recovery time less than half that of vecuronium



Spontaneous recovery time (from discontinuation of infusion) 5-95%. Duration of continuous infusion for MIVACRON: 86.2 ± 5.6 minutes; for vecuronium: 96.8 ± 6.6 minutes.

Adapted fom Ali et al, p. 544.[2]

*from discontinuation of infusion

Important note: Patients homozygous for the atypical plasma cholinesterase gene (1 in 2500) are extremely sensitive to Mivacron. Mivacron should be used with great caution, if at all, in these patients.

by Infusion

Minimal CV effects

During clinical trials with bolus dosing, the only adverse event with an incidence >1% was transient flushing (15%). No patient who received a 0.15 mg/kg bolus dose was treated for a decrease in blood pressure. Higher bolus doses (≥ 0.20 mg/kg, adults; ≥ 0.25 mg/kg, children) may be associated with transient decreases in MAP and increases in HR in some patients. During infusion, no significant CV effects were reported.

Individualization of infusion dosages

- Renal or hepatic disease
- Patients heterozygous for the atypical plasma cholinesterase gene

MIVACRON® INJECTION
MIVACRON® PREMIXED INFUSION
(MIVACURIUM CHLORIDE)

Brief Summary

This drug should be administered only by adequately trained individuals familiar with its actions, characteristics, and hazards.

INDICATIONS AND USAGE: MIVACRON is a short-acting neuromuscular blocking agent indicated for inpatients and outpatients, as an adjunct to general anesthesia, to facilitate tracheal intubation and to provide skeletal muscle relaxation during surgery or mechanical ventilation.

CONTRAINDICATIONS: MIVACRON is contraindicated in patients known to have an allergic hypersensitivity to mivacurium chloride or other benzylisoquinolinium agents, as manifested by reactions such as urticaria or severe respiratory distress or hypotension. Use of MIVACRON from multi-dose vials is contraindicated in patients with a known allergy to benzyl alcohol.

WARNINGS: MIVACRON SHOULD BE ADMINISTERED IN CAREFULLY ADJUSTED DOSAGE BY OR UNDER THE SUPERVISION OF EXPERIENCED CLINICIANS WHO ARE FAMILIAR WITH THE DRUG'S ACTIONS AND THE POSSIBLE COMPLICATIONS OF ITS USE. THE DRUG SHOULD NOT BE ADMINISTERED UNLESS PERSONNEL AND FACILITIES FOR RESUSCITATION AND LIFE SUPPORT (TRACHEAL INTUBATION, ARTIFICIAL VENTILATION, OXYGEN THERAPY), AND AN ANTAGONIST OF MIVACRON ARE IMMEDIATELY AVAILABLE. IT IS RECOMMENDED THAT A PERIPHERAL NERVE STIMULATOR BE USED TO MEASURE NEUROMUSCULAR FUNCTION DURING THE ADMINISTRATION OF MIVACRON IN ORDER TO MONITOR DRUG EFFECT, DETERMINE THE NEED FOR ADDITIONAL DRUG, AND CONFIRM RECOVERY FROM NEUROMUSCULAR BLOCK.

MIVACRON HAS NO KNOWN EFFECT ON CONSCIOUSNESS, PAIN THRESHOLD, OR CEREBRATION. TO AVOID DISTRESS TO THE PATIENT, NEUROMUSCULAR BLOCK SHOULD NOT BE INDUCED BEFORE UNCONSCIOUSNESS.

MIVACRON IS METABOLIZED BY PLASMA CHOLINESTERASE AND SHOULD BE USED WITH GREAT CAUTION, IF AT ALL, IN PATIENTS KNOWN TO BE OR SUSPECTED OF BEING HOMOZYGOUS FOR THE ATYPICAL PLASMA CHOLINESTERASE GENE.

MIVACRON Injection and MIVACRON Premixed Infusion are acidic (pH 3.5 to 5.0) and may not be compatible with alkaline solutions having a pH greater than 8.5 (*e.g.*, barbiturate solutions).

PRECAUTIONS:

General: Although MIVACRON (a mixture of three stereoisomers) is not a potent histamine releaser, the possibility of substantial histamine release must be considered. Release of histamine is related to the dose and speed of injection.

Caution should be exercised in administering MIVACRON to patients with clinically significant cardiovascular disease and patients with any history suggesting a greater sensitivity to the release of histamine or related mediators (*e.g.*, asthma). In such patients, the initial dose of MIVACRON should be 0.15 mg/kg or less, administered over 60 seconds; assurance of adequate hydration and careful monitoring of hemodynamic status are important (see **Hemodynamics** and **Individualization of Dosages** subsections of CLINICAL PHARMACOLOGY).

Obese patients may be more likely to experience clinically significant transient decreases in MAP than non-obese patients when the dose of MIVACRON is based on actual rather than ideal body weight. Therefore, in obese patients, the initial dose should be determined using the patient's ideal body weight (see **Hemodynamics** and **Individualization of Dosages** subsections of CLINICAL PHARMACOLOGY).

Recommended doses of MIVACRON have no clinically significant effects on heart rate; therefore, MIVACRON will not counteract the bradycardia produced by many anesthetic agents or by vagal stimulation.

Neuromuscular blocking agents may have a profound effect in patients with neuromuscular diseases (*e.g.*, myasthenia gravis and the myasthenic syndrome). In these and other conditions in which prolonged neuromuscular block is a possibility (*e.g.*, carcinomatosis), the use of a peripheral nerve stimulator and a dose of not more than 0.015–0.020 mg/kg MIVACRON is recommended to assess the level of neuromuscular block and to monitor dosage requirements (see **Individualization of Dosages** subsection of CLINICAL PHARMACOLOGY).

MIVACRON has not been studied in patients with burns. Resistance to nondepolarizing neuromuscular blocking agents may develop in patients with burns, depending upon the time elapsed since the injury and the size of the burn. Patients with burns may have reduced plasma cholinesterase activity which may offset this resistance (see **Individualization of Dosages** subsection of CLINICAL PHARMACOLOGY).

Acid-base and/or serum electrolyte abnormalities may potentiate or antagonize the action of neuromuscular blocking agents. The action of neuromuscular blocking agents may be enhanced by magnesium salts administered for the management of toxemia of pregnancy (see **Individualization of Dosages** subsection of CLINICAL PHARMACOLOGY).

No data are available to support the use of MIVACRON by intramuscular injection.

Renal and Hepatic Disease: The possibility of prolonged neuromuscular block must be considered when MIVACRON is used in patients with renal or hepatic disease (see **Pharmacokinetics** subsection of CLINICAL PHARMACOLOGY). Most patients with chronic hepatic disease such as hepatitis, liver abscess, and cirrhosis of the liver exhibit a marked reduction in plasma cholinesterase activity. Patients with acute or chronic renal disease may also show a reduction in plasma cholinesterase activity (see **Individualization of Dosages** subsection of CLINICAL PHARMACOLOGY).

Reduced Plasma Cholinesterase Activity: The possibility of prolonged neuromuscular block following administration of MIVACRON must be considered in patients with reduced plasma cholinesterase (pseudocholinesterase) activity.

Plasma cholinesterase activity may be diminished in the presence of genetic abnormalities of plasma cholinesterase (*e.g.*, patients heterozygous or homozygous for the atypical plasma cholinesterase gene), pregnancy, liver or kidney disease, malignant tumors, infections, burns, anemia, decompensated heart disease, peptic ulcer, or myxedema. Plasma cholinesterase activity may also be diminished by chronic administration of oral contraceptives, glucocorticoids, or certain monoamine oxidase inhibitors and by irreversible inhibitors of plasma cholinesterase (*e.g.*, organophosphate insecticides, echothiophate, and certain antineoplastic drugs).

MIVACRON has been used safely in patients heterozygous for the atypical plasma cholinesterase gene. At doses of 0.10 to 0.20 mg/kg MIVACRON, the clinically effective duration of action was 8 to 11 minutes longer in patients heterozygous for the atypical gene than in genotypically normal patients.

As with succinylcholine, patients homozygous for the atypical plasma cholinesterase gene (1 in 2500 patients) are extremely sensitive to the neuromuscular blocking effect of MIVACRON. In three such adult patients, a small dose of 0.03 mg/kg (approximately the ED_{10-20} in genotypically normal patients) produced complete neuromuscular block for 26 to 128 minutes. Once spontaneous recovery had begun, neuromuscular block in these patients was antagonized with conventional doses of neostigmine. One adult patient, who was homozygous for the atypical plasma cholinesterase gene, received a dose of 0.18 mg/kg MIVACRON and exhibited complete neuromuscular block for about 4 hours. Response to post-tetanic stimulation was present after 4 hours, all four responses to train-of-four stimulation were present after 6 hours, and the patient was extubated after 8 hours. Reversal was not attempted in this patient.

Malignant Hyperthermia (MH): In a study of MH-susceptible pigs, MIVACRON did not trigger MH. MIVACRON has not been studied in MH-susceptible patients. Because MH can develop in the absence of established triggering agents, the clinician should be prepared to recognize and treat MH in any patient undergoing general anesthesia

Long-Term Use in the Intensive Care Unit (ICU): No data are available on the long-term use of MIVACRON in patients undergoing mechanical ventilation in the ICU.

Drug Interactions: Although MIVACRON (a mixture of three stereoisomers) has been administered safely following succinylcholine-facilitated tracheal intubation, the interaction between the stereoisomers in MIVACRON and succinylcholine has not been systematically studied. Prior administration of succinylcholine can potentiate the neuromuscular blocking effects of nondepolarizing agents. Evidence of spontaneous recovery from succinylcholine should be observed before the administration of MIVACRON.

The use of MIVACRON before succinylcholine to attenuate some of the side effects of succinylcholine has not been studied.

There are no clinical data on the use of MIVACRON with other nondepolarizing neuromuscular blocking agents.

Isoflurane and enflurane (administered with nitrous oxide/oxygen to achieve 1.25 MAC) decrease the ED_{50} of MIVACRON by as much as 25% (see **Pharmacodynamics** and **Individualization of Dosages** subsections of CLINICAL PHARMACOLOGY). These agents may also prolong the clinically effective duration of action and decrease the average infusion requirement of MIVACRON by as much as 35% to 40%. A greater potentiation of the neuromuscular blocking effects of the stereoisomers in MIVACRON may be expected with higher concentrations of enflurane or isoflurane. Halothane has little or no effect on the ED_{50}, but may prolong the duration of action and decrease the average infusion requirement by as much as 20%.

Other drugs which may enhance the neuromuscular blocking action of nondepolarizing agents such as the stereoisomers in MIVACRON include certain antibiotics (*e.g.*, aminoglycosides, tetracyclines, bacitracin, polymyxins, lincomycin, clindamycin, colistin, and sodium colistimethate), magnesium salts, lithium, local anesthetics, procainamide, and quinidine. Drugs that may enhance the neuromuscular blocking effects of mivacurium by a reduction in plasma cholinesterase activity include chronic administration of oral contraceptives, glucocorticoids, or certain monoamine oxidase inhibitors and by irreversible inhibitors of plasma cholinesterase (see **Reduced Plasma Cholinesterase Activity** subsection of PRECAUTIONS).

Resistance to the neuromuscular blocking action of nondepolarizing neuromuscular blocking agents has been demonstrated in patients chronically administered phenytoin or carbamazepine. While the effects of chronic phenytoin or carbamazepine therapy on the action of the stereoisomers in MIVACRON are unknown, slightly shorter durations of neuromuscular block may be anticipated and infusion rate requirements may be higher.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Carcinogenesis and fertility studies have not been performed. MIVACRON was evaluated in a battery of four short-term mutagenicity tests. It was non-mutagenic in the Ames Salmonella assay, the mouse lymphoma assay, the human lymphocyte assay, and the *in vivo* rat bone marrow cytogenetic assay.

Pregnancy: *Teratogenic Effects*: Pregnancy Category C. Teratology testing in nonventilated pregnant rats and mice treated subcutaneously with maximum subparalyzing doses of MIVACRON revealed no maternal or fetal toxicity or teratogenic effects. There are no adequate and well-controlled studies of MIVACRON in pregnant women. Because animal studies are not always predictive of human response, and the doses used were subparalyzing, MIVACRON should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Labor and Delivery: The use of MIVACRON during labor, vaginal delivery, or cesarean section has not been studied in humans and it is not known whether MIVACRON administered to the mother has effects on the fetus. Doses of 0.08 and 0.20 mg/kg MIVACRON given to female beagles undergoing cesarean section resulted in negligible levels of the stereoisomers in MIVACRON in umbilical vessel blood of neonates and no deleterious effects on the puppies.

Nursing Mothers: It is not known whether any of the stereoisomers of mivacurium are excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised following administration of MIVACRON to a nursing woman.

Pediatric Use: MIVACRON has not been studied in children below the age of 2 years (see CLINICAL PHARMACOLOGY and DOSAGE AND ADMINISTRATION for clinical experience and recommendations for use in children 2 to 12 years of age).

Geriatric Use: MIVACRON was safely administered during clinical trials to 64 elderly (≥65 years) patients, including 31 patients with significant cardiovascular disease (see **General** subsection of PRECAUTIONS). The duration of neuromuscular block may be slightly longer in elderly patients than in young adult patients (see CLINICAL PHARMACOLOGY).

ADVERSE REACTIONS:

Observed in Clinical Trials: MIVACRON (a mixture of three stereoisomers) was well tolerated during extensive clinical trials in inpatients and outpatients. Prolonged neuromuscular block, which is an important adverse experience associated with neuromuscular blocking agents as a class, was reported as an adverse experience in 3 of 2074 patients administered MIVACRON. The most commonly reported adverse experience following the administration of MIVACRON was transient, dose-dependent cutaneous flushing about the face, neck, and/or chest. Flushing was most frequently noted after the initial dose of MIVACRON and was reported in about 20% of adult patients who received the recommended dose of 0.15 mg/kg MIVACRON over 5 to 15 seconds. When present, flushing typically began within 1 to 2 minutes after the dose of MIVACRON and lasted for 3 to 5 minutes. Of 60 patients who experienced flushing after 0.15 mg/kg MIVACRON, one patient also experienced mild hypotension that was not treated, and one patient experienced moderate wheezing that was successfully treated.

Overall, hypotension was infrequently reported as an adverse experience in the clinical trials of MIVACRON. None of the 397 adults or 63 children who received recommended doses was treated for a decrease in blood pressure associated with the administration of MIVACRON. Above the recommended dosage range, 1% to 2% of healthy adults given ≥0.20 mg/kg over 5 to 15 seconds and 2% to 4% of cardiac surgery patients given ≥0.20 mg/kg over 60 seconds were treated for decreases in blood pressure associated with the administration of MIVACRON.

The following adverse experiences were reported in patients administered MIVACRON (all events judged by investigators during the clinical trials to have a possible causal relationship):

Incidence Greater Than 1% -

Cardiovascular:	Flushing (15%)

Incidence Less Than 1% -

Cardiovascular:	Hypotension, Tachycardia, Bradycardia, Cardiac Arrhythmia, Phlebitis
Respiratory:	Bronchospasm, Wheezing, Hypoxemia
Dermatological:	Rash, Urticaria, Erythema, Injection Site Reaction
Nonspecific:	Prolonged Drug Effect
Neurologic:	Dizziness
Musculoskeletal:	Muscle Spasms

OVERDOSAGE: Overdosage with neuromuscular blocking agents may result in neuromuscular block beyond the time needed for surgery and anesthesia. The primary treatment is maintenance of a patent airway and controlled ventilation until recovery of normal neuromuscular function is assured. Once evidence of recovery from neuromuscular block is observed, further recovery may be facilitated by administration of an anticholinesterase agent (*e.g.*, neostigmine, edrophonium) in conjunction with an appropriate anticholinergic agent. (see **Antagonism of Neuromuscular Block**). Overdosage may increase the risk of hemodynamic side effects, especially decreases in blood pressure. If needed, cardiovascular support may be provided by proper positioning of the patient, fluid administration, and/or vasopressor agent administration.

Antagonism of Neuromuscular Block:

ANTAGONISTS (SUCH AS NEOSTIGMINE) SHOULD NOT BE ADMINISTERED WHEN COMPLETE NEUROMUSCULAR BLOCK IS EVIDENT OR SUSPECTED. THE USE OF A PERIPHERAL NERVE STIMULATOR TO EVALUATE RECOVERY AND ANTAGONISM OF NEUROMUSCULAR BLOCK IS RECOMMENDED.

Administration of 0.030 to 0.064 mg/kg neostigmine or 0.5 mg/kg edrophonium at approximately 10% recovery from neuromuscular block (range: 1 to 15) produced 95% recovery of the muscle twitch response and a T_4/T_1 ratio ≥75% in about 10 minutes. The times from 25% recovery of the muscle twitch response to T_4/T_1 ratio ≥75% following these doses of antagonists averaged about 7 to 9 minutes. In comparison, average times for spontaneous recovery from 25% to T_4/T_1 ≥75% were 12 to 13 minutes.

Patients administered antagonists should be evaluated for adequate clinical evidence of antagonism, *e.g.*, 5-second head lift and grip strength. Ventilation must be supported until no longer required.

Antagonism may be delayed in the presence of debilitation, carcinomatosis, and the concomitant use of certain broad spectrum antibiotics, or anesthetic agents and other drugs which enhance neuromuscular block or separately cause respiratory depression (see **Drug Interactions** subsection of PRECAUTIONS). Under such circumstances the management is the same as that of prolonged neuromuscular block (see OVERDOSAGE).

DOSAGE AND ADMINISTRATION: MIVACRON SHOULD ONLY BE ADMINISTERED INTRAVENOUSLY.

The dosage information provided below is intended as a guide only. Doses of MIVACRON should be individualized (see **Individualization of Dosages** subsection of CLINICAL PHARMACOLOGY). Factors that may warrant dosage adjustment include but may not be limited to: the presence of significant kidney, liver, or cardiovascular disease, obesity (patients weighing ≥30% more than ideal body weight for height), asthma, reduction in plasma cholinesterase activity, and the presence of inhalational anesthetic agents. The use of a peripheral nerve stimulator will permit the most advantageous use of MIVACRON, minimize the possibility of overdosage or underdosage, and assist in the evaluation of recovery.

Adults:

***Initial Doses*:**

A dose of 0.15 mg/kg MIVACRON administered over 5 to 15 seconds is recommended for facilitation of tracheal intubation for most patients. When administered as a component of a thiopental/opioid/nitrous oxide/oxygen induction-intubation technique, 0.15 mg/kg (2 x ED_{95}) MIVACRON produces generally good-to-excellent conditions for tracheal intubation in 2.5 minutes. Lower doses of MIVACRON may result in a longer time for development of satisfactory intubation conditions. Administration of MIVACRON doses above the recommended range (≥0.20 mg/kg) is associated with the development of transient decreases in blood pressure in some patients (see CLINICAL PHARMACOLOGY and ADVERSE REACTIONS).

STORAGE: Store MIVACRON Injection at room temperature of 15° to 25°C (59° to 77°F). Avoid exposure to direct ultraviolet light. DO NOT FREEZE.

Recommended storage for MIVACRON Premixed Infusion is room temperature (15° to 25°C/59° to 77°F). Avoid excessive heat. Avoid exposure to direct ultraviolet light. Protect from freezing.

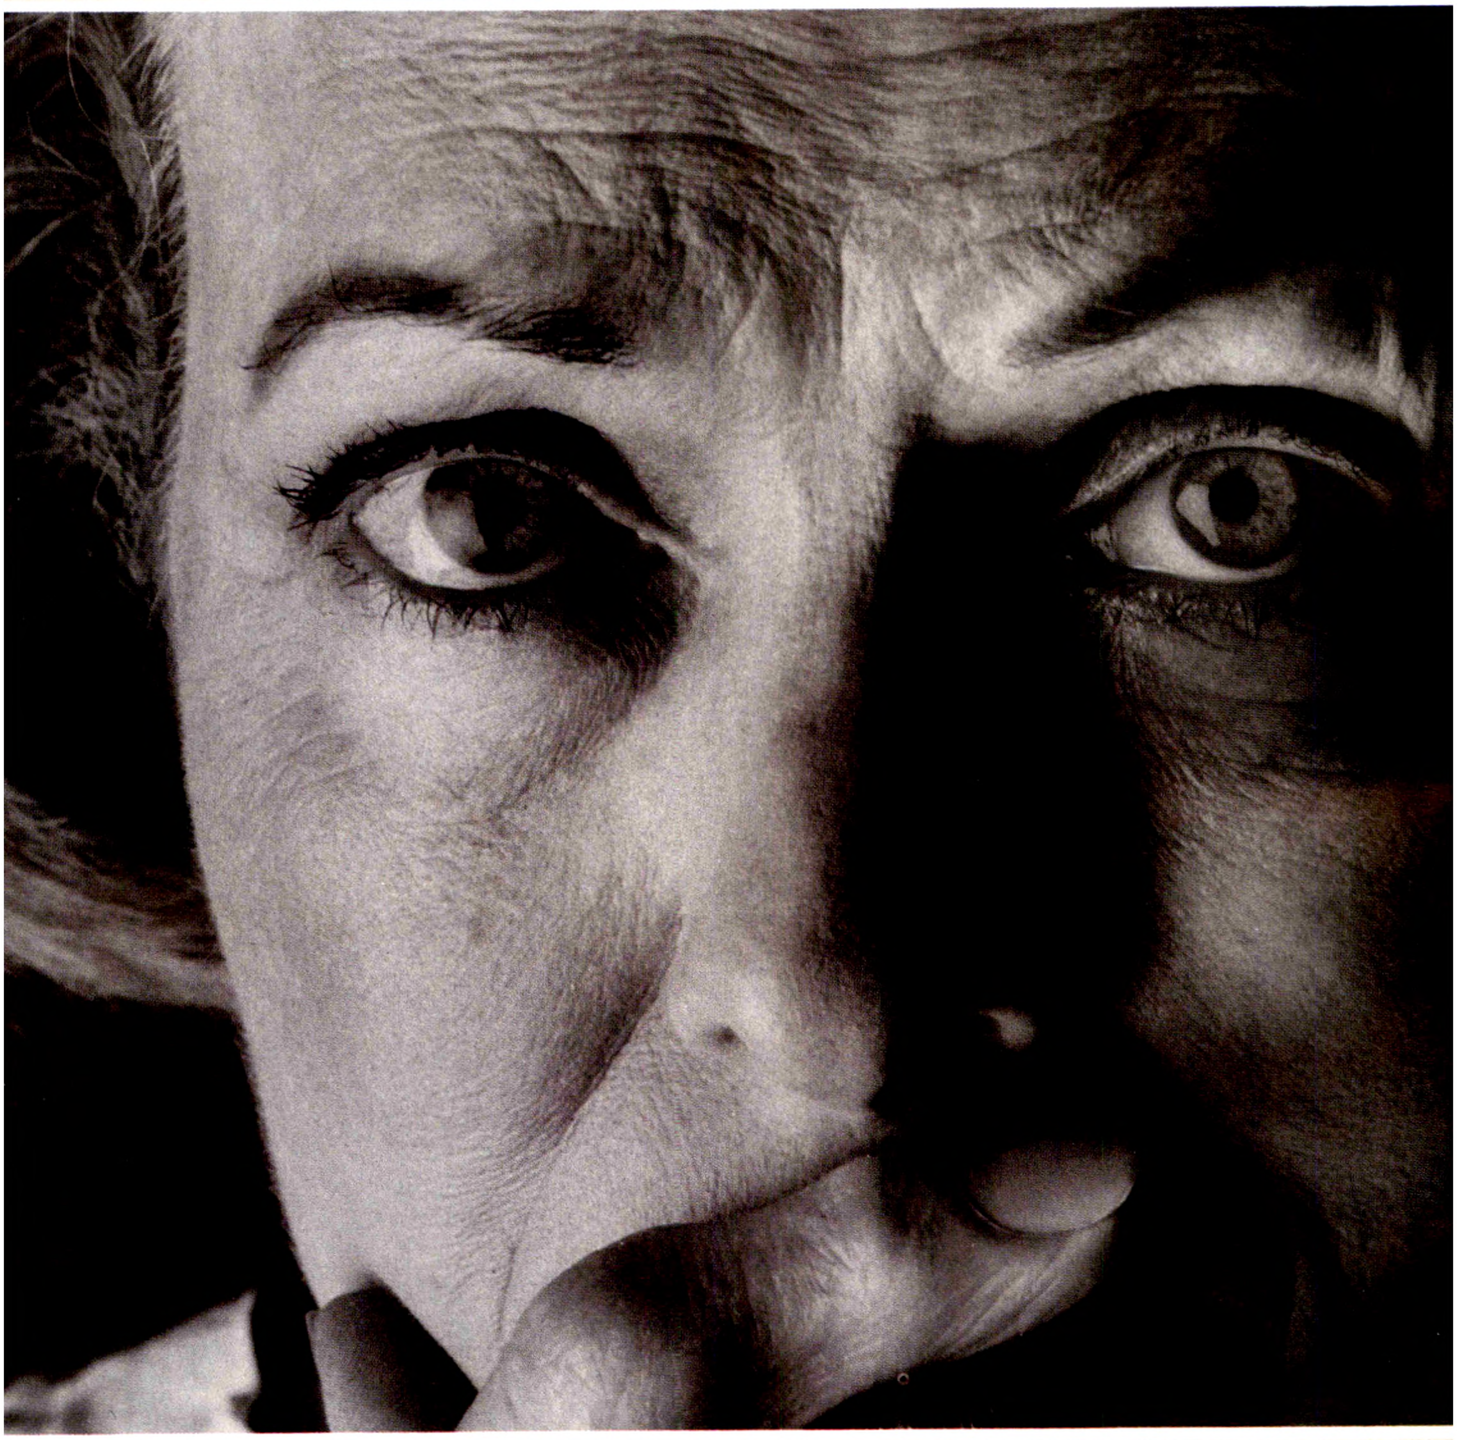
‘Doctor, I’m concerned about blood products. Is there something else you can use?”



In plasma volume expansion

YES!

Hespan®

(6% hetastarch in 0.9% sodium chloride injection)

Derived from corn, not blood...no risk of serum-transmitted diseases with HESPAN®

HESPAN® is derived from a waxy starch consisting almost entirely of amylopectin.[1] Consequently, there is no risk of serum-transmitted diseases, such as HIV or hepatitis, with HESPAN®.[2] Furthermore, HESPAN® is as effective as albumin for plasma volume expansion.[2,3]

Flexible bag, conveniently packaged for easy access and storage...won't shatter like glass

HESPAN® is packaged in a lightweight plastic bag. The compact, sturdy bag can be stored easily, retrieved quickly, and is designed for convenient setup and infusion.

For more information about HESPAN®, please call **1-800-543-8693.**

Hespan® ***EXCEL® CONTAINER***

(6% Hetastarch in 0.9% Sodium Chloride Injection)
BRIEF SUMMARY

CONTRAINDICATIONS
HESPAN is contraindicated in patients with known hypersensitivity to hydroxyethyl starch, or with bleeding disorders, or with congestive heart failure where volume overload is a potential problem. HESPAN should not be used in renal disease with oliguria or anuria not related to hypovolemia.

WARNINGS
Usage in Plasma Volume Expansion: Large volumes may alter the coagulation mechanism. Thus, administration of HESPAN may result in transient prolongation of prothrombin, partial thromboplastin and clotting times. With administration of large doses, the physician should also be alert to the possibility of transient prolongation of bleeding time.

Hematocrit may be decreased and plasma proteins diluted excessively by administration of large volumes of HESPAN. Administration of packed red cells, platelets, and fresh frozen plasma should be considered if excessive dilution occurs.

Use over extended periods: HESPAN has not been adequately evaluated to establish its safety in situations other than leukapheresis that require frequent use of colloidal solutions over extended periods. Certain conditions may affect the safe use of HESPAN on a chronic basis. For example, in patients with subarachnoid hemorrhage where HESPAN is used repeatedly over a period of days for the prevention of cerebral vasospasm, significant clinical bleeding may occur.

Usage in Leukapheresis: Slight declines in platelet counts and hemoglobin levels have been observed in donors undergoing repeated leukapheresis procedures using HESPAN due to the volume expanding effects of HESPAN and to the collection of platelets and erythrocytes. Hemoglobin levels usually return to normal within 24 hours. Hemodilution by HESPAN and saline may also result in 24 hour declines of total protein, albumin, calcium and fibrinogen values. None of these decreases are to a degree recognized to be clinically significant risks to healthy donors.

PRECAUTIONS
General: Regular and frequent clinical evaluation and complete blood counts (CBC) are necessary for proper monitoring of HESPAN® (6% hetastarch in 0.9% sodium chloride injection) use during leukapheresis. If the frequency of leukapheresis is to exceed the guidelines for whole blood donation, you may wish to consider the following additional studies: total leukocyte and platelet counts, leukocyte differential count hemoglobin and hematocrit, prothrombin time (PT), and partial thromboplastin time (PTT) tests.

The possibility of circulatory overload should be kept in mind. Caution should be used when the risk of pulmonary edema and/or congestive heart failure is increased. Special care should be exercised in patients who have impaired renal clearance since this is the principal way in which hetastarch is eliminated.

Indirect bilirubin levels of 8.3 mg/L (normal 0.0 - 7.0 mg/L) have been reported in 2 out of 20 normal subjects who received multiple HESPAN infusions. Total bilirubin was within normal limits at all times; indirect bilirubin returned to normal by 96 hours following the final infusion. The significance, if any, of these elevations is not known; however, caution should be observed before administering HESPAN to patients with a history of liver disease.

HESPAN has been reported to produce hypersensitivity reactions such as wheezing and urticaria. However, hetastarch has not been observed to stimulate antibody formation. If hypersensitivity effects occur, they are readily controlled by discontinuation of the drug and, if necessary, administration of an antihistaminic agent.

Elevated serum amylase levels may be observed temporarily following administration of HESPAN, although no association with pancreatitis has been demonstrated.

If administration is by pressure infusion, all air should be withdrawn or expelled from the bag through the medication port prior to infusion.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term studies of animals have not been performed to evaluate the carcinogenic potential of hetastarch.

Teratogenic Effects: Pregnancy Category C. Animal reproduction studies have not been conducted with HESPAN. It is also not known whether HESPAN can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. HESPAN should be given to a pregnant woman only if clearly needed.

Nursing Mothers: It is not known whether hetastarch is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when HESPAN is administered to a nursing woman.

Pediatric Use: The safety and effectiveness of HESPAN in children have not been established.

ADVERSE REACTIONS
The following have been reported: vomiting, fever, chills, pruritus, submaxillary and parotid glandular enlargement, mild influenza-like symptoms, headaches, muscle pains, peripheral edema of the lower extremities, anaphylactoid reactions (periorbital edema, urticaria, wheezing), bleeding due to hemodilution (see *Warnings*), and circulatory overload and pulmonary edema (see *Precautions*).

DOSAGE AND ADMINISTRATION
Dosage for Acute Use in Plasma Volume Expansion: HESPAN® (6% hetastarch in 0.9% sodium chloride injection) is administered by intravenous infusion only. Total dosage and rate of infusion depend upon the amount of blood or plasma lost and the resultant hemoconcentration. In adults, the amount usually administered is 500 to 1000 mL. Doses of more than 1500 mL per day for the typical 70 kg patient (approximately 20 mL per kg of body weight) are usually not required, although higher doses have been reported in postoperative and trauma patients where severe blood loss has occurred.

Dosage in Leukapheresis: 250 to 700 mL of HESPAN to which citrate anticoagulant has been added is typically administered by aseptic addition to the input line of the centrifugation apparatus at a ratio of 1:8 to 1:13 to venous whole blood. The HESPAN and citrate should be thoroughly mixed to assure effective anticoagulation of blood as it flows through the leukapheresis machine.

Do not use plastic container in series connection.

If administration is controlled by a pumping device, care must be taken to discontinue pumping action before the container runs dry or air embolism may result.

This solution is intended for intravenous administration using sterile equipment. It is recommended that intravenous administration apparatus be replaced at least once every 24 hours.

Use only if solution is clear and container and seals are intact.

The safety and compatibility of other additives have not been established.

Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration whenever solution and container permit.

If administration is by pressure infusion, all air should be withdrawn or expelled from the bag through the medication port prior to infusion.

HOW SUPPLIED
HESPAN® (6% hetastarch in 0.9% sodium chloride injection) is supplied sterile and nonpyrogenic in 500 mL EXCEL® Containers packaged 12 per case (NDC 0056-0037-46).

Exposure of pharmaceutical products to heat should be minimized. Avoid excessive heat. Protect from freezing. It is recommended that the product be stored at room temperature (25°C); however, brief exposure up to 40°C does not adversely affect the product.

CAUTION
Federal (USA) law prohibits dispensing without prescription.

To Open
Tear overwrap down at notch and remove solution container. Check for minute leaks by squeezing solution container firmly. If leaks are found, discard solution as sterility may be impaired.

Invert container and carefully inspect the solution in good light for cloudiness, haze, or particulate matter. Any container which is suspect should not be used.

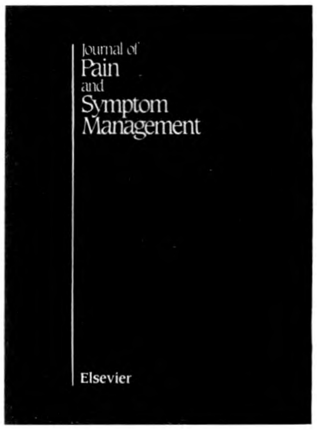
Covering the Full Spectrum
of Pain and Symptom Management

Journal of
Pain and Symptom
Management

Editor: **Russell K. Portenoy, M.D.,** New York, New York
Founding Editor: **George Heidrich, RN**

Journal of Pain and Symptom Management is a peer-reviewed, internationally respected forum for the exchange of ideas and information among clinicians and researchers working in pain and symptom management. It publishes original articles, review articles, clinical reports, letters, information exchanges, topical supplements, and media reviews.



The **Journal**'s original articles focus on the full spectrum of patient care: how to treat the patient presenting with pain; how to help the family cope and assist; and how to form and manage a strong medical team that will work as a unit. The **Journal**'s clinical reports discuss methods for symptom identification and pain management, and examine both pharmacologic and psychologic methods of treatment.

Broad in scope, the **Journal** will be of special benefit and interest to oncologists, anesthesiologists, neurologists, pharmacologists, nurses, therapists, psychologists, and psychiatrists. Be sure to subscribe today!

Abstracted and Indexed in: *Excerpta Medica; Psychological Abstracts; MEDLINE; Child Development Abstracts and Bibliography; Nursing Abstracts; Current Awareness in Biological Sciences; International Nursing Index; Oncology Information Service;* and *Cumulative Index to Nursing & Allied Health Literature (CINAHL).*

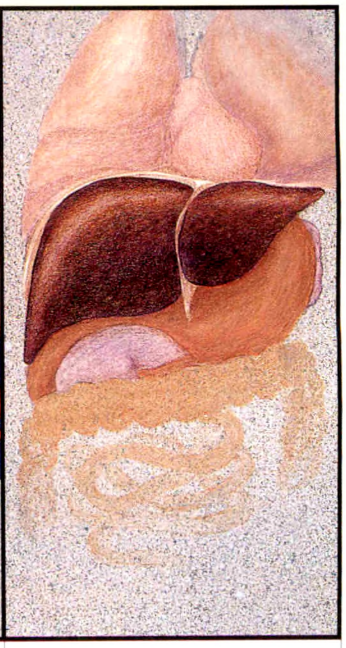
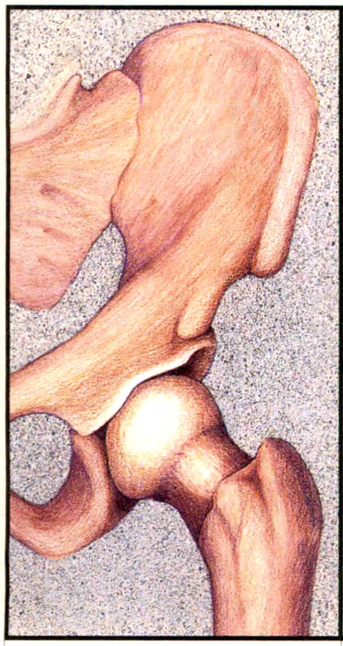
Tracrium®

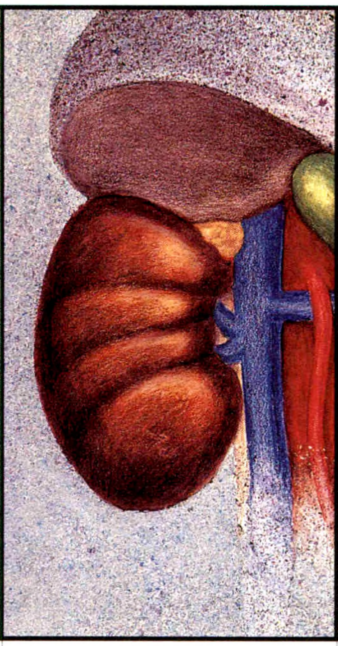
For many procedures

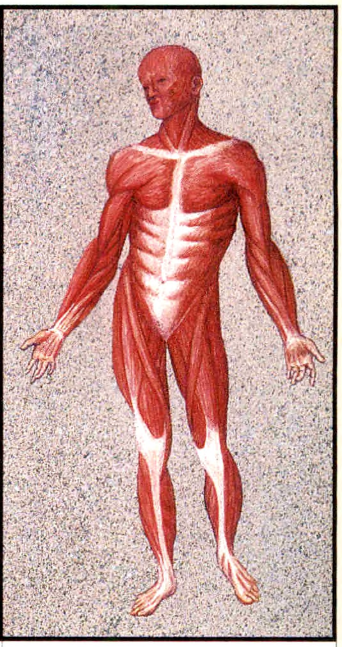
For many reasons



Cholecystectomy	**Biliary tract repair**
Common patient type Obese	**Common patient type** Both adults and children
Advantage of Tracrium No difference in recovery from neuromuscular blockade between normal and obese patients.[1]	**Advantage of Tracrium** Clinical response unaffected by hepatic function[2] or patient age.[3]







Total hip replacement	**Renal surgery**	**Neurosurgery for trauma**	**Everyday procedures**
Common patient type Elderly women and men	**Common patient type** Both adults and children	**Common patient type** Both adults and children	**Common patient type** Average
Advantage of Tracrium Recovery time unaffected by age.[3]	**Advantage of Tracrium** Recovery time unaffected by renal dysfunction.[2]	**Advantage of Tracrium** Effect unchanged by concomitant anticonvulsant medications (phenytoin, carbamazepine).[4,5]	**Advantage of Tracrium** The same reasons Tracrium is ideal for special patient types make it the choice for everyday procedures.

TRACRIUM® INJECTION

(atracurium besylate) 10 mg/mL

For predictable recovery

TR-Y03368

See brief summary of prescribing information on adjacent page.

TRACRIUM® INJECTION
(atracurium besylate)

Brief Summary
This drug should be used only by adequately trained individuals familiar with its actions, characteristics, and hazards.

INDICATIONS AND USAGE: Tracrium is indicated, as an adjunct to general anesthesia, to facilitate endotracheal intubation and to provide skeletal muscle relaxation during surgery or mechanical ventilation.

CONTRAINDICATIONS: Tracrium is contraindicated in patients known to have a hypersensitivity to it.

WARNINGS: TRACRIUM SHOULD BE USED ONLY BY THOSE SKILLED IN AIRWAY MANAGEMENT AND RESPIRATORY SUPPORT. EQUIPMENT AND PERSONNEL MUST BE IMMEDIATELY AVAILABLE FOR ENDOTRACHEAL INTUBATION AND SUPPORT OF VENTILATION, INCLUDING ADMINISTRATION OF POSITIVE PRESSURE OXYGEN. ADEQUACY OF RESPIRATION MUST BE ASSURED THROUGH ASSISTED OR CONTROLLED VENTILATION. ANTICHOLINESTERASE REVERSAL AGENTS SHOULD BE IMMEDIATELY AVAILABLE. DO NOT GIVE TRACRIUM BY INTRAMUSCULAR ADMINISTRATION. Tracrium has no known effect on consciousness, pain threshold, or cerebration. It should be used only with adequate anesthesia. Tracrium Injection, which has an acid pH, should not be mixed with alkaline solutions (e.g., barbiturate solutions) in the same syringe or administered simultaneously during intravenous infusion through the same needle. Depending on the resultant pH of such mixtures, Tracrium may be inactivated and a free acid may be precipitated. Tracrium Injection 10 mL multiple dose vials contain benzyl alcohol. Benzyl alcohol has been associated with an increased incidence of neurological and other complications in newborn infants which are sometimes fatal. Tracrium Injection 5 mL ampuls and 5 mL single use vials do not contain benzyl alcohol.

PRECAUTIONS: General: Although Tracrium is a less potent histamine releaser than d-tubocurarine or metocurine, the possibility of substantial histamine release in sensitive individuals must be considered. Special caution should be exercised in administering Tracrium to patients in whom substantial histamine release would be especially hazardous (e.g. patients with clinically significant cardiovascular disease) and in patients with any history (e.g., severe anaphylactoid reactions or asthma) suggesting a greater risk of histamine release. In these patients, the recommended initial Tracrium dose is lower (0.3 to 0.4 mg/kg) than for other patients and should be administered slowly or in divided doses over one minute. Since Tracrium has no clinically significant effects on heart rate in the recommended dosage range, it will not counteract the bradycardia produced by many anesthetic agents or vagal stimulation. As a result, bradycardia during anesthesia may be more common with Tracrium than with other muscle relaxants. Tracrium may have profound effects in patients with myasthenia gravis, Eaton-Lambert syndrome, or other neuromuscular diseases in which potentiation of nondepolarizing agents has been noted. The use of a peripheral nerve stimulator is especially important for assessing neuromuscular blockade in these patients. Similar precautions should be taken in patients with severe electrolyte disorders or carcinomatosis. Multiple factors in anesthesia practice are suspected of triggering malignant hyperthermia (MH), a potentially fatal hypermetabolic state of skeletal muscle. Halogenated anesthetic agents and succinylcholine are recognized as the principal pharmacologic triggering agents in MH-susceptible patients; however, since MH can develop in the absence of established triggering agents, the clinician should be prepared to recognize and treat MH in any patient scheduled for general anesthesia. Reports of MH have been rare in cases in which Tracrium has been used. In studies of MH-susceptible animals (swine) and in a clinical study of MH-susceptible patients, Tracrium did not trigger this syndrome. Resistance to nondepolarizing neuromuscular blocking agents may develop in burn patients. Increased doses of nondepolarizing muscle relaxants may be required in burn patients and are dependent on the time elapsed since the burn injury and the size of the burn. The safety of Tracrium has not been established in patients with bronchial asthma. **Long-Term Use in Intensive Care Unit (ICU):** Tracrium has been used to facilitate mechanical ventilation in ICU patients. When there is a need for long-term mechanical ventilation, the benefits to risk ratio of neuromuscular blockade must be considered. There is only limited information on the efficacy and safety of Tracrium administered by long-term (days to weeks) intravenous infusion to facilitate mechanical ventilation in intensive care facilities. For Tracrium, as with other neuromuscular blocking agents used in intensive care facilities, available evidence suggests that there is wide interpatient variability in dosage requirements and that these requirements may change with time. Limited data suggest that Tracrium infusion requirements may increase with prolonged administration in the ICU. As with other neuromuscular blocking agents, little information is available on the plasma levels or clinical consequences of atracurium metabolites following long-term (days to weeks) infusion of Tracrium in the intensive care unit setting. One metabolite of atracurium, laudanosine, when administered alone to laboratory animals, has been associated with cerebral excitatory effects. Physiological effects of laudanosine in humans have not been demonstrated. The effects of hemodialysis, hemoperfusion and hemofiltration on plasma levels of atracurium and its metabolites are unknown. **Drug Interactions:** Drugs which may enhance neuromuscular blocking action of Tracrium include: enflurane; isoflurane; halothane; certain antibiotics, especially the aminoglycosides and polymyxins; lithium; magnesium salts; procainamide; and quinidine. If other muscle relaxants are used during the same procedure, the possibility of a synergistic or antagonist effect should be considered. The prior administration of succinylcholine does not enhance the duration, but quickens the onset and may increase the depth, of neuromuscular blockade induced by Tracrium. Tracrium should not be administered until a patient has recovered from succinylcholine-induced neuromuscular blockade. **Carcinogenesis, Mutagenesis, Impairment of Fertility:** A positive response was observed in the mouse lymphoma assay under conditions which killed over 80% of the treated cells. A far weaker response was observed in the presence of metabolic activation at concentrations which also killed over 80% of the treated cells. **Pregnancy:** ***Teratogenic Effects:*** Pregnancy Category C. Tracrium has been shown to be potentially teratogenic in rabbits, when given in doses up to approximately one-half the human dose. There are no adequate and well-controlled studies in pregnant women. Tracrium should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus. **Labor and Delivery:** It is not known whether muscle relaxants administered during vaginal delivery have immediate or delayed adverse effects on the fetus or increase the likelihood that resuscitation of the newborn will be necessary. The possibility that forceps delivery will be necessary may increase. Tracrium (0.3 mg/kg) has been administered to 26 pregnant women during delivery by cesarean section. No harmful effects were attributable to Tracrium in any of the newborn infants, although small amounts of Tracrium were shown to cross the placental barrier. The possibility of respiratory depression in the newborn infant should always be considered following cesarean section during which a neuromuscular blocking agent has been administered. In patients receiving magnesium sulfate, the reversal of neuromuscular blockade may be unsatisfactory and Tracrium dose should be lowered as indicated. **Nursing Mothers:** It is not known whether this drug is excreted in human milk. Caution should be exercised when Tracrium is administered to a nursing woman. **Pediatric Use:** Safety and effectiveness in children below the age of 1 month have not been established.

ADVERSE REACTIONS: Observed in Controlled Clinical Studies: Tracrium produced few adverse reactions during extensive clinical trials. Most were suggestive of histamine release (see Precautions Section). The overall incidence rate for clinically important adverse reactions was 7/875 or 0.8%. Most adverse reactions were of little clinical significance unless they were associated with significant hemodynamic changes. Substantial vital sign changes greater than or equal to 30% observed in 530 patients, without cardiovascular disease, were as follows: in those patients given the recommended initial dosage range of 0.31 to 0.50 mg/kg of Tracrium, mean arterial pressure increased in 2.8% and decreased in 2.1% of patients while the heart rate increased in 2.8% of these patients. At doses of ≥ 0.60 mg/kg, 14.3% of the studied patients had a decrease in mean arterial pressure while 4.8% had an increase in heart rate. At doses ≤ 0.30 mg/kg, mean arterial pressure increased in 1.9% and decreased in 1.1% of patients, while heart rate increased in 1.6% and decreased in 0.8% of these patients. **Observed in Clinical Practice:** Based on clinical experience in the U.S. and the United Kingdom of approximately 3 million patients given Tracrium the following adverse reactions are among the most frequently reported: *General:* allergic reactions (anaphylactic or anaphylactoid) which, in rare instances, were severe (e.g., cardiac arrest); *Musculoskeletal:* inadequate, prolonged block; *Cardiovascular:* hypotension, vasodilatation (flushing), tachycardia, bradycardia; *Respiratory:* dyspnea, bronchospasm, laryngospasm; *Integumentary:* rash, urticaria, injection site reaction.

STORAGE: Tracrium Injection should be refrigerated at 2° to 8° C (36° to 46° F) to preserve potency. DO NOT FREEZE. Upon removal from refrigeration to room temperature storage conditions (25° C/77° F), use Tracrium Injection within 14 days even if rerefrigerated.

Oculopharyngeal Dystrophy: An Approach to Anesthetic Management

Alice L. Landrum, MD, and G. W. N. Eggers, MD

Department of Anesthesiology, University of Missouri-Columbia, Columbia, Missouri

Oculopharyngeal dystrophy is a rare variant of muscular dystrophy characterized by progressive dysphagia and ptosis (1). There have been a few reported cases of ocular myopathy with unusual sensitivity to succinylcholine (2) and to *d*-tubocurarine (3–5) and lack of response to anticholinesterases (3–5). There have been no reports in the anesthesia literature, however, of patients with oculopharyngeal dystrophy. This is the first report describing the anesthetic management of a patient with oculopharyngeal dystrophy.

Case Report

A 72-y-old woman with oculopharyngeal dystrophy was scheduled to undergo therapeutic cricopharyngeal myotomy. Her symptoms included recurrent aspiration of gastric contents, difficulty in swallowing, and a recent 25-kg weight loss over the previous 2 mo.

This patient had had mild dysphagia since age 15 yr that had become progressively worse during the previous year so that she could no longer swallow liquids or solids. She had had drooping eyelids for at least 35 yr. Other medical problems included hypertension for 10 yr and a productive cough for 2 yr. She had smoked for 50 yr. Surgical history included a cholecystectomy approximately 30 yr earlier under general anesthesia without any problems and eyelid surgery 4 yr earlier under local anesthesia.

Family members with a history of ptosis and dysphagia included the patient's mother, two brothers, two maternal uncles, and one son. Her two sisters did not have any symptoms of the condition. The patient reported that the condition was "brought from overseas," but she did not know the country of origin. Her mother had lived past the age of 70 yr but had developed severe weakness. When she died, there was food found in her throat. One of her brothers who had ptosis and dysphagia required mechanical ventilation before his death. The patient had seven children; however, only one son, age 57 yr, had developed symptoms of ptosis and dysphagia.

On physical examination, she was cachectic, weighed 36 kg, and measured 170 cm in height. She had bilateral ptosis, but extraocular movements were intact. She also had temporal muscle wasting and muscle wasting of the extremities; however, muscle strength and deep tendon reflexes were normal, as were serum creatinine phosphokinase and serum aldolase levels.

Other preoperative laboratory data were reported to be normal, except for arterial pH 7.40, $Paco_2$ 46 mm Hg, Pao_2 60 mm Hg, arterial O_2 saturation 91%, and fraction of inspired O_2 0.2.

A chest radiograph showed a wide lucency terminating at the clavicular level that was probably pharyngeal/cervical esophagus. An esophageal transit/gastrointestinal reflux study revealed markedly delayed pharyngeal and esophageal motility and evidence of right bronchial aspiration. On Holter monitoring, a wandering atrial pacemaker was evident.

Because of the history of ptosis and her progressive dysphagia, a diagnosis of myasthenia gravis was considered. A nerve conduction study with repetitive stimulation at 2 and 20 Hz did not reveal any decrementing response, and a single-fiber electromyograph showed no increased "jitter." A decrementing response on the nerve conduction study and "jitter," or blocking, of successive discharges from single-motor fibers belonging to the same motor unit would have been electrophysiologic evidence for myasthenia gravis (6). An edrophonium test was requested but not completed during this hospital stay. In patients with myasthenia gravis, there is a deficiency of acetylcholine receptors at the neuromuscular junction as a result of antibodies to acetylcholine receptor protein (6). Edrophonium inhibits the enzyme acetylcholinesterase, so that there is an excess of acetylcholine to intereact repeatedly with the limited number of acetylcholine receptors. After an intravenous dose of 2.0 mg, if muscle strength improves within 30 s, the test is considered positive for myasthenia gravis. If there is no response with a dose of 2.0 mg, an additional 8.0 mg can be administered intravenously. Muscle strength will improve visibly within 30 s and decrease after 5 min if the patient has myasthenia gravis (7).

The results of the nerve conduction studies and single-fiber electromyogram, the history of dysphagia, the clinical findings of bilateral ptosis and cachexia due to the dysphagia, and the significant family history all confirmed the diagnosis of oculopharyngeal dystrophy.

Before the procedure, the patient received no preanes-

Accepted for publication July 10, 1992.

0003-2999/92/$5.00

thetic medications. In the operating room, routine monitors were used, and neuromuscular blockade was monitored at the masseter muscle. After breathing oxygen via a mask, anesthesia was induced with 25 μg of fentanyl, 35 mg of lidocaine, and 75 mg of thiopental. After the application of cricoid pressure and the establishment of a patent airway by mask, 3.5 mg of vecuronium was administered intravenously, and the trachea was subsequently intubated. The anesthetic was maintained with oxygen (2 L/min), N_2O (3 L/min), and isoflurane (0.5%–1.0%). One hour after induction when she had four detectable responses to train-of-four stimulation, the patient received an additional 1.0 mg of vecuronium. At the conclusion of the procedure (approximately 150 min after the intubating dose of vecuronium), and after the patient had demonstrated return of all four twitches with train-of-four stimulation at the masseter muscle, neostigmine (3.0 mg IV) and glycopyrrolate (0.5 mg IV) were administered. After she was able to open her eyes and lift her head, the endotracheal tube was removed, and she was transported to the recovery room, with oxygen via face mask. Her postoperative course was uncomplicated.

Discussion

The muscular dystrophies represent a group of muscle disorders that are progressive, hereditary, degenerative diseases of the skeletal muscles (8). The dystrophies are thought to be mainly disorders of muscle fiber, because patients with muscular dystrophy demonstrate intact spinal motor neurons, nerves, and nerve endings, although the muscle fibers are severely degenerated (8). Characteristic features of this group of diseases include symmetric distribution of weakness and atrophy, intact sensation, preservation of reflexes, and a family history of the disorder (8).

Oculopharyngeal muscular dystrophy is a rare variant of muscular dystrophy first described in 1962 by Victor et al. (1). This syndrome of ocular ptosis and dysphagia has an autosomal dominant mode of inheritance. Onset is insidious, usually late in life, and progression is slow (1). Dysphagia usually precedes ptosis. This slowly progressive myopathic process primarily involves the levator palpebrae muscles, pharynx, hypopharynx and, upper one-third of the esophagus (9), with only the striated muscle of the esophagus disturbed (10). Some patients have also displayed weakness in the neck flexors and limb girdle muscles (9).

Cases of ocular dystrophy have been described in the anesthesia literature. Ocular dystrophy is manifested by ptosis and extraocular muscle weakness but not dysphagia (3–5). The presence of extraocular muscle weakness distinguishes ocular dystrophy from oculopharyngeal dystrophy. The patient described in our report had ptosis and dysphagia but not extraocular muscle weakness, so that her condition represents a case of oculopharyngeal dystrophy.

Special considerations in the anesthetic management of patients with oculopharygneal dystrophy include their dysphagia, which may increase their risk of aspiration, their response to neuromuscular relaxants and anticholinesterases, their pulmonary status preoperatively, and their respiratory muscle strength postoperatively. Our patient had clinical evidence of pooling of secretions in the piriform recesses, delayed pharyngeal emptying, and right bronchial aspiration on her gastroesophageal reflux scan. For these reasons, we chose to use cricoid pressure during our induction of anesthesia to help prevent aspiration of secretions.

Patients with neuromuscular disorders have exhibited varied responses to depolarizing and nondepolarizing muscle relaxants (11). Dresner and Ali (12) recently described a patient with facioscapulohumeral dystrophy who had a much faster than normal recovery from atracurium blockade. There has been a report of a 48-yr-old woman with ocular myopathy who exhibited unusual sensitivity to succinylcholine. A dose of 20 mg administered intravenously resulted in 60 min of apnea (2). Another report describes a 7-yr-old boy with ocular muscular dystrophy who demonstrated extreme sensitivity to *d*-tubocurarine, with lack of reversal by anticholinesterases. This patient had received succinylcholine on two previous occasions without any adverse reaction (5). Ross (3) in 1963 described four patients with ocular myopathy who exhibited extreme sensitivity to *d*-tubocurarine. He concluded that these patients had a form of progressive muscular dystrophy with abnormal sensitivity to *d*-tubocurarine. Their ptosis did not respond to prostigmine, as would have been expected if they had myasthenia gravis (3). Later, in 1966, Jacob and Varkey (4) described four more patients with ocular myopathy who exhibited unusual sensitivity to *d*-tubocurarine and no response to anticholinesterases. Both Ross (3) and Jacob and Varkey (4) used a *d*-tubocurarine test to evaluate neuromuscular transmission in these patients with ocular myopathies to determine whether they had myasthenia gravis.

The *d*-tubocurarine test as used by Ross (3) and Jacob and Varkey (4) has been used to study neuromuscular transmission in patients with primary disorders of nerve or muscle. In 1975, Brown et al. (13) described a regional technique to study *d*-tubocurarine sensitivity. This technique allowed the use of a reduced dose of *d*-tubocurarine to be injected into an ischemic limb. The effects on muscle strength in that limb alone could then be studied by measuring evoked muscle action potential amplitudes. Recovery usually occurs during the 20–30 min after release of the tourniquet. This technique allows assessment of the reserve of the neuromuscular junction when there is no evidence of a clinical disorder. The authors caution that whenever this test is performed, there should be staff and equipment immediately available to assist ventilation, because there is always the risk of respiratory arrest, even with very small doses of *d*-tubocurarine (13).

The use of the depolarizing muscle relaxant succinylcholine in patients with muscular dystrophy can be associated with serious complications. There has been the previously mentioned report of extreme sensitivity in a woman with ocular dystrophy (2). There have been several reports of rigidity (14), rhabdomyolysis (15), myoglobinuria (15,16), malignant hyperthermia (16–19), and cardiac arrest (20–22) in children with Duchenne's muscular dystrophy. In this case, we chose to use the nondepolarizing muscle relaxant vecuronium during induction to aid intubation; however, we might have either avoided using any muscle relaxants or used a much smaller dose.

Preoperative pulmonary status should be evaluated carefully because some of these patients may have weakness of the limb girdle muscles (9) that could lead to the need for mechanical ventilation postoperatively. Our patient did have mild carbon dioxide retention with an oxygen saturation of 91% while breathing room air, indicative of underlying pulmonary disease. She did not have any evidence of limb girdle weakness. Before tracheal extubation, she was able to open her eyes and lift her head for 5 s, which indicated adequate muscle strength to ventilate postoperatively. In the recovery room before discharge, her oxygen saturation was 96% on room air.

In summary, this report describes the anesthetic management of a patient with oculopharyngeal dystrophy, a rare form of progressive muscular dystrophy that has not been previously described in the anesthesia literature.

Bilateral Interpleural Injection of Lidocaine After Bilateral Lung Surgery Through Median Sternotomy in Four Patients

Mikito Kawamata, MD, Keiichi Omote, MD, and Akiyoshi Namiki, MD

Department of Anesthesiology, Sapporo Medical College and Hospital, Sapporo, Japan

Unilateral interpleural analgesia has been used to provide pain relief in a variety of clinical situations; however, its usefulness for postthoracotomy pain relief still remains controversial (1). In addition, Kambam et al. (2) reported that unilateral interpleural administration of bupivacaine produces no pain relief after anterior thoracotomy.

There have been a few reports describing the effects of bilateral interpleural analgesia for pain relief after abdominal surgery and thoracic pain secondary to carcinoma and multiple rib fractures (3,4). However, the analgesic effects and pharmacokinetics of the bilateral technique with lidocaine after median sternotomy are unknown.

We describe four patients in whom lidocaine was administered into both pleural spaces for postoperative pain relief after bilateral lung surgery through median sternotomy. In these patients, the degree of pain was assessed, and the plasma concentrations of lidocaine were determined after bilateral injection of lidocaine with epinephrine.

Case Reports

The present study was approved by the Ethical Committee of our institute, and informed consent was obtained from each patient. Table 1 displays the demographic characteristics of the four patients. Analgesic assessment and measurement of the plasma levels of lidocaine were performed before and 5, 10, 20, 30, 60, 90, 120, 150, and 180 min after the injection. The arterial plasma levels of lidocaine were measured by enzyme immunoassay, as described previously by Pape et al. (5). The degree of postoperative pain was evaluated with a visual analogue scale (VAS) (0 mm = no pain; 100 mm = intolerable pain). The extent of analgesia was assessed by the pinprick test. The duration of analgesia was defined as the time from the injection of lidocaine until the patient again complained of pain. The arterial blood pressure (BP), heart rate (HR), and respiratory rate (RR) were continuously recorded. Analysis of arterial blood gases was performed before and after the injection. The time-course of VAS values and plasma levels of lidocaine in the four study patients are shown in Figures 1–3.

Patient 1

This patient was scheduled for wedge resection of each of the upper lobes for metastatic pulmonary lesions due to carcinoma of the ascending colon. Premedication consisted of atropine (0.5 mg) and hydroxyzine (50 mg) administered intramuscularly. Anesthesia was induced with intravenous thiamylal followed by intravenous succinylcholine to facilitate endotracheal intubation. Anesthesia was maintained with halothane (0.6%–2.5%) and nitrous oxide (60%–70%) in oxygen, supplemented with intravenous pancuronium. No systemic opioids were administered during surgery. Bilateral thoracotomy was performed through median sternotomy. Before chest closure, an 18-gauge nylon epidural catheter was inserted 10 cm into each pleural space through a 16-gauge Tuohy needle at the seventh intercostal space 5 cm posterior from the midaxillary line of both sides. The catheter tip was positioned posterolaterally, and chest tubes were anterolaterally inserted into both pleural spaces, according to McIlvaine et al. (6). Ten milliliters of 1.5% lidocaine with 1:200,000 epinephrine was injected into each side via the interpleural catheter in the supine position when the patient was alert and complained of pain after the trachea was extubated. Both chest tubes were clamped for 10 min.

The VAS value preinjection was 82 mm and decreased to 8 mm at 30 min after the injection (Figure 1). The maximal extent of analgesia was T4-8, and duration of analgesia was 3.8 h. The maximal concentration of lidocaine in plasma (Cmax) was 3.60 μg/mL, occurring at 10 min after the injection (Figure 2). No significant changes in BP, HR, or RR were observed either before or after the injection. Before the injection, $Paco_2$ and Pao_2 were 44 and 123 mm Hg, respectively, under the face mask (inspired O_2 concentration, 0.4). One hour after the injection, $Paco_2$ decreased to 38 mm Hg and Pao_2 increased to 143 mm Hg under the face mask (inspired O_2 concentration, 0.4).

Patient 2

This patient underwent bilateral bullectomy of bullae of the lower lobes through median sternotomy. Anesthesia was induced, and interpleural catheters were placed in the same

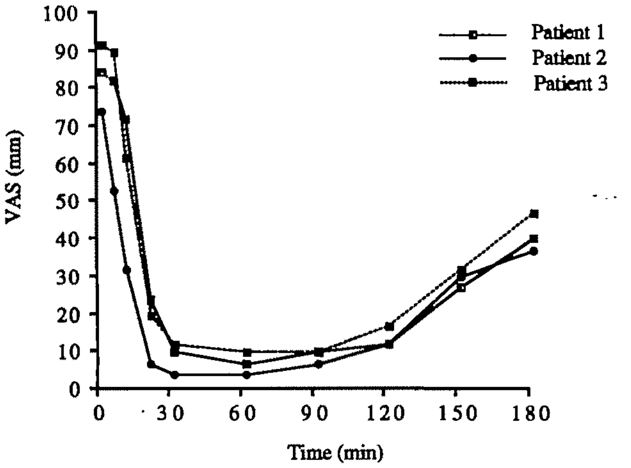

Figure 1. Time-course of visual analogue scale (VAS) (0–100 mm) after the injection of 10 mL of 1.5% lidocaine with 1:200,000 epinephrine into each pleural space in patients 1–3.

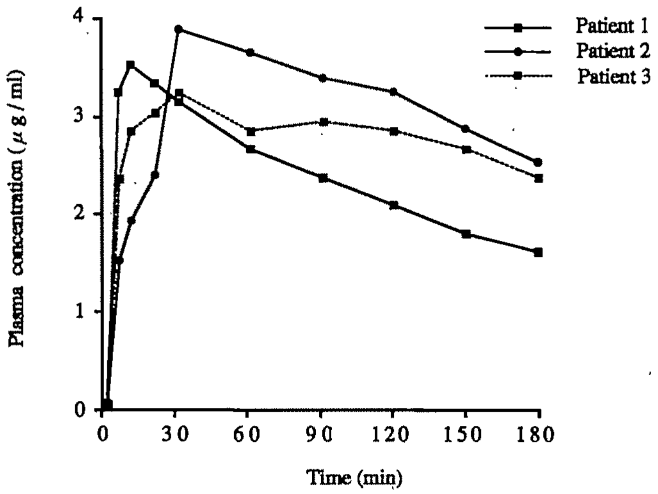

Figure 2. Plasma concentrations of lidocaine after the injection of 1.5% lidocaine with epinephrine (10 mL) into each pleural space in patients 1–3.

manner as described for patient 1. No systemic opioids were administered during the surgery. Ten milliliters of 1.5% lidocaine with 1:200,000 epinephrine was injected into each pleural space via the interpleural catheters when the patient complained of postoperative pain, and both chest tubes were clamped for 10 min. The VAS value preinjection was 72 mm and decreased to 5 mm at 20 min after the injection (Figure 1). The maximal extent of analgesia was T4-8, and duration of analgesia was 3.5 h. The Cmax of lidocaine was 3.87 μg/mL, occurring at 30 min after the injection (Figure 2). No changes in BP, HR, or RR either before or after the injection were observed. Preinjection, Pa_{O_2} and Pa_{CO_2} were 39 and 74 mm Hg in room air, respectively. One hour after the injection, Pa_{CO_2} decreased to 35 mm Hg and Pa_{O_2} increased to 81 mm Hg in room air.

Patient 3

This patient underwent bilateral wedge resection of the upper lobes through median sternotomy for metastatic pulmonary lesions due to carcinoma of the ascending colon. Anesthesia was performed in the same manner as described for patient 1. No systemic opioids were administered during surgery. At the end of surgery, bilateral interpleural catheters were placed in the same manner as described for patient 1. Ten milliliters of 1.5% lidocaine with 1:200,000 epinephrine was injected into each pleural space when the patient requested relief of postoperative pain, and both chest tubes were clamped for 10 min. The VAS value before the injection was 90 mm and decreased to 18 and 10 mm at 20 and 30 min after injection, respectively (Figure 1). The maximal extent of analgesia was T2-10, and duration of analgesia was 4.0 h. The Cmax of lidocaine in the plasma was 3.30 μg/mL, occurring 30 min after injection (Figure 2). No changes in BP, HR, RR, or arterial blood gases either before or after the injection were observed.

Patient 4

This patient was scheduled for bilateral wedge resection of the lower lobes through median sternotomy for metastatic pulmonary lesions due to adenocarcinoma of the kidney. Anesthesia was induced in the same manner as described for patient 1 and was maintained with isoflurane (0.8%–3.0%) and nitrous oxide (60%–70%) in oxygen, supplemented with intravenous vecuronium. No systemic opioids were administered during surgery. Bilateral interpleural catheters were placed after surgery, and 10 mL of 1.5% lidocaine with epinephrine was injected into each pleural space in the same manner as described for patient 1. Both chest tubes were clamped for 10 min. The 82-mm VAS value at preinjection decreased to 10 mm at 10 min after the

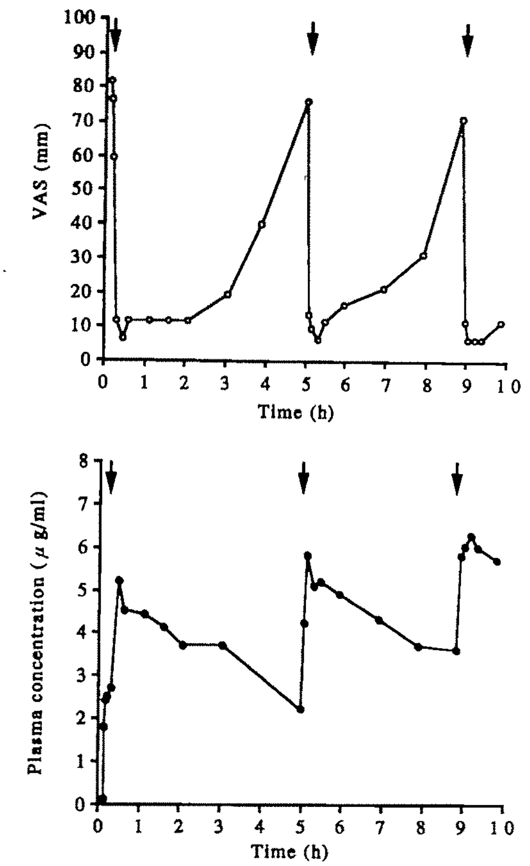

Figure 3. Time-course of visual analogue scale (VAS) (*upper panel*) and plasma concentrations of lidocaine (*lower panel*) during bilateral interpleural "topping-up" injection in patient 4. *Left arrow,* injection of 10 mL of 1.5% lidocaine with 1:200,000 epinephrine through each catheter; *middle and right arrows,* injection of 7.5 mL of 1.5% lidocaine with epinephrine into each pleural space.

injection. The VAS values did not exceed 20 mm for 3 h (Figure 3). When the patient complained of pain again (5 h after injection), 7.5 mL of 1.5% lidocaine with epinephrine was injected into each pleural space, and both chest tubes were clamped for 10 min. The second injection provided excellent pain relief, and the VAS values showed 5–8 mm; however, the patient showed incoherent speech, followed by drowsiness. Four hours after the second injection, the patient complained of pain (VAS 70 mm), and another 7.5 mL of 1.5% lidocaine with epinephrine was injected into each pleural space, and both chest tubes were clamped for 10 min. Although the VAS values decreased to 5 mm (Figure 3), the early signs of lidocaine toxicity of muscular tremor and incoherent speech, followed by drowsiness, appeared.

The time-course of the plasma concentrations of lidocaine in patient 4 is also shown in Figure 3. The initial Cmax was 5.1 µg/mL, occurring at 20 min after the initial injection, and when the patient complained again, the plasma concentration had decreased to 2.1 µg/mL. The Cmax of lidocaine was 5.7 µg/mL at 10 min after the second injection. The concentration of lidocaine was 3.5 µg/mL when the patient subsequently complained of pain (VAS 70 mm), and Cmax after the third injection was 6.2 µg/mL. No changes in BP, HR, RR, or arterial blood gas tensions either before or after the injection were observed.

Discussion

Median sternotomy has recently gained popularity as an approach for the excision of bilateral multiple metastatic pulmonary nodules and bilateral pulmonary bullous disease (7). Pain management after thoracotomy is important not only to ensure the patient's comfort, but also to minimize pulmonary complications. Systemic opioid administration has been the frequently utilized treatment for postthoracic surgery. Appropriate opioid use achieves a balance between adequate patient comfort and avoidance of excessive sedation or respiratory depression. However, some reports have documented that the analgesia produced by intercostal nerve blocks or epidural anesthesia is superior to that produced by conventional opioid analgesia (8,9). Although epidural local anesthetic administration would appear to solve the problem of postoperative pain in patients after sternotomy, this technique produces hypotension, and epidural opiates cause respiratory depression.

Interpleural analgesia is clinically useful in pain management after lateral and posterior thoracotomy (2). Lack of sympathetic blockade, systemic hypotension, and respiratory depression are the advantages of interpleural blockade compared with epidural blockade. In addition, phrenic nerve palsy associated with interpleural analgesia is less likely in humans (10). With regard to the mechanism of analgesia produced by this technique, it has been suggested that the local anesthetic solution diffuses from the pleural space through the parietal pleura and the innermost intercostal muscle to reach the intercostal space, where blockade of the intercostal nerves occurs unilaterally (11). On the other hand, because the terminal ends of the intercostal nerves often pass the midline to the opposite side (12), the technique of bilateral anterior intercostal nerve blocks of eight or more is necessary to relieve the pain of sternotomy or fracture of the sternum (1). Accordingly, bilaterial interpleural injection of local anesthetics may be useful to provide pain relief after median sternotomy. These case reports demonstrate that bilateral interpleural injection of lidocaine with epinephrine was effective against postoperative pain for >3 h without systemic administration of analgesics in patients who had undergone bilateral lung surgery through median sternotomy. The Cmax of bupivacaine of the unilateral interpleural blockade in patients who have undergone thoracotomy has been reported to be as low as 1.2 µg/mL and as high as 3.2 µg/mL (13–15). The arterial plasma level of bupivacaine associated with central nervous system toxicity is generally 2–4 µg/mL (16). Therefore, the plasma concentration of bupivacaine after bilateral interpleural block with bupivacaine will exceed the limits, resulting in convulsion and cardiac depression. It has been reported that bilateral interpleural injection of 20 mL of 0.75% bupivacaine with epinephrine provides profound, prolonged, and repeatable pain relief after midline and across-midline abdominal surgical interventions; however, the injection of 20 mL of 0.5% bupivacaine with epinephrine is ineffective, and, furthermore, the mean plasma concentration of bupivacaine after bilateral injection of 30 mL of 0.75% bupivacaine with epinephrine has been above the toxic level (3). These results suggest that the differences between doses that are ineffective and those that are toxic may be small with regard to bilateral interpleural analgesia.

We used this technique with lidocaine because of the rapid onset of analgesia with only slight cardiovascular depression. Although no clinical signs of local anesthetic toxicity were observed in our patients after the initial injection of 10 mL of 1.5% lidocaine with 1:200,000 epinephrine into each side, the Cmax of lidocaine showed 3.3–5.1 μg/mL, which seems to be relatively high. Furthermore, in patient 4, an initial peak plasma level of lidocaine was achieved in 20 min, followed by a slow decay, so that 180 min after the initial injection, the plasma level was 70% of the peak value. With two subsequent injections, peak levels increased above those of the preceding injections, the third values ranging from 5.3 to 6.2 μg/mL. Thus, it was likely that the lidocaine accumulated to a significant level in plasma and clinically produced the early toxic signs corresponding to the plasma level. Although the occurrence of cumulative toxicity as a result of repeat injections of local anesthetics has been reported in relation to epidural anesthesia (17), it has not been well appreciated with regard to interpleural analgesia. Rosenberg et al. (18) demonstrated that the plasma concentrations of bupivacaine rise markedly during continuous interpleural infusion and that after a 2-day infusion, are at a level regarded as toxic in humans. This suggests that caution may be necessary to avoid cumulative toxicity with repeat injections of local anesthetics in bilateral as well as unilateral interpleural analgesia.

In conclusion, bilateral interpleural blockade with lidocaine was effective against postoperative pain in the early phase after bilateral lung surgery through median sternotomy in the four patients presented here. However, these cases also showed that the peak plasma concentrations of lidocaine were relatively high after the initial injection and, furthermore, that repeat injections produced early toxic signs, with plasma concentrations nearly at the toxic level. From the clinical point of view, this case report suggests the need for cautious administration of bilateral interpleural lidocaine as well as bupivacaine. Further studies are needed to examine dosage regimens for this technique and to compare it with other ways of achieving analgesia (e.g., systemic opioids, epidural opioids, intercostal blocks).

We acknowledge the help and cooperation of Dr. Mayumi, Assistant Professor, Department of Anesthesiology, Hokkaido University School of Medicine, and Dr. Miyabe, Chief Anesthesiologist, Department of Anesthesiology, Kushiro City General Hospital.

A Fractured Epidural Needle: Case Report and Study

Steven M. Dunn, MD, Robert B. Steinberg, MD, PhD, Patricia S. O'Sullivan, EdD,
Wade T. Goolishian, MD, and Evelyn A. Villa, MD

Department of Anesthesiology, Baystate Medical Center, Tufts University School of Medicine,
Springfield, Massachusetts

Epidural blocks are most commonly performed using a 17-gauge needle to permit easy passage of the catheter. The durability of these large-gauge needles can be inferred by the lack of any reports of breakage other than separation at the hub-needle shaft junction (1). Recent improvements in catheter technology and the availability of smaller gauge catheters have generated increased interest in using smaller needles for both epidural and continuous spinal anesthesia. We report a case of a midshaft fracture of an 18-gauge Tuohy needle during an attempted administration of epidural anesthesia.

Case Report

A healthy 18-yr-old, 114-kg, 170-cm woman, gravida 2, para 1, at term was admitted to the labor suite in active labor. At 6–7-cm cervical dilatation, consent was obtained for epidural anesthesia. A CA-3 anesthesiology resident in the fourth month of an obstetric anesthesia subspecialty rotation attempted the block. The bony landmarks were difficult to palpate owing to obesity, so the patient was placed in the sitting position, and the skin was painted with an antiseptic solution and draped in the usual manner. The L3-4 interspace was approximated, and an 18-gauge, thin-walled Tuohy needle (American Medical Instruments, New Bedford, Mass.) was advanced until resistance was encountered. The stylet was removed, and a Pulsator syringe (Concord/Portex, Keene, N.H.) filled with 0.9% saline was attached. The needle was advanced with constant pressure on the syringe plunger. After inserting the needle an additional 1 cm, the resistance to advancement increased. The resident thought that this was due to calcified ligament, and the resistance was overcome with a transient increase in the pressure applied to the needle. The needle was then advanced to the hub with no perceived loss of resistance. On attempting to withdraw the needle, moderate resistance was encountered followed by a sudden release. The needle had fractured at the midshaft, leaving a 4.5-cm fragment in the patient. Epidural placement was abandoned. The patient was positioned on her side for the remainder of her labor and delivery without problems. After delivery, the patient was brought to the operating room, and the needle fragment was located by a neurosurgeon using fluoroscopy. The needle was lateral to the midline and had encountered the lamina of L4 rather than the interspinous ligament or the spinous process. Under local anesthesia, a small incision was made, and the fragment was grasped with a forceps and removed. Postoperatively, the patient complained of localized back pain with no radiation or signs of nerve injury.

We postulated that as the axial force on the needle against the bone increased, it bowed and eventually kinked. After this kink occurred, the resistance to forward movement decreased. This was misinterpreted as the "give" when a needle is passed over a vertebral spine, and the needle continued to bend as it was advanced to the hub. The action of withdrawing the needle caused it to break at the kink point. Our initial perception was that the needle involved in this incident might have been defective. However, studies of additional 18-gauge Tuohy needles from the same manufacturer revealed that they kinked easily when axial force was applied to the needle without the stylet in place. In view of this, we initiated a more systematic study of the stiffness and malleability of epidural needles to see whether there were differences among manufacturers.

Sample lots of ten 18- and 17-gauge epidural needles were obtained from seven manufacturers for comparison (Table 1). The outer diameter of each needle was measured at its midpoint using a micrometer. The needles were placed in a Luer lock fitting and compressed at a fixed rate of speed by an Instron Universal Testing Device (Instron Corporation, Canton, Mass.). This machine applies a variable axial force to the needle (Figure 1). Buckling force, the force applied when the needle first began to bend, was chosen as an index of needle stiffness. Malleability was assessed by measuring the distance (displacement) by which the needle was compressed in the axial direction when kinking first occurred. Descriptive statistics were obtained for each type of needle. To determine the association among selected variables, correlation coefficients were calculated. Comparisons among different groupings of needle types were made with nonparametric analysis of variance.

The outer diameters, buckling forces, and displacements for the different needles are displayed in Table 1. Each

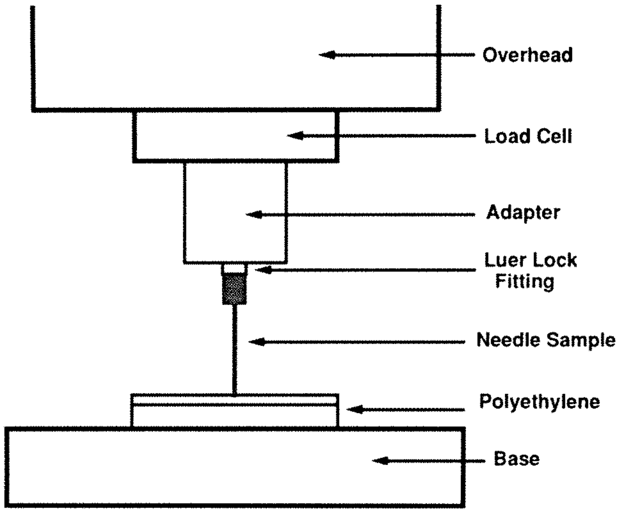

Figure 1. A schematic representation of the Instron Universal Testing Device.

entry in the table represents the mean of 10 samples with the standard error of the mean. The measured diameters stratified the needles into three different groups, as seen in Figure 2. The 17-gauge needles had an average diameter of 0.058 in. The 18-gauge needles fell into two distinct groups, with mean diameters of 0.053 and 0.050 in. Figure 2 also shows how the buckling force correlates with the measured outer diameter ($r = 0.93$; $P = 0.0001$). The three groupings of points differed significantly from each other with respect to buckling force ($P < 0.02$; Kruskal-Wallis nonparametric analysis of variance). Figure 3 shows the mean displacement plotted against the mean outer diameters for each brand of needle. Displacement did not correlate significantly with needle diameter ($r = 0.41$; $P = 0.24$). The Becton Dickinson, Burron, and Manan needles (Figure 3, solid dots) had displacement values significantly higher than the others ($P < 0.008$; Mann-Whitney U test).

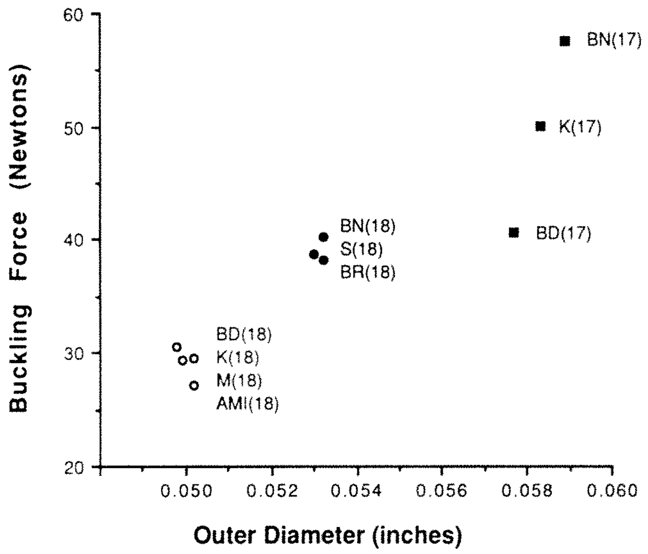

Figure 2. The needle buckling force (stiffness) plotted against measured needle outer diameter. Numbers in parentheses are gauges. Each buckling force and diameter measurement represents the mean of 10 samples. Abbreviations as in Table 1.

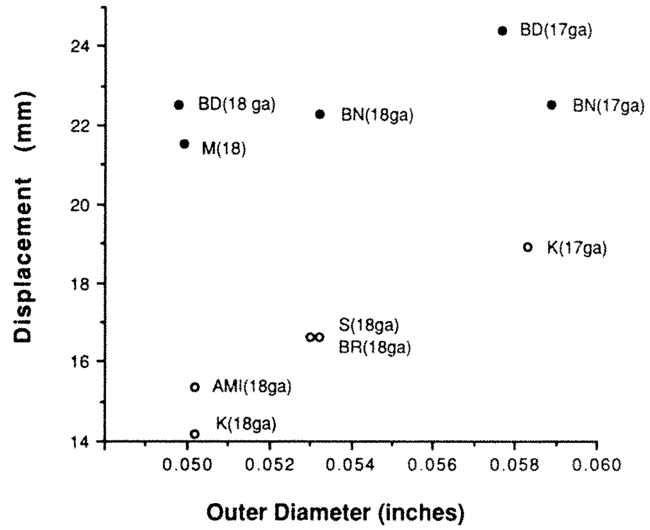

Figure 3. The distance the needle was compressed (displacement) plotted against the measured needle outer diameter. Each displacement measurement and diameter measurement represents the mean of 10 samples. ga, gauge. Other abbreviations as in Table 1.

Discussion

Epidural needles are often subjected to a substantial degree of axial force. This is due to the combination of the size and dullness of the needle, as well as the firmness of the interspinous ligaments and frequent impingement on bone. The standard procedure for placement of an epidural needle requires the removal of the stylet after the needle is advanced into the interspinous ligament. This allows the use of the loss of resistance or hanging drop technique to detect entry into the epidural space. With the stylet removed, the stiffness of the needle decreases, making it easier to buckle. After some critical amount of bending without the stylet in place, the shaft will kink, occluding the lumen. Once this kinking occurs, if the needle is then bent back toward its original shape, it is very likely to break. We cannot be certain that the fracture mechanism we propose, and partially verified in the laboratory, represents the events in our case. In vivo, the tissues surrounding the needle may apply forces in a nonaxial direction; if the patient should move, or if the needle is "walked off" the spinous process improperly, significant lateral or twisting forces may result.

Buckling force was proportional to the outer diameter of the needle, whereas displacement correlated poorly with diameter. Among needles of a given diameter, variations in displacement values probably arise from differences in the composition of the alloy from which the needle is constructed and from differences in wall thickness. We did not attempt to quantify these two variables.

In conclusion, we report a case of midshaft fracture of an 18-gauge epidural needle. As a result of this case, we studied epidural needles from seven manufacturers and found significant variation in their stiffness and malleability, as assessed by buckling force and displacement, respectively. The needle that failed in our case has the lowest buckling force and the second lowest displacement value of the needles we tested. This would suggest that this needle is more likely to bend than the others and will kink very soon after it begins to bend. Stiffness correlates with the measured needle diameter but malleability does not. Although midshaft fracture of an epidural needle occurs infrequently, this is a serious complication, because the retained needle fragment, being rigid and sharp, ought to be removed. The potential for further injury is obvious. If needle fractures indeed occur as we postulate, the needles that have the best combination of resistance to buckling and greater malleability once buckling occurs should be least likely to break.

REVIEW ARTICLE

Extracorporeal Membrane Oxygenation

Fiona H. Levy, MD, P. Pearl O'Rourke, MD, and Robert K. Crone, MD

Department of Anesthesiology, University of Washington School of Medicine, and Children's Hospital and Medical Center, Seattle, Washington

Extracorporeal life support has evolved from a need for improved methods of gas exchange and cardiac support for patients with severe respiratory or cardiac failure, or both. Its development has been linked to that of cardiopulmonary bypass technology used in the operating room for cardiothoracic surgery. The first oxygenators to be widely used were bubble oxygenators, characterized by a direct blood-gas interface. Although effective, hemolysis limited the duration of safe exposure (1). The subsequent development of membrane oxygenators with a physical separation between the blood and gas phases minimized hemolysis and introduced the potential for long-term support (2). Membrane oxygenators are now used in many variations of extracorporeal life support, including venoarterial (VA) and venoveno (VV) extracorporeal membrane oxygenation (ECMO), extracorporeal carbon dioxide removal ($ECCO_2R$), and intravascular oxygenation (IVOX). This review will discuss all of these technologies but will focus primarily on the technique, history, and clinical indications for VA ECMO.

Venoarterial Extracorporeal Membrane Oxygenation

Venoarterial ECMO describes a circuit in which blood exits from the venous system, is oxygenated and ventilated, and is then returned to the arterial circulation (Figure 1). A drainage (venous) cannula is placed into the right atrium via the right internal jugular vein, which is distally ligated. Blood flows from the right atrium by gravity to a bladder and then onward to an occlusive blood pump. The bladder, with a volume of 30–50 mL, adds capacitance to the system, acts as a safeguard against inconsistent venous return, provides an access site for sampling and blood and drug administration, and "traps" any air entrained in the venous limb of the circuit. The occlusive, nonpulsatile blood pump is servoregulated to the pressure of the venous return. Venoarterial ECMO flows are usually directed to achieve approximately 100 $mL \cdot kg^{-1} \cdot min^{-1}$, that is, one-half to two-thirds of the patient's cardiac output. This flow, although usually adequate and easily achieved in neonates, is more problematic in adults. Venous drainage is the greatest limitation to ECMO flow, and, as such, it is important to cannulate the right atrium with the largest venous catheter possible (12–14F for neonates, 16–22F in children, and up to 28F in adults). After the pump, the blood enters the membrane oxygenator, which is a silicon envelope coiled around a spool and then encased in a plastic sleeve. The membranes are rated for gas transfer capability, which is a function of surface area: from 0.4 m^2 for a neonate to 3.5–4.5 m^2 for an adult. Fresh gas flows through the inside of the envelope while blood travels outside in a countercurrent direction. The sweep gas is responsible for delivering oxygen and washing out carbon dioxide; its composition and flow rate are adjusted in response to arterial blood gases; the usual fraction of inspired oxygen (FIO_2) ranges from 40% to 100%, with 1%–5% CO_2 added to maintain normocarbia. After the oxygenator, blood passes through a countercurrent heat exchanger and is then returned to the ascending aorta by way of a single end-hole catheter. At the time of cannulation, the arterial catheter is advanced through the right common carotid artery, which is ligated distal to the catheter.

There is a safety bridge connecting the proximal venous and distal arterial tubing, which is used to ensure continued circulation of blood through the membrane in the event that temporary discontinuation of ECMO is necessary. Normally occluded, the bridge can be opened while the catheters proximal to the patient are clamped, effectively separating the patient from the circuit.

Before cannulation, the circuit is primed with crystalloid and albumin, followed by heparinized blood corrected to normal pH and calcium concentration. The standard circuit volume, including the prime, is 500–650 mL in a neonate and as high as 2400 mL in the older child and adult. The patient and the circuit are

then heparinized by a continuous infusion maintaining an activated clotting time of 200–240 s (1.5–2 times normal). This maintains a balance between catastrophic clot formation and bleeding complications.

While on VA ECMO, the native lungs participate little in gas exchange; therefore, the ventilator is set at "rest" settings. Although the more conventional settings would include room air, rate of 4 breaths/min with a peak inspiratory pressure of 20 cm H_2O, and positive end-expiratory pressure of 5 cm H_2O, some authors have reported improved native lung recovery with the use of higher positive end-expiratory pressures in the range of 12–14 cm H_2O (3). The ECMO flows maintained in any particular patient are chosen to support adequate gas exchange and mean arterial pressure. While on ECMO, the goal is Pao_2 60–100 mm Hg and $Paco_2$ 30–45 mm Hg. Hypocarbia is not routinely attempted.

The duration of ECMO support is a function of both the patient's rate of recovery from the underlying disease and from the frequent development of near complete opacification of the lung fields as seen by chest radiograph after the initiation of ECMO support. The etiology of this "whiteout" is poorly understood; however, it corresponds to a period of markedly decreased lung compliance during which time the patient's ability to exchange gas by way of the lungs is nearly impossible to support in the absence of ECMO (4,5). The decision to wean from ECMO is made when the lung compliance and radiographic image improve and the right-to-left shunt has decreased. The ECMO flow is slowly decreased while the patient's ability to support adequate gas exchange is tested. When the patient can demonstrate gas exchange with acceptable levels of conventional support, the ECMO catheters are removed, and routine conventional ventilatory support is continued.

Extracorporeal membrane oxygenation was first attempted in the early 1970s in a select population of adult patients with acute respiratory failure (ARF) refractory to conventional therapy (4,6,7). The first adult survivor was reported by Hill et al. in 1972 (8), and over the next 5 yr >150 adults were supported with ECMO with a reported survival rate of 10% (7). In response to these early reports, the National Institutes of Health sponsored a multicentered study to compare the effects of ECMO and conventional mechanical ventilation (CMV) in an adult population with terminal ARF. Ninety-six patients with an 80% predicted mortality were selected and randomized to CMV or ECMO. Unexpectedly, the results showed no difference in survival rates, with 8.7% survival with CMV and 9.3% survival rate with ECMO (6). Critics of this study claimed that the study entry criteria selected too heterogeneous a group of patients who, at the time they met study entry criteria, already had irreversible lung damage either from their primary disease or secondary to their ventilator management. They proposed that earlier institution of ECMO might have prevented pulmonary fibrosis, thus improving survival (4,7). The study also imposed a 5-day run limit on the use of ECMO in patients without clearly defined improvement. It is possible that this led to the premature termination of what might have proved to be an effective means of support. However, this study essentially halted the use of ECMO in adults with ARF. In retrospect, these results may not be applicable to the use of ECMO in the 1990s. During the period of the National Institutes of Health study, many patients were victims of an extremely virulent form of influenza virus with resultant pulmonary necrosis, limiting the possibility of reversible lung pathology. Also, compared to the newer, more efficient ECMO circuits, the circuits used during the 1970s captured much less of patients' cardiac output and relied much more on their lungs to achieve oxygenation and ventilation.

Neonatal Extracorporeal Membrane Oxygenation

A new population of neonatal patients with reversible lung disease have emerged as candidates for

ECMO. There are a number of obvious differences between potential adult and neonatal ECMO patients. Adults supported with ECMO often had ARF from destructive primary lung disease or from adult respiratory distress syndrome, which may result in severe parenchymal injury and fibrosis (9). In contrast, neonatal ARF is usually secondary to an abnormality of the pulmonary vasculature, immaturity of the surfactant system, or a chemical pneumonitis with small-airway obstruction, as in meconium aspiration (10). It is unusual for the neonate to have a primary destructive pulmonary process. This gives the neonate a higher likelihood of having reversible lung disease. Despite this advantage, the neonate, as well as the adult, is still subject to secondary lung damage from mechanical ventilation associated with barotrauma and elevated levels of inspired oxygen. Therefore, it would not only be important to select patients with reversible lung processes, but also to identify these patients early in the course of their disease and therapy before irreversible iatrogenic damage can occur. Fortunately, the usual natural history of neonatal respiratory failure makes it possible to identify infants with increased predicted mortality within the first few days of life, before major ventilator toxicity has occurred.

Each of these factors contributed to the success of neonatal ECMO. After a number of scattered case reports (11–15), in 1982 Bartlett et al. (16) published the first series of neonatal patients as a phase I study evaluating the safety and efficacy of ECMO support in infants. An experience of ECMO support in 45 infants during 1974–1982 was reported. The patient population was broad, with gestational ages of 27–44 wk and birth weights of 1–5.2 kg. The investigators tried to identify patients with a <10% chance of survival by devising a scoring system called the Neonatal Pulmonary Insufficiency Index in the first 24 h of life or by the attending neonatologist's clinical assessment that the patient was about to die with routine management. Patient diseases included respiratory distress syndrome, meconium aspiration syndrome (MAS), persistent fetal circulation, and sepsis. The overall survival was 50% and, by diagnosis, respiratory distress syndrome 43%, meconium aspiration syndrome 68%, persistent fetal circulation 60%, and sepsis 25%. Clearly the survival was considerably greater than the anticipated 10%, and the authors concluded that ECMO was effective and had improved outcome compared with conventional management.

As a result of cooperation among neonatal ECMO centers, the national experience has been continuously collected since 1981 in the national ECMO registry. This registry is sponsored by the Extracorporeal Life Support Organization and was created for the purpose of capturing the ECMO experience to track growth, success, or failure. Although patient reporting is voluntary, it is estimated that the registry captures at least 95% of the ECMO cases in the United States. However, because the registry includes different institutions, it reflects different degrees of local expertise with implementing and maintaining ECMO as well as different modes of conventional ventilatory support, and different criteria for predicting anticipated mortality. This results in a very heterogeneous population. In 1988, Toomasian et al. (17) reported the first formal review of the registry: 715 infants treated at 18 centers between 1980 and 1987 were included. These infants met their own institutional criteria for 80% predicted mortality. With ECMO support, 81% survived.

Table 1. Inclusion/Exclusion Criteria for Neonatal Extracorporeal Membrane Oxygenation

Inclusion criteria
1. 80% predicted mortality with conventional therapy
2. 34 wk completed gestation
3. Minimal weight 2 kg

Exclusion criteria
1. Sonographic evidence of significant massive intraventricular hemorrhage (>grade I)
2. Previous mechanical ventilation of >10 days
3. Hypoxemia secondary to congenital heart disease
4. Other anomalies precluding survival

Inclusion and exclusion criteria for neonatal ECMO have been formulated to include patients with a high predicted mortality and a reversible pulmonary process, and to exclude patients with a physiologic process that would not benefit from ECMO, or an underlying condition that would greatly increase the inherent risk of ECMO (Table 1). Specific entry criteria for neonates include an 80% predicted mortality, at least 34 wk completed gestation, and a minimal weight of 2 kg. The exclusion of infants <35 wk of gestation results from an early limited ECMO experience in which premature infants had massive intraventricular hemorrhages (IVH) (18,19). Neonates are also excluded if they have sonographic evidence of a significant IVH (4), with most ECMO centers accepting patients with grade I IVH (hemorrhage into the germinal matrix) and some centers accepting patients with IVH of grade II severity (extension of the hemorrhage into the ventricles). The inherent risk is that with systemic heparinization, the hemorrhage will increase in severity. Extracorporeal membrane oxygenation is not a cure for lung or heart disease; rather, it is a form of cardiopulmonary support while the patient's underlying pathophysiologic process abates. Therefore, infants are excluded if the hypoxemia is secondary to congenital heart disease or if they have other anomalies precluding reasonable survival. To identify these infants, all prospective ECMO candidates must first undergo a cardiac echocardiogram. In addition, to avoid supporting infants with preexisting ventilator damage, >10 days of previous mechanical ventilation is usually considered an exclusion criterion.

The greatest problem with patient selection has been the questionable validity of indicators of predicted mortality based on historical experience. The criteria presently used were formulated from retrospective chart reviews of infants with persistent pulmonary hypertension of the newborn (PPHN) (18,20–22). Most indicators use some measurement of oxygenation: alveolar-arterial oxygen difference, oxygenation index, and Pa_{O_2} (Appendix). Oxygenation index is the most commonly applied predictor, with an 80% predicted mortality identified by oxygenation indices ranging from 0.40 to 0.55 at various centers. It is important that every center determine what is most accurate at their own institution. Despite best efforts, historical control data provide a number of problems and inaccuracies. Historical data evaluate the care given during a prescribed time, and its relevance to current management is questionable. The use of historical controls has been criticized for potentially overestimating mortality. Cole et al. (23) reported that when retrospective ECMO criteria were prospectively applied to a neonatal population, the predicted 80% mortality was in reality only 23%, using only conventional mechanical ventilation. Dworetz et al. (24) from Yale reported a similar study and found only a 17% true mortality.

There have been two prospective randomized studies designed to overcome the limitations and criticisms of historical control populations and advances in CMV. The first by Bartlett et al. (25) compared ECMO with conventional management in patients with a predicted 80% mortality. The study design utilized play-the-winner randomization, which resulted in only 1 patient receiving CMV and 11 patients receiving ECMO. All the ECMO patients survived, but the conventionally treated patient died. This study was published in support of ECMO but was accompanied by much criticism (26). In a second study, O'Rourke et al. (27) again compared ECMO and conventional therapy. This study used an adaptive design; the first stage of 50:50 randomization was followed by a second stage with all patients receiving the "better" therapy. Initially, 10 patients were supported conventionally and 6 survived; whereas of the 10 patients receiving ECMO, all 10 survived. An additional 19 patients were supported with ECMO, with only one death. This study also supported ECMO, but like that of Bartlett, has been criticized for study design (28,29). Despite the limitation of patient selection and paucity of controlled studies, ECMO is now considered standard care for many full-term neonates with pulmonary diseases.

Table 2. Extracorporeal Life Support Organization Registry; Neonatal Entries as of October 1991

Disease	No. of patients	Survived (%)
MAS	2067	93
RDS/HMD	788	85
CHD	996	61
Pneumonia/sepsis	752	77
PPHN	692	88
Other	184	79
Total	5479	83

MAS, meconium aspiration syndrome; RDS, respiratory distress syndrome; HMD, hyaline membrane disease; CHD, congenital diaphragmatic hernia; PPHN, persistent pulmonary hypertension of the newborn.

Presently there are 5479 neonates enrolled in the registry, with an overall survival rate of 83% and a disease breakdown as shown in Table 2. What becomes clear from this is that survival is a function of primary diagnosis, with infants with meconium aspiration syndrome and PPHN experiencing a higher survival rate, and infants with congenital diaphragmatic hernia a much lower survival rate. Although ECMO "run times" are not standardized, some expected time frames do exist. The average run for all neonates is 5.5 ± 2.5 days, with meconium aspiration syndrome and PPHN usually lasting 5 days, neonatal sepsis 5–7 days, and congenital diaphragmatic hernia 7–14 days.

There are many interventions associated with ECMO that increase risk of morbidity. These include ligation and cannulation of the right common carotid artery and right internal jugular vein, systemic heparinization, exposure to blood products, being sick enough to meet entry criteria, and exposure to and possible failure of any of the component parts of the ECMO circuit.

The most frequent complication is bleeding. The most common sites of bleeding include the neck cannulation site, the central nervous system (CNS), and the tracheobronchial tree. Although systemic heparinization and alterations in normal platelet number and function are thought to be responsible for much of this observed bleeding, the etiology of CNS hemorrhage appears to be multifactorial. Possible additional factors include alteration of the normal arterial and venous cerebral circulations (30), the return of unfiltered blood to the systemic circulation, and systemic hypertension. Central nervous system hemorrhage is certainly the most problematic, with a reported 15% incidence in most centers (17,31). During ECMO, serial cranial ultrasound scans are obtained to detect CNS hemorrhage, and ECMO is discontinued in the presence of large or expanding hemorrhage.

Results from the ECMO registry disclose an 11%–30% incidence of CNS injury, leading to anything from subtle to devastating damage (32). Long-term neurologic follow-up of the ECMO survivors has been hindered by the young age of this population and the lack of a comparable control group. The results are limited to reports from several institutions. Towne et al. (33) published one of the first reports from the early ECMO experience at the University of California, Irvine. A 1–14-yr evaluation of 18 patients was reported: 13 (72%) had normal growth and development; 3 (17%) had moderate neurologic deficit; and 2 (11%) were severely injured. More recent clinical experience has been reported from Washington, D.C. (Children's National Medical Center), University of Virginia, and University of Michigan. The Children's National Medical Center studied 42 consecutive patients over a 2-yr period (31). The patients were evaluated with cranial ultrasound while on ECMO, computer tomography studies of the head before discharge, and neurodevelopmental tests and neurologic examinations at 1 yr of age. Despite the fact that 17 (41%) of the patients had abnormal radiographic findings by cranial ultrasound and computed tomography, only 9 (21%) of the children were delayed, 8 (20%) had suspect examinations but were not delayed, and the remaining 25 (59%) patients had normal neurologic examinations. Krummel et al. (34) evaluated six patients and reported five (83%) normal 1–3 yr after ECMO. Andrews et al. (35) reported the follow-up of their first 14 survivors: 9 (64%) had normal motor development; 10 (71%) had normal mental ability. Two more recent studies have interpreted their data by comparison with previously reported morbidity statistics among neonates with severe respiratory failure treated with conventional therapy (36,37). Essentially, they reported no statistical differences between the developmental outcome of ECMO survivors and conventionally treated neonates.

Renal complications also occur commonly during ECMO. The development of renal failure, thought to be suggestive of the development of either pre- or intra-ECMO multisystem organ failure, carries a predicted mortality of >80% shown in one study (38). Hypertension, manifested as systolic pressure >100 mm Hg while on ECMO, is another commonly observed phenomenon, with an incidence as high as 58% in one study (39). The occurrence of hypertension does not correlate with plasma renin levels, colloid volume infused, or milliequivalents of sodium delivered. Possible etiologies include an increase in cardiac stroke volume, preexisting myocardial damage in the nonhypertensive patients, or an alteration in the patient's ability to handle sodium or water.

To circumvent the complications associated with carotid ligation, some centers are attempting carotid artery reconstruction. A recent study, published in 1991, utilized noninvasive magnetic resonance imaging and ultrasound to demonstrate patency of the right common carotid artery in 14 of 18 infants undergoing reconstruction (40). Infants were considered ineligible for this procedure if they demonstrated neurologic abnormalities before decannulation or if they had undergone reexploration for excessive bleeding at the cannulation site. Six-month follow-up was obtained in only seven of the infants; however, the patency rate was 100%.

The registry review (17) also pointed out the importance of the institution's previous experience with ECMO. The patient data were analyzed to see whether outcome improved with technologic experience. Survival of the first 10 patients at all centers was 73.5%, compared with 83.7% if the first 10 patients were excluded. This difference could not be explained by any differences in pre-ECMO characteristics of these patients. Of note, the first 10 patients had a higher incidence of complications (2.26 per patient) compared with later patients (1.6 per patient).

The current status of neonatal ECMO can best be described as controversial and changing. The national experience has steadily grown over the past years. The results of that experience suggest a very high survival rate, and short- and long-term follow-up studies suggest a tolerable morbidity. However, like so many therapies aimed at critically ill patients, ECMO has not undergone the rigors of a large conventional, prospective, randomized study to prove or disprove efficacy. What makes this increasingly difficult is that as ECMO technology has improved, so has CMV, and perhaps these improvements may diminish the disparity in patient outcome from these two methods of support.

The main change in CMV is a progression toward "gentle," less aggressive ventilator support. The mainstay of conventional management of PPHN has been to maximize pulmonary vasodilation by maintaining relative hyperoxia and inducing both a respiratory and metabolic alkalosis (41,42). However, this approach exposes the infant's lungs to 100% oxygen and often markedly elevated airway pressures. Some clinical investigators believe that not only does this approach inflict significant damage to the lungs, but that there is no clearly proved benefit (43,44). These clinicians suggest the use of low airway pressures and F_{IO_2} to maintain just adequate arterial blood gases: Pa_{O_2} 50–60 mm Hg and Pa_{CO_2} <60 mm Hg. Wung et al. (45) from Columbia University have been one of the proponents of this "gentle" therapy. In

1985, they reported 90% survival without the use of ECMO in term neonates with severe respiratory failure. In addition, they also suggest that their method of ventilation results in a much lower incidence of bronchopulmonary dysplasia. Proponents of ECMO state that the risk of residual lung disease in ECMO patients (0%–8%) compares favorably with those treated with conventional mechanical therapy (up to 35%), and some individuals speculate that earlier ECMO intervention may help to eliminate chronic lung disease altogether (18,35,46). These reports do demonstrate dramatically the institutional and chronologic heterogeneity of CMV and the potential problems in utilizing ECMO criteria developed in one institution at a fixed time.

Pediatric Extracorporeal Membrane Oxygenation

As the technology for neonatal ECMO became routine in many pediatric centers, ECMO was soon applied to older children who were thought to be at risk for dying of pulmonary disease. In most situations, it has been offered as a "last resort" or rescue therapy on an individual case basis (8,47–51).

The existing experience of pediatric ECMO for ARF is documented in several small clinical reports and in the Extracorporeal Life Support Organization registry (48,50,52). As of October 1991, 285 pediatric patients have been reported in the registry. There are no specific entry criteria for pediatric ECMO. Typically, ECMO is reserved for those patients with an anticipated 100% mortality, as judged by their physician. The heterogeneity of patient age, development, and etiology of disease makes it even more difficult to define this population compared with neonates.

In the older child, ARF is caused by a number of diseases, which, although different, may share some common pulmonary pathophysiology. Unlike the neonate with PPHN, many of the acute respiratory diseases in children are associated with direct air-space injury, with necrotizing alveolitis, and with deposition of fibrin (53,54). In addition, most older children are exposed to longer periods of ventilatory support before meeting criteria for CMV failure. As a result, the older child has a much higher probability of iatrogenic injury from elevated airway pressure and oxygen exposure. In addition, while most lung diseases share a final common pathophysiology, the inciting event can be remarkably different. It is not clear that ARF from hydrocarbon ingestion is the same as ARF from viral pneumonia or near drowning. Also, because pediatric patients represent a wide spectrum of ages, and because the child's lungs continue to grow, mature, and remodel during the first years of life, one wonders whether equivalent injuries have the same morbidity and mortality in a child aged 10 mo compared with one aged 10 yr.

The natural history of ARF in older children is poorly understood. Specifically, is death caused by inadequate gas exchange? Studies of adult patients with ARDS show that <20% of these patients die of respiratory failure (55,56). The majority die of multisystem organ failure, and mortality is particularly elevated in the presence of sepsis or malignancy, or both. Similar studies in pediatric patients are scant, but the existing evidence supports the same findings (57–59). This is in sharp contrast to the neonate with PPHN who often succumbs to hypoxemia. Therefore, in the older child can maintenance of gas exchange change the natural course of the disease? Should ECMO be offered earlier before multisystem organ failure occurs, or should it be a contraindication for ECMO?

To date, most pediatric ECMO has used the same technologic approach as routine neonatal VA ECMO, with cannulation of the right internal jugular vein and the right common carotid artery. The risks of ECMO in the older patient are similar to those in the neonate. Although there is anecdotal evidence that the older child has more hemorrhagic complications with pulmonary and cannulation site bleeding, there appear to be fewer CNS hemorrhagic complications (60).

Cardiac Extracorporeal Membrane Oxygenation

Venoarterial ECMO has also been used to support cardiac function in pediatric patients with cardiovascular dysfunction. The majority of these patients are children who develop low cardiac output syndrome or severe pulmonary artery reactivity, or both, after surgical repair of congenital heart defects. There are also a few children who have been placed on ECMO preoperatively, and others with myocarditis or cardiomyopathy in whom ECMO has provided a bridge to cardiac transplant or hemodynamic support until their myocardial function resolves.

As of the end of 1991, 494 children have been supported with ECMO for acute cardiovascular failure. The majority (90%) of these patients were placed on ECMO after surgical repair of congenital heart disease; the remainder had cardiac failure from myocarditis or a cardiomyopathy (52). The overall survival rate is reported to be 47%. A few patient series have been reported (61–65), and a number of patterns have emerged. The average duration of ECMO support in these patients was much shorter than for ARF patients. Pennington et al. (66) reported an average

ECMO duration of <4 days in survivors and noted that those requiring >7 days subsequently died. Another observation was that survival correlated with the time of ECMO initiation; patients who required ECMO support either in the operating room or within the first six postoperative hours experienced a high mortality of >90%, whereas those who demonstrated more perioperative stability and were placed on ECMO at >4 h had an improved outcome. This dramatic difference may represent the fact that the group requiring early ECMO intervention had greater myocardial damage or that they suffered more hemorrhagic complications, or both, as a result of the resumption of systemic heparinization before adequate hemostasis.

The indications for ECMO as postoperative support are poorly defined. Similar to the pediatric ARF population, there have been no retrospective or prospective controlled studies. The heterogeneity of the population makes it difficult to identify predictors of mortality. Most clinicians select ECMO candidates on the basis of evidence of decreased end-organ perfusion and the failure of pharmacologic support of the circulation. Dosage of inotropic agents, elevation of right or left atrial pressures, decreased mixed venous oxygen saturation, metabolic acidosis, decreased urine output, and increased serum levels of liver enzymes are all factors used to select patients. Investigators have reviewed their experience with selected groups of patients to predict mortality and to guide patient selection for ECMO. As an example, Klein et al. (65) reported in a retrospective chart review that there was a <3% survival in postoperative cardiac patients, who at 8 h after bypass required >10 $\mu g \cdot kg^{-1} \cdot min^{-1}$ of dopamine and had <2.0 $mL \cdot kg^{-1} \cdot h^{-1}$ urine output. Obviously, these findings vary with the types of cardiac diseases studied, the preoperative status of the patients, the surgical repair, and the institutional approach to inotropic management. These results must be evaluated independently in each institution, and regardless of the indicators used, it is important to identify these ECMO candidates before the development of irreversible end-organ failure and cardiac arrest. Two clear prerequisites for postoperative ECMO include a successful surgical repair and cardiac anatomy compatible with ECMO cannulation. Contraindications for postoperative ECMO include irreversible neurologic damage and active uncontrolled bleeding at the surgical site.

The ECMO procedure in acute cardiovascular failure is similar to VA ECMO used for ARF. The flow rates required to support perfusion are often greater: 100–200 $mL \cdot kg^{-1} \cdot min^{-1}$. This emphasizes the need for very large venous catheters. Transthoracic cannulation is often used to allow larger catheters; however, the main disadvantage of this is the difficulty in assessing and treating cannula site bleeding.

During ECMO, the blood returning at high flow rates to the ascending aorta can increase left ventricular afterload. This can have a negative impact on those patients with left or biventricular failure. Decompression of the left side of the heart can be achieved through placement of a left atrial or left ventricular catheter (65,66). Although this may help unload the left ventricle, it is obviously more invasive and provides added risks.

Other forms of extracorporeal oxygenation and support have evolved from the original techniques and applications of VA ECMO. These include VV ECMO, $ECCO_2R$, and IVOX.

Venoveno Extracorporeal Membrane Oxygenation

In VV ECMO, blood is drained from the right side and returned to the right side of the circulation. This can be accomplished with either a single- or double-catheter system. In the double-catheter system, one catheter is used for drainage and the other for return (67,68). Most commonly, outflow is through a right atrial catheter, and blood is returned to the femoral vein (68). Unfortunately, with this system there is recirculation when some of the oxygenated blood returned via the femoral vein is captured by the outflow catheter in the right atrium and is recirculated through the ECMO circuit.

Various types of single-catheter VV ECMO have been attempted. The most promising is a double-lumen catheter that allows continual outflow through the proximal port and inflow through the distal port (69). Despite the two ports, there is some recirculation of oxygenated blood. Another single-catheter system uses a single-lumen catheter. Similar to dialysis systems, there are separate infusion and outflow times that are controlled by a tidal flow system (70,71).

Regardless of which system is used, VV ECMO has some basic differences compared with VA ECMO. Perhaps most important is the fact that VV ECMO does not support cardiovascular function. Second, the patient's Pa_{O_2} is lower in VV ECMO than in VA ECMO; this reflects the fact that there is some degree of recirculation of oxygenated blood back into the ECMO circuit. Because the efficiency of gas exchange is less than in VA ECMO, often the patient's lungs have to be used to augment oxygenation. This obviates the ability to totally rest the lungs, which may cause further lung injury and impact the ability of the patient's lungs to heal. Despite these differences, many centers are now involved in neonatal VV ECMO, and in some institutions it is the treatment of choice over VA ECMO.

Extracorporeal CO_2 Removal

Another approach to extracorporeal gas exchange is extracorporeal CO_2 removal ($ECCO_2R$). This mode of support dissociates oxygenation and carbon dioxide elimination into essentially two separate functions. The lungs are used for oxygenation, and the ECMO circuit maintains ventilation or removal of carbon dioxide. Because the circuit only supports ventilation, a relatively small fraction of the cardiac output is obligated to go through the ECMO circuit. This can be accomplished by using VV ECMO, either with a single catheter placed in the internal jugular system or via a two-catheter system, using a combination of the jugular-to-femoral or femoral-to-femoral systems. Oxygenation is then supported by the lungs. Low-frequency positive pressure ventilation is used and incorrectly called "apneic oxygenation." In the described series, a catheter delivers low-flow 100% oxygen at the level of the carina, while the ventilator delivers 4–12 breaths/min with peak pressures of 40–50 cm H_2O and peak end-expiratory pressures of 8–15 cm H_2O. While the patient is on this support, systemic heparinization is required (72).

The advantage of this system, as well as VV ECMO, over more routine VA ECMO is the fact that the arterial system does not need to be accessed. This is particularly important in consideration of the fact that the standard arterial approach involves cannulation and ligation of the common carotid artery in the infant and child.

$ECCO_2R$ requires the patient's lungs for oxygenation. This implies that $ECCO_2R$ should be instituted before impairment of gas exchange is too severe. If the lungs cannot support any oxygenation, $ECCO_2R$ is not an option.

In 1986, Gattinoni et al. (72) reported the results of $ECCO_2R$ in 43 patients who, in their estimation, had an expected mortality of >90% with conventional therapy. These patients were placed on $ECCO_2R$ as rescue therapy. Thirty-one (72.8%) showed improvement in lung function, and 21 (48.8%) survived. Although this was an uncontrolled study, it was stated that $ECCO_2R$ was a safe and effective method to support gas exchange and that it should be considered as an alternative to standard methods of mechanical ventilation (72).

Intravascular Oxygenation

A new investigational method of gas exchange is the intracorporeal intravenous mechanical gas exchange system, which has been referred to by the acronym IVOX. The concept is simple: a small-diameter holofiber membrane oxygenator is placed into the inferior vena cava, thereby obviating the need for an extracorporeal circuit. The oxygenator is introduced via a sheath placed through a common femoral venotomy. The oxygenator is advanced in a cephalad direction with the distal tip lying in the superior vena cava or the right atrial appendage. Once inserted, the oxygenator unfurls, exposing the expanded surface area necessary for gas exchange. The oxygenator has a double-lumen gas transport tube that allows for an inflow and outflow limb. Oxygen passes through the inflow limb, driven either by positive pressure or by suction, and provides oxygenation and washes out carbon dioxide. The oxygenators are made in three different sizes, with surface areas that range from 225 to >9000 cm^2 with external diameters of 1.8–10.8 mm. Gas exchange is a function of the oxygenator surface, the sweep gas through the oxygenator, the mixed venous Po_2 and Pco_2, and the patient's cardiac output. The oxygenator surface in IVOX cannot entirely support gas exchange, and similar to $ECCO_2R$, the patient's lungs must be used (73,74).

The IVOX system has successfully supported gas exchange in 20–40-kg dogs and 60-kg sheep. There have been no reportable complications. There was little or no hemodynamic effect on central venous pressure or cardiac output after insertion. There has been no evidence of gas emboli or bubbling; and, finally, neither clotting nor thrombi deposition was observed in any of these animals. Of note, all animals were fully heparinized.

Under surveillance of the Food and Drug Administration, clinical trials are in progress to test the efficacy of IVOX in adults. In the phase II trial, IVOX is being offered to patients with at least a 90% predicted mortality from continued conventional methods of support (75).

Summary

Extracorporeal membrane oxygenation is still a relatively new technology that has recently achieved recognition after initial clinical disappointment in the late 1970s. At present, it is considered standard therapy for the full-term infant with PPHN who fails CMV and extraordinary, heroic therapy for older children and adults with ARF or cardiac failure, or both. Currently, the emphasis is on developing new technologies for increasing safety and effectiveness. Areas of interest include heparinless circuits, carotid artery reconstruction, improved monitoring, and expanding applications of VV ECMO. As ECMO becomes safer and more effective, it is believed that new and expanding patient populations will emerge to include premature infants, earlier intervention in term infants, and more liberal application to pediatric and adult populations.

Appendix

1. Oxygenation index (OI):

$$\mathrm{OI} = \frac{(\mathrm{MAP})(\mathrm{FIO_2})(100)}{\text{Postductal } \mathrm{PaO_2}},$$

where MAP = mean alveolar pressure; $\mathrm{FIO_2}$, fraction of inspired O_2; and $\mathrm{PaO_2}$ = arterial oxygen tension.

2. Alveolar/arterial oxygen difference ($\mathrm{AaDO_2}$):

$$\mathrm{AaDO_2} = \mathrm{PAO_2} - \mathrm{PaO_2},$$

where $\mathrm{PAO_2}$ = alveolar oxygen tension = $[\mathrm{FIO_2} \times (\mathrm{P_B} - \mathrm{P_{H_2O}})] - \mathrm{PaCO_2}/R$, and $\mathrm{P_B}$ = barometric pressure; $\mathrm{P_{H_2O}}$ = water vapor pressure; $\mathrm{PaCO_2}$ = arterial CO_2 tension; and R = respiratory quotient difference.

LABORATORY REPORT

Local Anesthetic-Sensitive Electrodes: Preparation of Coated-Wire Electrodes and Their Basic Properties In Vitro

Atsuko Yokono, MD, Hiromu Satake, PhD, Shoji Kaneshina, PhD, Satoshi Yokono, MD, and Kenji Ogli, MD

Department of Anesthesiology and Emergency Medicine, Kagawa Medical School, Kagawa, Japan, and Department of Biological Science and Technology, Faculty of Engineering, The University of Tokushima, Tokushima, Japan

---

Coated-wire electrodes with local anesthetic (LA) cation-selective membranes were prepared, and their properties in vitro were investigated. Copper wires (0.8-mm diameter) were coated with gel membranes of 110 mg of poly(vinyl chloride), 5 mg of ion pairs of tetraphenylborate anion with LA cation, 100 mg of dioctylphtalate, and 1.5 mL of tetrahydrofuran. This was the composition determined to be most suitable. Their electromotive force relative to an Ag/AgCl electrode was measured in LA solutions. The lidocaine, dibucaine, and mepivacaine electrodes all showed good Nernstian response at 25°C in aqueous solutions in the concentration ranges of 1×10^{-4} to 1×10^{-2} mol/L, 4×10^{-5} to 1×10^{-2} mol/L, and 5×10^{-5} to 1×10^{-2} mol/L, respectively. The response time was within 10 s. The electrode potential decreased as the pH in the solution increased, with a corresponding decrease of the protonated form of LA. The hydrophobic nature of the LA was closely related to the electromotive force and to the selectivity of the electrode toward various LA cations. Dibucaine, the most hydrophobic, had the highest electrode potential. The more hydrophobic the LA of the electrode, the less it is interfered with by other LA molecules. The more hydrophobic the interferent cation, the more it acts on the electrode potential. The electrode system could also measure LA in human plasma at 37°C, although the responsiveness was depressed in the low concentration range owing to binding of LA to the serum protein. Its small size, convenience of handling, good response, and simplicity of measurement indicate the feasibility of the electrode system for in vivo application.

(Anesth Analg 1992;75:1063–9)

The concentration of local anesthetics in plasma, like that of many other drugs, is usually assayed by high-performance liquid chromatography, gas chromatography, radioimmunoassay, or fluorescence polarization immunoassay. These methods require special techniques and equipment and are expensive for routine use. They also require the sampling of a certain amount of blood. As a result, it is difficult to discern the detailed pharmacokinetics concerning the effects or intoxication of local anesthetics. We have developed coated-wire electrodes sensitive to local anesthetic cations that are small and feasible for future use in vivo. This report describes the basic principle of the sensor system, preparation, and some properties of the electrodes in vitro.

Principle

Local anesthetics used clinically are basically tertiar amine compounds. Most of the molecules exist in protonated form (cation) in vivo, according to th Henderson-Hasselbalch equation. In general, the a tivity (which is nearly equal to "concentration" i dilute solutions) of a cation or anion can be dete mined electrochemically. When two solutions wit different concentrations of an ion are separated by certain ion-selective membrane, ions keep movin through it until equilibrium is attained, where th chemical diffusion force balances the electromotiv force. This is just the basic concentration cell. Th Nernst equation shows that the ratio of the io activity of both solutions corresponds to the electr potential difference between them; pH/mV meters i general use are based on this principle. The mai problem with this method is how to make the men brane selective only to the particular ion concerned

Local anesthetics are amphiphilic. The amine en is hydrophilic and can be positively charged, wherea the aromatic end is greatly hydrophobic. If a catior

exchange membrane (e.g., poly(vinyl chloride) [PVC] membrane) incorporates a certain kind of local anesthetic cation with some hydrophobic anions as ion carriers, the hydrophobic nature enables this membrane to react only to the local anesthetic cations concerned in the surrounding solution.

Thus, a local anesthetic cation-selective electrode can be obtained that consists of this ion-selective membrane and an inner solution of a known concentration of the local anesthetic. When this electrode is immersed in an ionic solution of unknown concentration (the outer solution), the ratio of the two concentrations can be calculated from the electromotive force between the inner and outer solutions.

This type of sensor is easily made, and its use in potentiometry exhibits good response; however, it is still too large to insert into blood vessels for the purpose of in vivo investigations.

We developed another type of electrode: a coated-wire electrode that operates as described earlier. This sensor simply consists of a copper wire coated with the membrane described previously and has no inner solution. The details of the mechanism by which the activity of local anesthetic cations surrounding the sensor membrane is converted to the electric potential of the wire are still unknown. However, this simple sensor also works in accordance with the Nernst equation (Appendix 1) (1). Because it needs no inner solution and can be miniaturized, it may be applicable to in vivo use.

In the following, we report the preparation of the coated-wire electrodes sensitive to some amide-type local anesthetics: lidocaine electrodes, dibucaine electrodes, and mepivacaine electrodes, and their basic properties for potentiometric analysis in vitro.

Methods

Construction of Electrodes

The coated-wire electrodes were prepared by the same method described previously (2). As shown schematically in Figure 1, copper wires (0.8 mm diameter) were coated to a thickness of about 0.4 mm with membranes of PVC matrix that included the ion pairs, dioctylphtalate (DOP), and tetrahydrofuran (THF) in various compositions.

A high-molecular-weight PVC (Wako, Japan) was used. To make the ion exchangers of the membrane, local anesthetic–tetraphenylborate ion pairs were prepared from hydrochlorides of local anesthetics and sodium tetraphenylborate (NaTPB) (Aldrich) according to the same method described previously (2) for other ion pairs. Hydrochlorides of local anesthetics used were purchased from Sigma Chemical Co. (St. Louis, Mo.), except for lidocaine/HCl (Fujisawa Yakuhin, Japan). Dioctylphtalate (Tokyo Kasei, Japan) was used to plasticize the PVC membrane. Tetrahydrofuran (Wako, Japan) was used as a common solvent for the ion pair, DOP, and PVC.

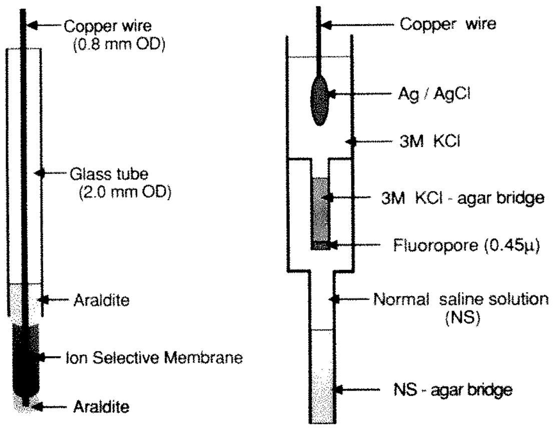

Figure 1. The structure of the coated-wire electrode (**left**) and the reference electrode (**right**).

Glass and epoxy resin (Araldite) covered the surface of the wires to maintain isolation, except for the membrane portion. The electrodes were allowed to stand for at least 10 h in contact with air, and afterward were stored by immersion in 10^{-3} mol/L solutions of the local anesthetics for which they were selective.

Potential Measurement

The coated-wire electrodes were used as the indicator electrodes, whereas an Ag/AgCl electrode connecting a normal saline agar bridge was the reference electrode (Figure 1). Immersing both the electrodes in test solutions (i.e., local anesthetics to which the electrode was selective in 0.15 M, pH 7 phosphate buffer), we recorded the electromotive force. The electrochemical system was as follows: local anesthetic coated-wire electrode/test solution/normal saline agar bridge/3 mol/L KCl solution/Ag/AgCl electrode. The electromotive force was measured with a multi-ion monitor (Yamashita Giken, Tokushima, Japan) at 25°C in the constantly stirred solution. A circulating water bath controlled the temperature of the test solution. To construct calibration curves (electromotive force vs concentration), suitable increments of local anesthetic solution were added so as to cover the concentration range 10^{-6} to 10^{-2} mol/L.

We prepared five coated-wire electrodes, each with 8 to 13 types of membrane compositions. We investigated the effect of membrane composition on the responsiveness, stability, and reproducibility of the electrode potential and determined the suitability of the composition according to these points. Using the electrodes with the most suitable composition, we performed the following tests.

pH change of the solution. We examined the effect of pH of the test solution on the electrode potential for 10^{-4} mol/L solutions of local anesthetics in normal saline at 25°C. The pH was changed repeatedly in the range 4–11 by the addition of 10^{-1} mol/L hydrochloric acid or sodium hydroxide solutions, or both, containing 10^{-4} mol/L of the corresponding local anesthetic.

Selectivity of the electrodes. The influence of other local anesthetic cations toward each electrode potential was investigated. Selectivity coefficients (Appendix 2) were determined by the separate solution method (3,4) using 10^{-2} mol/L of local anesthetic solutions.

Response in plasma. The response of the electrodes in human plasma was also examined to ascertain the feasibility of their use in vivo. Sensitivity, stability, and reproducibility of the electrode potential were checked at 37°C in constantly stirred Plasmanate (Miles Inc.) with the same electrode system.

Results

Composition of Electrode Membrane

The best results were obtained with an electrode with a membrane prepared from mixtures of 100 mg of DOP, 110 mg of PVC, and 1.5 mL of THF for all local anesthetic ion-selective membranes. As for ion pairs, the potential response curves shifted in a parallel manner to the negative side as the membrane content of the local anesthetic–TPB ion pairs increased. However, the slope of the linear part of the curve did not change when the range of the ion pair content was within 1–25, 1–10, and 1–25 mg for lidocaine, mepivacaine, and dibucaine, respectively, the mixtures DOP, PVC, and THF being held constant as above. When the contents of DOP (<50 mg) and ion pair (<1 mg) decreased, the electrode potential became unstable owing to the increased resistance of the membrane. A large excess of DOP and ion pair in the membrane caused the surface of the copper wire to gradually become black, shortening the electrode lifetime and decreasing the slope of the potential curve. We adopted 5 mg of the local anesthetic–TPB ion pairs for all the electrode membranes to standardize the quality of electrodes and to evaluate the potential differences between electrodes of various local anesthetics.

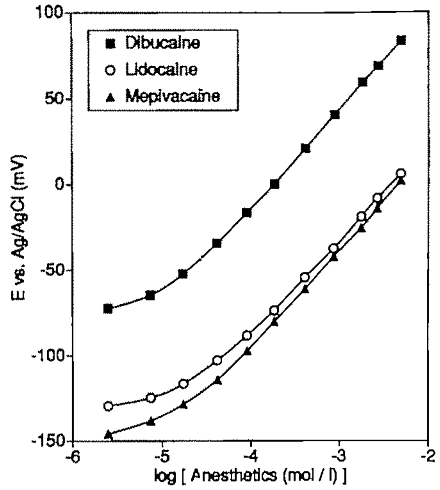

Figure 2. Relationship between the local anesthetic concentration in phosphate-buffered solution and the electrode potential relative to the Ag/AgCl electrode at 25°C.

Response of the Electrodes

The typical calibration curves of each electrode with this composition are shown in Figure 2. The linear response range of the calibration curves, their Nernstian slope, and the coefficients of variation of the slopes are shown in Table 1. The potential changes of the lower concentration range compared with the linear response range are also shown in Table 1.

The response time was within 5–10 s for all of the electrodes in the local anesthetic concentration range 10^{-5} to 10^{-2} mol/L and 30 s in 10^{-6} mol/L. Figure 3 shows a typical response curve. Reproducibility of electrode potential was checked by increasing or decreasing the concentration. Fluctuations of the electrode potentials were within 1% of the coefficient of variation when the concentration was changed from 10^{-4} to 10^{-2} mol/L or from 10^{-2} to 10^{-4} mol/L. Although continuous measurements of the electrode potential were taken over an 8-h period, the change in the electrode potential remained within 3 mV in this concentration range. We confirmed that the electrode could be repeatedly used to determine the local anesthetic concentration every day for 30 days.

Effect of pH

Figure 4 shows the potential variation versus pH change in one of the five electrodes of each local anesthetic electrode prepared. All of the other electrodes for the same local anesthetic showed a similar curve.

Table 1. Potential Characteristics of the Electrodes

Electrode	Linear response range Concentration (mol/L)	Slope (mV/decade)	CV (n = 5) (%)	Lower concentration range Potential difference[a] (mV/decade)	CV (n = 5) (%)
Lidocaine	1×10^{-4} to 1×10^{-2}	55.9	0.9	21.5	2.3
Mepivacaine	5×10^{-5} to 1×10^{-2}	56.8	0.6	25.0	1.3
Dibucaine	4×10^{-5} to 1×10^{-2}	58.6	0.3	31.0	0.5

CV, coefficient of variation.

[a] Differences in the electrode potentials between $10^{-5.5}$ M and $10^{-4.5}$ M of the local anesthetics.

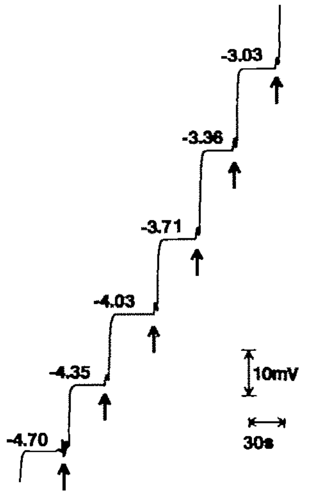

Figure 3. Continuous recording of the potential response of the lidocaine electrode with successive additions of lidocaine to the test solution. *Arrows* indicate the points at which lidocaine was added. *Small spikes* in the curve are the noise due to adding lidocaine with a microsyringe. *Values* on the curve represent the lidocaine concentration ($\log_{10}$ of mol/L) of the test solution.

Selectivity of the Electrodes

Results are summarized in Table 2. Value of selectivity coefficients means that the smaller the value of the interferent ion, the less the ion can interfere with the electrode potential. The dibucaine electrode was the least affected by the presence of other local anesthetics.

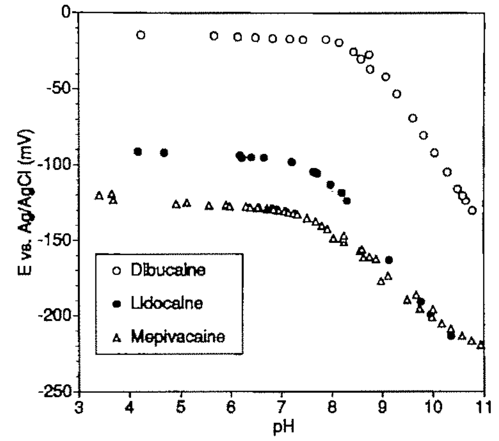

Figure 4. Effect of pH on the response of the local anesthetic electrodes.

Table 2. Selectivity of Electrodes Toward Other Local Anesthetics[a]

Interferent	Electrode Mepivacaine	Lidocaine	Dibucaine
Benzocaine	−1.26	−1.79	−3.40
Procaine	−0.17	−0.85	−2.59
Mepivacaine	—	0.05	−1.99
Lidocaine	0.05	—	−2.09
Tetracaine	1.10	1.05	−0.92
Bupivacaine	1.50	1.30	−0.78
Dibucaine	1.74	1.97	—

[a] Values are expressed as $\log_{10}$ of selectivity coefficients of the interferent to the electrode cation.

Electrode Response in Plasma

The typical calibration curves of each electrode are shown in Figure 5. The general potential level in the plasma showed some displacement from that in the crystalloid solution. The response curve was less linear than that in the crystalloid solution, and the potential difference versus concentration change of the curve was smaller, especially in the low-concentration range of the local anesthetic (Table 3). The response time was within 10–20 s for all of the electrodes in the concentration range 10^{-5} to 10^{-3} mol/L and 30 s at 10^{-2} mol/L. Reproducibility of electrode potential was checked by increasing or decreasing the concentration. Fluctuations in electrode potentials are also shown in Table 3. Electrode potential change over 4 h of continuous measurement was within 3 mV in the concentration range 10^{-4} to 10^{-2} mol/L. After measurement in Plasmanate, we checked the calibration curve of the electrodes in the crystalloid solution again and found no deterioration in the response.

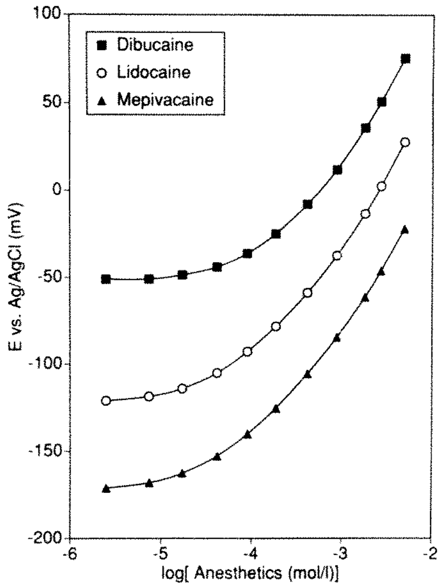

Figure 5. Relationship between local anesthetic concentration in Plasmanate and the electrode potential relative to the Ag/AgCl electrode at 37°C.

Discussion

The measurement of drug concentrations in the body usually involves the removal of some blood or body fluid, which prevents the evaluation of changes in concentration in small animals from many collection points. To examine the distribution of a drug to various body components, radiologic methods are also used, which require sequential killing of animals and cannot be applied to human studies. In any case, these methods cannot quantitate the real clearance of special organs (e.g., the difference between pre- and posthepatic circulation) or the dynamic uptake in small but critical compartments of the body (e.g., cerebrospinal fluid).

Ion-selective membrane electrodes have been well researched and are frequently used in the field of analytical chemistry. Some have involved the preparation of a coated-wire type (5–10) because of simplicity of fabrication and manipulation. But analysis in vivo with such a coated-wire electrode has not yet been reported. This is especially true in the case of electrodes that are selective for certain types of clinical drugs. The present report indicates the feasibility of future application of drug-selective electrodes in vivo for pharmacokinetic research.

The coated-wire electrodes that we developed were sensitive to local anesthetics of concentration range 10^{-6} to 10^{-2} mol/L. That the slopes approximate 59 mV/concentration decade at 25°C means that the membranes have good selectivity for the local anesthetic cations and work in accordance with the Nernst equation (Appendix 1).

Although the responsiveness of the electrodes is excellent and slope versus concentration is stable, the relative potential to the reference electrode cannot immediately indicate the absolute concentration. Calibration for each pair of electrodes is always necessary before measurement. Even minute changes in the content of the ion pairs in the membranes during long-term use can affect the general potential shift. The condition of the reference electrode may also change over time. All potentiometric analysis equipment, even pH/mV meters in general use, need calibration before use.

In an alkaline media, the electrode potential decreased as the pH value increased. This is probably due to a decrease in the concentration of the protonated form (or cation) with a corresponding increase of uncharged form (or base) of the local anesthetic. According to the Henderson-Hasselbalch equation for basic drugs, the proportion of cation to total drug (cation + base) is 0.5 when the pH is equal to the pKa of the drug: pH = pKa + log([base]/[cation]). The recently reported pKa values for lidocaine, dibucaine, and mepivacaine at 25°C are 7.91, 8.72, and 7.76, respectively (11). The pH of the solution in which the ratio of cation decreases from 0.5 to 0.05 and 0.005 is calculated from the equation to be pKa + 1.28 and pKa + 2.30, respectively. These decadal changes in cation concentration should show a correspondingly negative shift in the electromotive force with the value of Nernstian slope. This fits well with the alkaline portion of the curves in Figure 4, although the slope of mepivacaine is moderate compared with dibucaine or lidocaine. On the other hand, when the pH decreases by 1 from the pKa, this ratio increases steeply to 91%. When pH decreases by 1.28 or more, the ratio increases to over 95%. Then pH less than 6.5, 7.4, and 6.5 for lidocaine, dibucaine, and mepivacaine, respectively, should make the cation concentration almost constant. This is consistent with our results. Here the concentration of cation equals that of the total drug.

The difference in the hydrophobicity of local anesthetic molecules seems to be responsible for the difference in the electrode potentials among the anesthetics shown in Figure 2. Strichartz et al. (12) reported that the values of the distribution coefficients between *n*-octanol and buffer solution (pH 7.4, 25°C), which reflect the hydrophobicity of the anesthetic molecules, were 1.7, 21, 43, 221, and 346 for procaine, mepivacaine, lidocaine, tetracaine, and bupivacaine, respectively. Fazly Bazaz and Salt (13) reported that the partition coefficients between *n*-octanol and an aqueous medium (pH 6.4, 22°C) were 5.23, 17, and 100 for lidocaine, tetracaine, and dibucaine, respectively, whereas Cassidy et al. (14) reported figures of 9.1 and 33.9 for tetracaine and

Table 3. Potential Characteristics of the Electrodes in Plasmanate

	Anesthetic concentration					
	$10^{-5.5}$ to $10^{-4.5}$ mol/L		$10^{-4.5}$ to $10^{-3.5}$ mol/L		$10^{-3.5}$ to $10^{-2.5}$ mol/L	
Electrode	Potential difference (mV/decade)	CV ($n = 5$) (%)	Potential difference (mV/decade)	CV ($n = 5$) (%)	Potential difference (mV/decade)	CV ($n = 5$) (%)
Lidocaine	11.5	3.0	44.0	1.3	74.5	0.8
Mepivacaine	14.5	2.8	43.5	1.3	72.5	0.8
Dibucaine	5.5	3.2	30.5	1.6	62.0	0.6

CV, coefficient of variation.

dibucaine (pH 7.4, 37°C), respectively. Although these reported partition values vary greatly, presumably owing to the different temperature conditions, ion strengths of the aqueous solutions, or the method of measurement of the local anesthetic concentration, it is true that mepivacaine is more soluble in water than lidocaine, and dibucaine has a much larger partition coefficient for oil than the other local anesthetics. Dibucaine has a butoxyquinoline group instead of a benzene, which accounts for its strong hydrophobicity. The larger the distribution coefficient, the higher the electrode potential or electromotive force, because hydrophobic interaction between the anesthetic cation and the hydrophobic TPB anion becomes stronger. The difference in the selectivity coefficients toward various local anesthetics is also closely related to their lipid solubility as determined by Strichartz et al. (12). The more hydrophobic the electrode's local anesthetic, the less it is interfered with by other local anesthetic molecules. The more hydrophobic the interferent cation, the more it acts on the electrode potential.

As is seen from Figure 5, the potential response in the plasma loses its linearity in the aqueous solution. This is because the local anesthetics bind to albumin and globulin in the plasma, and the free local anesthetic cations decrease. An electromotive force originates only from the free local anesthetic cations and not from the bound ones. In the low-concentration range of local anesthetics, the ratio of the bound to total drug is high, thus depressing the potential response. However, in the high-concentration range, the free fraction increases markedly as the total drug concentration increases; hence the slope of the potential response can be higher than that in protein-free solutions. These effects are remarkable when the affinity of local anesthetics to protein is strong. Dibucaine has a stronger affinity for proteins than lidocaine or mepivacaine, so that its response is more depressed than the others in the low-concentration range. It may be difficult to measure dibucaine concentrations of $<10^{-4}$ mol/L in plasma. However, for lidocaine and mepivacaine, which are drugs in clinical use, the usable range nearly corresponds to the clinical concentration. For example, 10 μg/mL of lidocaine corresponds to $10^{-4.37}$ mol/L. This system is more responsive and useful for the study of the concentration in cerebrospinal fluid, which contains very little protein.

Plasmanate contains the same components as human plasma except for fibrinogen and γ-globulin. The stability and reproducibility without deterioration of the electrode response in Plasmanate are predictable for the practical use of the electrodes in vivo. Of course the influence of fibrinogen and blood cells on the electrodes has to be taken into consideration when we plan their intravascular use, but these electrodes are not likely to accumulate fibrin or coagula easily, because the surface of the electrode tips is quite smooth. They are made by dipping the wire into the membrane gel or epoxy resin and allowing gravity to form a thin, smooth drop shape on the tip when drying. Moreover, measurement in vitro is accompanied by a constant stirring of test solutions in small experimental glass cells; thus, whole blood when used as a test solution can easily provoke hemolysis and requires the addition of anticoagulants. Such experimental conditions are different from normal intravascular bloodstream conditions. The direct application of the electrode in vivo is worth considering as the next experimental step. In our experiment, the coated-wire electrodes were found to be reliable when used repeatedly over several days. In practice, however, we will be able to use and discard a new electrode each time because many electrodes of identical quality made of the same membrane gel can be easily produced at low cost.

The response time of the electrodes of <10 s is reasonable for potentiometric measurement. Still, it may not be fast enough to directly read the fluctuating values in vivo (e.g., plasma drug concentration after intravenous administration). The time taken to be to near equilibrium is shorter than the response time that we determined, as is shown in Figure 3. Hence each potential response can be promptly extrapolated to discern the final value at equilibrium.

The measured potential can be processed with some appropriate calculation to express the final value, which may be practical for analysis in vivo.

There are several advantages with this type of electrode. The absence of inner solutions makes handling and maintenance of the electrodes convenient for daily use. This measuring system is economical because it needs no special equipment or reagent except for a potentiometer with a large internal resistance. The electrodes are very small, and the use of ever-thinner copper wire and flexible fine plastic tubing instead of glass may further miniaturize them in the future and make their insertion into small animals easy. These very small electrodes may find other uses besides pharmacokinetic study. Although most local anesthetic molecules exist in charged form in normal plasma conditions, the uncharged form assumes an important role in the drug effect on organs or cells. The coated-wire ion-selective electrode that responds only to the charged form can be used for the assessment of biological activity in situ of charged and uncharged species separately.

In conclusion, the properties of the coated-wire electrodes are consistent with the electrochemical nature of the local anesthetics. Their small size, stability, and good response in measurement will facilitate their use in vivo.

Appendix 1

Assuming that there is a nonaqueous organic phase (β), with strong hydrophobic anions (A_2^-) (i.e., tetraphenylborate$^-$) and their counter-cations (B^+) (i.e., local anesthetic cation) as ion exchangers, and an adjoining aqueous phase (α) that includes hydrophilic anions (A_1^-) (i.e., Cl^-) and the same cations (B^+), activity of B^+ in the organic phase is fixed by the A_2^-, because A_2^- cannot cross the interface or go into hydrophilic phase because of their hydrophobicity:

$$\begin{array}{c|c} \text{Aqueous phase } \alpha & \text{Organic phase } \beta \\ B^+ \quad A_1^- & B^+ \quad A_2^- \end{array}$$

As long as the concentration of the ion pairs in β is constant, the electric potential difference between these phases depends solely on the activity of B^+ in the aqueous phase and is expressed as follows:

$$\Delta E = 2.303\,(RT/F) \log a_{B(\alpha)} + \text{constant},$$

where $a_{B(\alpha)}$ is activity of B^+ in α, R is the gas constant, F is the Faraday constant, T is temperature (K). This organic phase can be incorporated into a solid membrane of high molecular matrix (i.e., PVC), as mentioned in the text. The Nernstian slope is 59.1 mV/decade in standard situation (25°C), because

$$R = 8.314\ \mathrm{J \cdot mol^{-1} \cdot K^{-1}},$$

$$T = (273 + 25)\ \mathrm{K},$$

$$F = 96.5\ \mathrm{J \cdot mV^{-1} \cdot mol^{-1}}.$$

Appendix 2

If cations of another type (C^+) dissolve in both of the phases, th C^+ cations may act as interferents. The interference relates to th strength of C^+ to purge B^+ from the organic phase and is expresse as

$$B^+(\beta) + C^+(\alpha) \rightleftharpoons B^+(\alpha) + C^+(\beta).$$

The equilibrium constant of this exchange reaction is a function o the Gibbs standard transference energy between α and β of the tw ions. The potential of this ion-selective electrode (E_{ISE}) is ex pressed, finally, in the following Nikolsky equation:

$$E_{ISE} = E_0 + 2.303(RT/Z_DF) \log(a_D + K_{DI}a_I^{Z_D/Z_I}),$$

where a_D is the activity of the drug to be measured; a_I is the activit of the interferent; Z_D is the charge number of the drug; Z_I is th charge number of the interferent; and K_{DI} is the selectivity coefficient of the interferent to the drug.

Letters to the Editor

The Genioglossus Muscle Belongs Not to Inspiratory But to Expiratory Muscle?

To the Editor:

Respiratory muscles are basically divided into inspiratory and expiratory muscles. Respiratory muscles that discharge in the inspiratory phase belong to the inspiratory group, whereas those in the expiratory phase belong to the expiratory group. The most representative inspiratory muscle is the diaphragm, excitation of which gives a reference of inspiratory phase. Under normal conditions, most of the expiratory muscles are inactive in the expiratory phase. The silent period of the diaphragm usually serves as the expiratory phase.

Ochiai et al. (1) recently reported that among the inspiratory muscles in kittens, the genioglossus, which maintains upper airway patency during inspiration, was most vulnerable to halothane anesthesia. In their article, Figure 1 shows a typical recording of an electromyogram of three inspiratory muscles (diaphragm, intercostal, and genioglossus muscles) during 1% halothane anesthesia in a kitten as a control. If we carefully evaluate each tracing of the figure, we will easily discover that the genioglossus muscle discharged completely out of phase compared with the other inspiratory muscles, the diaphragm and intercostal muscles. This means that this muscle, studied in this experiment, did not belong to the inspiratory muscles. Based on the aforementioned definition, it should belong not to the inspiratory but to the expiratory muscles. In other words, it was not the genioglossus muscle. The genioglossus muscle recorded in adult cats actually discharged in phase with other inspiratory muscle discharges (2).

It must be very difficult to record the activity of a tiny muscle such as the genioglossus in kittens. Probably, expiratory muscle activity was unexpectedly recorded on some occasions. It could be said that some expiratory muscles in kittens are vulnerable to halothane anesthesia.

Intravenous Halothane—Questions Remain

To the Editor:

Drs. Kawamoto, Suzuki, and Takasaki (1) presented a study of the pulmonary and circulatory effects of intravenous (IV) halothane in dogs. Previous studies have suggested that halothane-induced pulmonary edema is accompanied by structural damage to the pulmonary microvasculature, resulting in increased capillary permeability. In permeability edema, the oncotic pressure gradient is substantially decreased. Therefore, the most important determinant for the development of pulmonary edema is the pressure gradient across the pulmonary microcirculation. Indeed, the authors report increased mean pulmonary artery pressure and pulmonary vascular resistance in the injured lungs, with no significant change in pulmonary arterial occlusion (wedge) pressure or central venous pressure. It has been noted in numerous studies that an elevated capillary pressure can be present despite a normal or subnormal wedge pressure (2–6). The increased lung water measured after IV halothane could have resulted from either hydrostatic or permeability changes or from a combination of both factors. The contribution of the hydrostatic capillary pressure to the development of pulmonary edema and increased extravascular lung water cannot be determined by this study. Moreover, histologic studies were not a part of this study. Therefore, the conclusion reached by the authors that "pulmonary edema induced by IV liquid halothane was due to direct pulmonary vascular damage" is not substantiated.

Second, the authors state that prostaglandin E_1 resulted in myocardial damage. It is unclear how this damage was determined. Although LV dp/dt and SV decreased early in the PGE_1-treated group, which is consistent with depression of myocardial contractility, no evidence was presented to substantiate a claim of myocardial "damage."

Finally, as the authors state in their study, it should be noted that the dose of IV halothane used in this study does indeed represent a massive overdose of halothane compared with customary clinical doses. The injection of 7.5 mmol represents approximately 170 mL of 100% halothane vapor, or about one tidal volume of the dogs studied. The 7% end-tidal concentration indicates that a large volume of halothane was not eliminated during first pass through the lungs. Perhaps an investigation of the cardiopulmonary effects of a smaller IV dose or dilute infusion, with a more

©1992 by the International Anesthesia Research Society

physiologic end-tidal concentration, might have intriguing implications for the clinical setting.

Relocation of a Double-Lumen Tube During Patient Positioning

To the Editor:

It is well known that the position of a tracheal tube during anesthesia may be altered by surgical manipulation, patient coughing, or movement of the head, neck, or the entire patient (1–3). We wish to report a case of movement of a double-lumen tube (DLT) from the left to right mainstem bronchus during patient repositioning.

A 61-yr-old man (ASA physical status III) was scheduled for open thoracotomy. Anesthesia was induced with intravenous propofol, and muscle relaxation was achieved with intravenous vecuronium. A 39F left-sided Broncho-Cath (Mallinckrodt) DLT was placed during laryngoscopy. Manual ventilation commenced, and compliance seemed reduced. Auscultation of the axillae revealed right-sided breath sounds when the endobronchial (left) tube was ventilated, and no breath sounds were heard when ventilation via the tracheal lumen was attempted. The DLT was withdrawn to the vocal cords and reintroduced. Ventilation appeared normal, and a "leak test" was performed (4). With the tracheal cuff inflated and the endobronchial cuff deflated, the test indicated successful isolation of each lung. No leak was detected across the endobronchial cuff, and it was therefore left deflated. Controlled mechanical ventilation was commenced, and the DLT was firmly tied in position with a long piece of gauze.

With the anesthesiologist supporting the head, the patient was then turned 90° to the left lateral position and secured by evacuation of air from a large beanbag. Peak airway pressures were then noted to be approximately 40 cm H_2O. Manual ventilation was begun while a flexible fiberoptic bronchoscope was quickly passed through the tracheal lumen. However, on exit from the distal lumen, it came to rest on the tracheal wall. Right mainstem intubation by the endobronchial tube was diagnosed. Meanwhile, the surgeon had made rapid progress and requested deflation of the right lung at this time. Ventilation of the left lung was attempted but was impossible. The bronchoscope was then passed down the endobronchial (left) lumen and the DLT withdrawn slowly. When the carina came into view, the bronchoscope was advanced into the left mainstem bronchus. The DLT was then easily advanced into its correct position. The right lung was then deflated with ease, and surgery proceeded uneventfully.

For the distal end of a DLT to migrate to the contralateral side, several factors need consideration. First, it is likely that the tip of the DLT was not positioned far into the left mainstem bronchus. Flexible bronchoscopy could have been used to optimize tube position before turning. Second, some movements of the head and neck are inevitable during a patient turn, allowing distal tube movement to occur, cephalad and then caudad. Double-lumen tube movement is always possible during turning of patients, and although it has been previoulsy suggested that deflation of the endobronchial cuff should occur to reduce the possibility of mucosal damage (5), relocation of a DLT to the contralateral side has not been recorded. This report, then, describes yet another consequence of movement of a tracheal tube during the turning of patients.

Removal of a Tenacious Epidural Catheter

To the Editor:

Quite a lot has been written lately about removal of epidural catheters that seem to have become firmly lodged in patients' backs. So, I thought I would offer my words of wisdom on the subject.

I'm sure all of us who perform many epidurals have at some time encountered varying degrees of difficulty in extracting epidural catheters. Of note in the recent literature is a case report by Drs. Sia-Kho and Kudlak in *Anesthesia & Analgesia* (1), advocating extreme flexion of the patient in the lateral decubitus position. This case report reemphasizes Dr. Blackshear's report (2) that more tension is needed to remove epidural catheters with patients sitting versus lying.

Another case report of interest was that of Shantha and Mani (3) in which a sterile Tuohy needle was passed over the epidural catheter and advanced to the epidural space, after which the Tuohy needle and lodged catheter were pulled out together. Although this method was carried out successfully, it has the obvious danger of possibly shearing the catheter and compounding the problem.

I have found on occasion when extreme flexion in the lateral decubitus position was not adequate to facilitate removal of the epidural catheter, that rapidly injecting sterile saline, while at the same time exerting steady traction on the epidural catheter with the patient in the flexed position, enabled removal of the catheter.

It would appear that increasing the turgor of the catheter by continuously filling it with saline, plus lubricating the surroundings of the catheter with the saline, allows the catheter to be released with greater ease.

I hope that this simple technique will be of some clinical value to anesthesiologists who encounter the problem of trapped epidural catheters.

Cyclosporine A and Cardiopulmonary Bypass

To the Editor:

In a recent case report, Eide and Beflenker (1) described reduced cyclosporine A (CsA) levels with the initiation of cardiopulmonary bypass (CPB). The patient was receiving CsA for 5 yr after renal transplant. We observed similar changes in CsA levels with the initiation of CPB in a patient who underwent CPB surgery 14 mo after liver transplantation and present the data to underscore the role of hemodilution.

The patient, a 56-yr-old, 78-kg man, received CsA (175 mg every 12 h), along with azathioprine (150 mg every day), and prednisone (10 mg every day) for immunosuppression. Plasma CsA levels on the 3 days before surgery were 290, 307, and 275 ng/mL, respectively, on his usual oral dose of CsA. On the morning of surgery, he received oral CsA (175 mg) 6 h before the start of the procedure. Each CsA sample consisted of 4 mL of blood taken from the radial artery catheter and immediately analyzed using a fluorescent immunoassay of a monoclonal antibody to CsA. This technique measures total CsA and does not measure the metabolites. The specificity and sensitivity of this method is >95% and 95%, respectively.

Table 1. Changes in Blood Cyclosporine A Concentration During the Pericardiopulmonary Bypass Time

	Before CPB (min)			During CPB (min)			After CPB (min)	
	135	90	1	14	24	30	3	30
CsA (ng/mL)	553	406	295	259	225	216	240	223
Temp (°C)	35	35	35	28	30	30	35.2	35.6
Hct (%)	39	35	33	18	18	18	18	26

CPB, cardiopulmonary bypass; CsA, cyclosporine A; Temp, temperature; Hct, hematocrit.

In the operating room, CsA samples were drawn before, during, and after bypass. The CsA levels, along with the corresponding temperatures and hematocrits, are shown in Table 1.

In our patient, as in the previous report, CsA levels decreased in the prebypass period. There was a further reduction in the CsA levels with the initiation of CPB. The CsA levels remained decreased during the postbypass period (Table 1).

Although there are many factors that may alter the pharmacokinetics of a drug, factors uniquely associated with CPB are dilution of red blood cells and plasma proteins via the pump priming volume, hypothermia, and binding to the bypass circuit on membrane oxygenator. Most evidence suggests that the latter two do not appear to be important (2,3).

The most likely explanation for the decreases in CsA noted is hemodilution because this would explain the reduced CsA levels before, during, and after bypass. The major contribution to the dilution of course is the pump prime, which in our case consisted of 2500 mL of plasmalyte A, 100 mL of 25% albumin, and heparin (7300 U), although the 1100 mL of crystalloid administered before CPB accounted in part for the decrease before bypass along with continued metabolism.

Nevertheless, because chronic administration of CsA results in accumulation of tissue stores in the peripheral compartment (3), it is unlikely that the decreased levels seen intraoperatively in patients on such chronic CsA therapy are clinically significant, and the intraoperative monitoring of CsA levels may not be useful.

More important, although these decreases are noted in two patients who underwent CPB, this decrease in CsA levels and hemodilution can occur in many other patients not undergoing CPB if a large amount of volume of either blood or cystalloid is administered. Such patients receiving short-term therapy may experience an acute lowering of CsA levels, which may affect organ survival.

Touchscreen Technology: Potential Source of Cross-Infections

To the Editor:

Documented cross-infection by contaminated anesthesia equipment is relatively rare. There is no agreement on how much sterilization should be attempted between cases, but most would agree that meticulous cleaning of the nondisposable components of the anesthesia machinery is imperative after use in patients suspected of harboring an infectious organism (1).

The introduction of touchscreen technology, demanding more hands-on contact with the anesthesia machine and equipment (2,3), may have increased the possibility for cross-infections in the operating room. These potentially contaminated surfaces represent an expansion of the interaction among the patient, the anesthesiologist, and the machinery. If neglected and not properly cleaned, they can potentially become the source of infections.

These surfaces of some modern anesthesia equipment may be regarded as just a monitor and not as a frequently touched control surface. Consequently, these superficies may not be properly disinfected after each case to prevent cross-contamination. It is recommended that one refer to the manufacturer's cleaning instructions for disinfection, because these surfaces may be damaged by certain chemicals. Given the fact that immunosuppressed patients are increasingly undergoing surgical procedures (4), it is prudent to assume that only the best disinfection and sterilization standards will control the spread of disease.

Unexpected Results: Consider a Medication Error

To the Editor:

McLean et al. (1) report the failure of negative aspiration, a test dose with epinephrine, a test done with 100 μg of fentanyl, and fractionation of the local anesthetic dose in detecting migration into a vein by an epidural catheter that had been working well for 4 h previously.

Their evidence for intravascular injection is a seizure after 18 mL of 2% lidocaine with 1:200,000 epinephrine administered over 12 min. The seizure developed 2 min after the last dose of local anesthetic was administered via the catheter.

If this was indeed a case of catheter migration, it would be highly unusual. Four usually successful methods of detecting intravascular injection would have failed in the same patient, including the administration of 90 μg of epinephrine intravenously without a significant change in heart rate and 100 μg of fentanyl that had no effect on sensorium. In addition, the 2-min delay in the onset of a seizure after the last fractionated dose and the very modest dose of lidocaine administered allow one to consider other plausible causes for this clinical picture.

I believe that the course of events depicted may best be explained by a medication error. Physician-prepared lidocaine (pH adjusted) and multiple test doses with different agents give ample opportunity for error. Succinylcholine was present in the operating room and was used when this patient was urgently converted to a general anesthetic. Medication errors with epidural catheters do occur. There is a long list of medications that have erroneously been injected into the epidural space (2–4). The events in this case presentation are consistent with an epidural injection of succinylcholine. I have heard the exact words that this patient uttered before "seizing" in a patient given 10 mg of succinylcholine when awake ("What's happening to me?").

Although this patient's adverse result could have been related to an overdose of intravenous lidocaine, I believe that a medication error must also be considered and would recommend that this be part of any differential diagnosis where a drug does not perform as expected.

In Response:

Thank you for the opportunity to respond to Dr. Groudine's letter. I disagree with his conclusion that the case report (1) may be best explained by a medication error.

Dr. Groudine believes that the events in our case presentation are consistent with an epidural injection of succinylcholine, in part because he heard an awake patient given 10 mg of succinylcholine say the exact words that our patient used before "seizing." Dr. Groudine did not mention by what route the succinylcholine was administered to his patient. Although I have no personal experience in the administration of 10 mg of succinylcholine to awake patients by any route, I am quite sure that the phrase, "What's happening to me," is not pathognomonic of its use.

In addition after the administration of the last 5-mL dose of pH-adjusted 2.0% lidocaine with 1:200,000 epinephrine, the patient described in our report had an unmistakable grand mal seizure. This was not succinylcholine-induced fasciculations. In fact, her muscle tone was markedly increased, and it was necessary to paralyze her with succinylcholine (100 mg) to be able to intubate the trachea and to ventilate her.

I agree with Dr. Groudine that medication errors with epidural catheters do occur and that a medication error should be considered whenever a drug does not perform as expected. I do not believe that a medication error occurred in the case that we described. Rather, the case report (1) demonstrates that it may not always be possible to detect an intravascular placement or migration of an epidural catheter.

Laryngeal Mask Airway in Cervical Spine Injuries

To the Editor:

We read with interest the correspondence by Day (1) and Hastings (2) with regard to the use of the laryngeal mask airway (LMA) in patients with cervical spine injury and wish to take issue with some of the points raised.

The LMA has been successfully used in airway management in *elective* cases with cervical spine injury and disease (3) but is contraindicated when aspiration of gastric contents is possible because it may not, in all cases, protect the airway from contamination. However, in situations where immobilization of the cervical spine is required, conventional tracheal intubation may be impossible, and the LMA may prove a safer alternative than mask ventilation (where the airway is completely unprotected). The small risk of aspiration when using the LMA is outweighed by the disastrous consequences of hypoxemia secondary to failed tracheal intubation. We believe the LMA should always be available for managing the difficult airway and should be used before transtracheal ventilation or cricothyroidotomy (4).

Although we would agree with Hastings (2) that the LMA is inappropriate as a first-line airway management device in *emergencies* and in cases with laryngeal injury or edema, we cannot endorse his opinion that the LMA has a high complication rate. "Epiglottic obstruction" has not been reported with the LMA. Epiglottic *downfolding* is commonly observed when a fiberoptic bronchoscope is passed through the LMA (5), but ventilation is not impaired. Laryngospasm and coughing are avoidable if an adequate anesthetic depth has been obtained, and most studies report a 90%–95% success rate after one insertion attempt using the LMA, even when the operators are unskilled (6).

We have recently submitted for publication in this journal a study comparing both the ease of intubation and the time taken to successfully ventilate with the LMA and tracheal tube in patients immobilized in a rigid cervical collar. Our findings (as yet unpublished) suggest that the LMA is an easier and faster method of securing the airway. The relatively atraumatic insertion of the LMA imparts less force to the cervical spine than a difficult laryngoscopy. Extrapolation to the field scenario where patients may be combative, obese, or have full stomachs can only be speculative, but nevertheless, we believe that the LMA should be available if rapid, gentle tracheal intubation using a laryngoscope and in-line stabilization of the neck is impossible. We concur with Hastings (2) that further studies, particularly of outcome, are warranted.

6. Pennant JH, Walker MB. Comparison of the endotracheal tube and laryngeal mask in airway management by paramedical personnel. Anesth Analg 1992;74:531–4.

In Response:

My letter was directed against use of the LMA as a first-line airway management technique in emergencies. I believe that the contraindications are the risk of aspiration and the possibility of inadequate airway control. If the LMA does not work properly, the anesthesiologist must manipulate the patient's airway, head, and neck a second time, under what may be more trying circumstances. Studies have been published in which LMA use was associated with airway obstruction (1,2), possibly secondary to epiglottic downfolding (1). Difficulty with ventilation, especially if high airway pressures are required, is another potential problem. I agree that the LMA may be an alternative in the event of a failed tracheal intubation. The safety of any airway management technique for patients with injured cervical spines is speculative without studies of the amount of spine movement during execution and the resultant clinical outcome. I thank Drs. Pennant, Gajraj, and Pace for their comments, and I await publication of their study.

Is Your Scavenger System Functional?

To the Editor:

The scavenging of anesthetic waste gas according to OSHA standards is a vital part of protecting the operating room personnel from the adverse effects of breathing residual anesthetic agents. We would like to report the finding in our institution of numerous machines with inoperable scavenging systems on random survey.

Recently, we purchased 10 Narkomed 2B anesthesia systems equipped with an open scavenging system. Our previous machines used the traditional closed scavenging systems that were familiar to our anesthesia providers. The closed system utilized a spring-loaded valve for positive and negative pressure relief. The open system, however, uses continually open ports to provide positive and negative pressure relief. The open system, when connected to suction and in the functional position, makes an audible sound that may have caused operating room personnel to disconnect or inactivate the system to eliminate the sound.

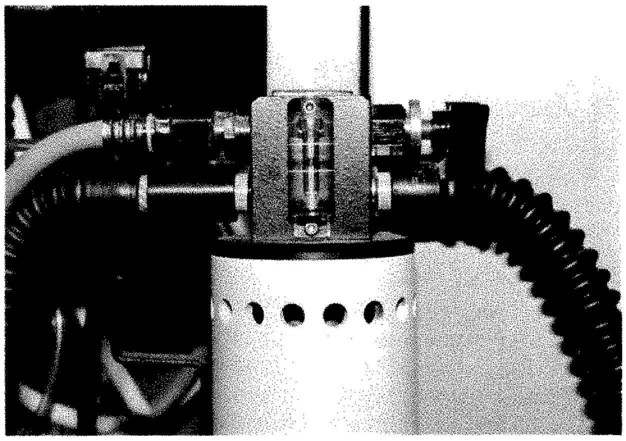

Figure 1. Narkomed 2B showing correct position for functioning scavenger system.

On a random survey, we found that 10 of 10 anesthesia systems were being used with the scavenging device in the "off" mode. The head technician at Narkomed Inc. reported that if the machine is used with the scavenger system in the off position, the anesthetic gases accumulate in the chamber and spill into the room, polluting the operating room environment.

Figure 1 indicates the correct "on" position with the "ball" in between the two white lines. We would like to emphasize that the scavenging system is a routine part of the anesthetic machine checkout. However, we have consistently noted that the system is turned off by operating room personnel.

We hope that our reporting this to the anesthesia community will prevent exposing operating room personnel to anesthetic agents and thereby assist them to conform to OSHA standards.

Epidural Kits: Incompatible Contents

To the Editor:

I recently reported a problem associated with the use of a particular epidural needle (1). On two occasions, the plastic hubs on these needles cracked during use. We stated that these needles were manufactured by Burron Medical. This is incorrect. When we were testing a number of different needles for use in our department, the faulty needles were kept for later inspection. Later, as a result of a breakdown in communication between our purchasing department and myself, Burron Inc. was named as the manufacturer. The needles in question were in fact manufactured by Portex.

We are now using Burron epidural needles and have experienced no problems with them. The hub on the Burron needle is resistant to cracking because it is made of Polycarbonate.

Book Reviews

Clinical Anaesthetic Pharmacology

John W. Dundee, R. S. J. Clarke, and William McCaughey, eds. New York: Churchill Livingstone, 1991, 627 pp, $89.00, ISBN 0-4430-2073-6.

The practice of anesthesia begins and ends with pharmacology; it is not possible to separate one from the other. Therefore, textbooks of applied pharmacology should be the foundation on which anesthetic expertise is based. Surprisingly, there have been only a few attempts to produce a comprehensive text on anesthetic pharmacology, and there is no true market leader as there has been for other subjects within the practice of anesthesia.

The present offering was conceived as an authoritative text on the pharmacology of anesthetic drugs, with a strong scientific foundation but relating also to everyday practice. It has been written largely by the staff of the University Department of Anaesthesia, Belfast, with 28 total contributors. The fact that so many are well known is a credit to the productivity of this department under the guidance of the senior editor while he was head of the department.

The 36 chapters that make up the text are grouped in six sections: Basic, Central Nervous System, Peripheral Nervous System, Cardiovascular System, Other Systems, and Special Drug Problems in Patient Management. The chapters themselves vary in size from 8 to 30 pages of text, and each is referenced with approximately one page of references per chapter. The most recent reference in the pharmacokinetics chapter is 1988, and 1990 in the anesthetic gases chapter.

Each chapter attempts to highlight the basic data of pharmacology, such as the pharmacokinetics and pharmacodynamics, as well as include details of clinical use. This attempt at a comprehensive review has a superficial appeal, but it has the inherent weakness that advances in knowledge in different disciplines occur at different rates. Therefore some aspects of the text will need to be revised more often than others. For example, only one paragraph is devoted to sevoflurane and 18 lines to desflurane, whereas more than one page each is devoted to chloroform, diethyl ether, and trichloroethylene. Ondansetron receives fewer lines of text than acupuncture in the management of emesis. Cisapride and terfenadine are not indexed at all. Propanidid and alphaxolone are described, but pregnanolone is not.

Throughout the text, the interests of the senior editor are emphasized, and there is much information about intravenous agents, premedicants, benzodiazepines, the influence of age on drug disposition, and acupuncture. The formulas of most, if not all, drugs are given, and there are illustrations to guide the reader in mechanisms of action, rate of onset, and duration of action of drugs.

The subject matter of this book is accurate and well presented as far as it goes. More modern aspects of anesthetic pharmacology are omitted or covered only superficially (e.g., pharmacokinetic/pharmacodynamic modeling, design of intravenous dosage regimens, novel drug delivery). This is a pity, not only because it diminishes the value of the book in modern anesthetic practice, but also because it does not reflect the life and work of Professor Dundee who was at the forefront of anesthetic pharmacology research for so many years. This reviewer regrets that this book, produced after Professor Dundee's retirement, should appear to be quite old-fashioned and out of date almost from its date of publication.

British textbooks do not usually sell very well in the United States for a variety of reasons (e.g., drug names may be different, dosages and anesthetic regimens may vary, and the examination structure is different from the United Kingdom). There has been no obvious attempt to make this book appropriate for the U.S. anesthesiologist. Although some will find this book useful, it is not comprehensive, and other sources of reference will be required by most anesthetists.

A Manual for Acute Postoperative Pain Management

F. B. Sevarino and L. M. Preble. New York: Raven Press, 1992, 242 pp, $55.00.

Although pain in the postoperative period is commonly encountered, that symptom complex has received little attention until recently. Today, in part because of quality of life issues, both patients and medical staff consider postoperative pain management an important issue. As an example of this, at the 1992 Annual Meeting of the Japanese Society of Anesthesiologists, a symposium on postoperative pain attracted many anesthesiologists and generated considerable interest.

This reviewer believes that postoperative pain management should be started preoperatively. For example, premedication and personal contact with the patient are very important determinants of postoperative pain. Intraoperatively balanced anesthesia with analgesics and general anesthesia supplemented with epidural anesthesia may also contribute to postoperative pain relief. This manual does not address either preoperative or intraoperative management of postoperative pain relief. However, a vari-

©1992 by the International Anesthesia Research Society

ety of methods for postoperative pain management are described, such as intravenous patient-controlled analgesia and spinal opioids.

The authors' aim is to outline the establishment of an acute pain service, which will provide a team of clinical specialists to manage acute pain. The manual consists of two parts. The first part outlines the basics of planning analgesic therapy in Chapters 1–5. The second part discusses patient management in Chapters 6–12. Each part has appendices that address nursing education, policies and procedures, guidelines, credentialling, physician and patient education, and various record/flow sheets (in the first part) and drugs and their indications in acute pain management as well as products and company addresses (in the second part). These appendices will be very useful for those who are setting up an acute pain service.

A student or inexperienced resident will find the manual educational because of the many illustrations and detailed explanations. The manual is highly recommended to all who are interested in acute pain, especially those who are in the process of setting up an acute pain service.

Clinical Procedures in Anesthesia and Intensive Care

J. L. Benumof, ed. Philadelphia: J.B. Lippincott, 1992, 972 pp, $125.00, ISBN 0-3975-0950-2.

Atlas of Procedures in Anesthesia and Critical Care

J. F. Butterworth IV. Philadelphia: W.B. Saunders, 1992, 256 pp, $30.00, ISBN 0-7216-2916-4.

Although the titles of these two books may appear similar, their purposes differ. It is hardly fair to compare them, for each book merits individual attention.

Clinical Procedures in Anesthesia and Intensive Care is wonderful! It is such a beautiful book, you may want to display it on your coffee table. This comprehensive text contains practically everything you need to know about almost all modern clinical procedures. Benumof has recruited 45 contributors; many are anesthesiologists, others are cardiologists, surgeons, neurosurgeons, urologists, obstetricians, gynecologists, pediatricians, nurses, and bioengineers.

Butterworth's *Atlas of Procedures in Anesthesia and Critical Care* is exactly that—an atlas. Clear and concise, it is intentionally limited to the essentials.

Benumof states in the Preface to *Clinical Procedures in Anesthesia and Intensive Care* that his goal is "to bring together in one book a description of all modern clinical procedures that anesthesiologists must be familiar with." The book does precisely that. Its 44 chapters are grouped into six sections according to the basic system treated: Preparing and Using the Anesthesia Machine, Respiratory Procedures, Cardiovascular Procedures, Central Nervous System Procedures, Peripheral Nerve Procedures, and Gastrointestinal, Obstetric, and Renal Procedures. *Clinical Procedures in Anesthesia and Intensive Care* contains wonderful illustrations, photographs, tables, graphs, x-rays, and even a few xerograms. There are 27 color plates taken from interesting transesophageal echocardiograms, as well as a color figure obtained from a Lifescan EEG analyzer during cross-clamping of the carotid artery. Chapters are uniformly organized with Introduction, Indications, How to do the procedure (along with reasonable alternatives), Discussion, Complications, and References. Chapters are centered around "how to do it," with each step carefully detailed for the reader. This book is a pleasure to read and own.

Although many topics might seem to overlap, the text is rarely redundant. We were hard put to find any problems, but the chapter on pulmonary artery catheterization makes no distinction between relative indications and absolute indications. Perhaps this is best illustrated by the statement, "Patients with progressive renal insufficiency despite conservative therapy should have PA catheterization unless the cause of renal deterioration is known to be untreatable." Progressive renal insufficiency, as they have defined it, is not a widely accepted *absolute* indication for PA catheterization. Overall, the chapters are very well written and contain many pearls that cannot be found in another single source. For example, the chapter on transtracheal ventilation describes the technique with clear photographs (that have illustrations superimposed), as well as a detailed discussion of equipment that can be used in an emergency situation.

Butterworth's *Atlas of Procedures in Anesthesia and Critical Care* contains 31 chapters divided into four sections: Airway Management, Intravascular Cannulation, Regional Anesthesia, and Positioning the Patient on the Operating Room Table. This book was not planned to be all-inclusive but to "illustrate the more representative regional anesthetic, airway management, invasive monitoring, and positioning techniques in one volume." The illustrations were done by one artist; this makes it clean and easy to follow. The text accompanying the illustrations is intentionally limited to essentials. Each procedure is handled individually and organized as such. This atlas does not pay as much attention to detail as does Benumof's text, but the essentials are clearly discussed. The book is well indexed to facilitate its use as a quick reference. There is a most interesting chapter on positioning patients. This atlas is very easy to read. It makes an excellent teaching guide for medical students and residents.

In short, both Drs. Benumof and Butterworth have succeeded in attaining the different goals that they each set out to accomplish. Both books will find a place in departmental libraries. Butterworth's *Atlas of Procedures in Anesthesia and Critical Care* will serve well as a quick reference for operating rooms and intensive care units. In contrast, Benumof's *Clinical Procedures in Anesthesia and Intensive Care* is a complete reference guide that every anesthesiologist and intensivist will want to own personally. Despite its cost, it is a great investment. Watch your copy—your friends may "liberate" it.

Prehospital Emergency Medicine

J. Schou. Lorrach, Germany: Alix, 1992, 348 pp, $60.00, ISBN 3-928811-01-0(D).

Although it may seem strange to review a book on prehospital emergency care in an anesthesiology journal, *Prehospital Emergency Medicine* is written by an anesthesiologist who discusses a subject quite appropriate for anesthesiologists. The author points out that when he was assigned to work on an emergency helicopter service in 1981 as part of his duties as an anesthetist in Northern Germany, he essentially had to learn from his own experience. This book is based on his experience in prehospital emergency medicine (PHEM) and is designed and written to act as a guide to clinical practice rather than as a theoretical textbook of PHEM. As an anesthesiologist reading this book, this reviewer was impressed that the skills required to practice PHEM successfully are similar to the skills required to practice anesthesia successfully. This book will help anesthesiologists to broaden their professional horizons and to realize that our discipline's activities are not confined to the operating room for perioperative care of the surgical patient but also involve prehospital care of emergency patients.

The author uses his personal experience instead of extensive laboratory research to provide material for this book. It is quite apparent when reading the book that the author has "been there" and has learned much from extensive personal experience with PHEM. The book is organized in section format with short, easy to read subsections or chapters. The organizational themes of the chapters in the seven sections are arranged to cover the scope of practice of PHEM as well as to develop some of the qualifications for physicians practicing this speciality.

The book depends heavily on case reports to illustrate important points. These case reports include both positive and negative outcomes and are particularly well chosen to illustrate needed teaching points. The author has used not only case reports from his own experience but also those from other providers. Besides developing the scope of practice of PHEM, the case illustrations also address the advantages of providing a physician on the scene for emergency care.

Section A develops the theme of three principal tasks of PHEM—diagnosis, therapy, and assignment (patient disposition). These tasks are developed throughout the rest of the book. Choice of a suitable receiving clinic and vehicle for transport is included in assignment. This section also discusses the difficult issue of triage and treatment priorities during mass casualties and disasters. Sections B through E cover therapy during PHEM in great detail, beginning with resuscitative skills. Following the discussion of resuscitation in Section B, the author covers therapy for diseases, beginning with life-threatening injuries in Section C, and emergency therapy of diseases in Section D. Section E covers miscellaneous emergencies, including obstetric emergencies, drowning, electrical accidents, and environmental emergencies.

Section F covers organization and formalities and Section G supplies and security. The term security is used to mean not only security of patient care but security for personnel providing the patient care in a hostile environment. Included in this section are safety tips for helicopter and rescue missions. There are several appendices that cover a personal tribute to Henning Ruben (the developer of the self-inflating resuscitation bag), abbreviations used in the book, a drug index, conversion factors, and a general index.

Some of the important issues covered in the book that are unique in the anesthesia literature are rescue techniques, including extrication of the injured from difficult scenes. Special problems of managing patients in the helicopter as well as safety tips on how to avoid injury to medical personnel by the helicopter are also covered. The special problems of land transport by ambulance, a useful list of supplies needed for emergency medical practice, and the pros and cons of different drugs for use in the prehospital area are also covered in the book. The book also covers organizational issues, and Chapter F,5 discusses the thorny issue of when is the physician required in the prehospital arena. The duties of a physician in the field are thoroughly covered, with a differentiation between triage from disasters versus the assignment of single casualties to an appropriate medical facility. Again, this section is well illustrated with clinical examples demonstrating both potential good outcomes and poor outcomes.

The quality of the book is reasonable, with a sewn binding and hard cover that appears to be sturdy. The pages are generally printed well and easy to read; however, I was disappointed that my copy came with a few blank pages, which may suggest some quality assurance problems with the publishing company.

Who would benefit from the purchase of this book? As an anesthesiologist with a strong interest in trauma care, this reviewer found the book fascinating to read and would recommend it to anyone who is interested in knowing more about the care of the injured patient. The concept of providing the ultimate preoperative anesthetic consult for the trauma patient by going to the scene of the accident is exciting. The International Trauma Anesthesia and Critical Care Society (ITACCS), founded following the 9th World Congress of Societies of Anesthesiology in Washington, D.C. in 1988, has members who are involved in just such endeavors in different countries around the world. These anesthesiologists are witness to the wisdom of anesthesiologists taking their practice to the field to treat injured and acutely sick patients.

This book should also be on the shelves of libraries in anesthesia departments that maintain a residency program. Many of the problems discussed in providing prehospital emergency care are the same problems encountered by anesthesia residents responding to "Code" calls in various locations inside and outside the hospitals they work in. A reading of pertinent sections in this book would help the residents solve the problems that they encounter in this risky task of extending anesthesia care outside of the operating room.

In summary, this is a well-written, important book that covers a facet of anesthesia practice that is common in Europe but very uncommon in the United States. It is also one of the few books to describe in detail clinical lessons from prehospital practice. Furthermore, there are many good clinical lessons in this book that can be applied to our current anesthesia practice in the United States, which is increasingly expanding out from the operating room.

Epidural and Spinal Anaesthesia With Bupivacaine: Effects of Age on Neural Blockade and Pharmacokinetics

B. T. Veering. Leiden: University Hospital Leiden, 1991, 217 pp.

This is not really a textbook. This doctoral thesis provides an excellent summary of the current state of knowledge about the influence of aging on bupivacaine regional blockade. As such, it is a reference rather than a text and may not be practical for the clinician but would be a useful addition to the library of the academic anesthesiologist, particularly one who deals with regional anesthesia.

The core of the book is a presentation of the author's eight research projects on the issue of the effects of aging on bupivacaine pharmacokinetics and pharmacodynamics during epidural and spinal anesthesia and the implications for toxicity. These articles summarize the current state of knowledge in this area and contain an excellent review of the other data collected on this subject. The gathering of all of the research findings in one manuscript (previously published in six separate journals) is very helpful. Although this book is ostensibly limited to a discussion of bupivacaine, the format adds an excellent review of the problems of aging on anesthetic pharmacokinetics and pharmacodynamics. This first chapter is applicable to many other drugs and situations other than bupivacaine behavior. Chapters 5–12 repeat the specific publications, as mentioned. This leads to a certain redundancy in the references and discussions but allows each chapter to "stand alone" in addressing its specific question.

The presentation is clear and pleasant reading. Only rarely is the English idiom stretched, such as the description of the quality of neural blockade as "feeble." Overall, this book contains a wealth of information and can serve as the current definitive reference on the questions of age and bupivacaine epidural and spinal anesthesia.

There are shortcomings. The format of repeating the scientific papers makes for an erratic flow of thought. The conclusion section serves as an excellent summary but is almost too brief. The absence of an index makes it difficult to find the answer to very specific questions without reading entire pages and sections. The book is also frustrating in its limited scope. Although bupivacaine is covered well, there are only intermittent references to the previous data on lidocaine pharmacokinetics and pharmacodynamics. Naturally, there will be questions soon about ropivacaine also. More important, these studies do not address the issues of the pharmacokinetics and pharmacodynamics of epidural or spinal opioids in the elderly, which has become a common question in current practice. These questions were clearly beyond the scope of this dissertation, but their absence is tantalizing.

In summary, this is an excellent review of the current knowledge on this specific subject. It is a useful reference for the academician (especially the regional anesthesiologist) but may not be practical for the clinician.

Perioperative Myocardial Ischemia and Infarction, Volume 30, No. 1 of the International Anesthesiology Clinics

Charles Beattie and Lee A. Fleisher, eds. Boston: Little, Brown, 1992, 258 pp, $81.00 (annual subscription).

Perioperative Myocardial Ischemia and Infarction is a well written, up to date, clinically oriented monograph dealing with the detection, pathophysiology, and current treatment of myocardial ischemia and infarction in the perioperative period. In this issue of International Anesthesiology Clinics, well-known contributing authors have written 14 separate articles devoted to four primary management issues: (1) the detection of myocardial ischemia and risk assessment using continuous electrocardiography, echocardiography, and dipyridamole-thallium scintigraphy; (2) mechanisms and potential causes of perioperative myocardial ischemia; (3) prophylaxis and treatment of myocardial ischemia; and (4) pathogenesis, diagnosis, and treatment of perioperative myocardial infarction. In this regard, the overall approach of the editors, Beattie and Fleisher, is fairly traditional and customary; so much so, that this monograph bears a striking resemblance to two earlier efforts that appeared in a competing clinics format (Clinics of North America in 1988 and 1991). Reasonable questions then arise—How does this particular monograph fit in with similar works that preceded it—and along with this—Does this work represent new and unique material, or is it merely a leg-weary rehash of old information?

The Beattie and Fleisher monograph duplicates to a small degree the work of J. G. Reeves, which appeared in Clinics of North America in September 1988. This repetition is noticeable in the articles devoted to the detection of ischemia using electrocardiography, the role of hemodynamics and anesthetic technique in perioperative myocardial ischemia, and the cardiologist's treatment of acute myocardial infarction. The marked similarity in the articles devoted to echocardiography and to the treatment of ischemia and myocardial protection is not surprising because each article is authored by the same person in both monographs.

In contrast, the Beattie and Fleisher monograph is quite different from the work of Peter Duke, which appeared again in Clinics of North America in September 1991. In the latter, the emphasis heavily favors the fundamentals of basic coronary anatomy and physiology as well as the cellular and biochemical effects of myocardial ischemia in relation to ventricular function. Duke's monograph also includes excellent articles devoted to silent ischemia, risk assessment, and management of right and left ventricular dysfunction.

What emerges as the main strength and most cogent reason for purchasing the Beattie and Fleisher monograph are the articles dealing with perioperative risk assessment and perioperative factors contributing to myocardial ischemia and infarction. First, the stage is set with an overview of the existing literature with regard to the relationship between perioperative myocardial ischemia and infarction. This is followed by an excellent article concerning the use of ambulatory electrocardiography for the detection of myocardial ischemia as well as its use as a screening tool before noncardiac surgery. The article on dipyridamole-thallium scintigraphy is especially outstanding and runs the gamut from describing thallium uptake and its response to dipyridamole to its use as a preoperative screening test to assess cardiac risk. This article very nicely summarizes the existing literature to date.

Last, but not least, the articles dealing with the various perioperative factors that may contribute to myocardial ischemia are truly the crown jewels of the monograph. These include individual articles on the stress response, oxygen-carrying capacity, circadian variation in coronary vasomotion, and perioperative hemostatic changes that cause a hypercoagulable state. The unifying theme here is decreased myocardial oxygen supply secondary to factors that promote coronary thrombosis and vasospasm as well as atherosclerotic plaque rupture. These articles are an intriguing tour de force that focuses attention on the emerging importance of the postoperative period in the pathogenesis of myocardial ischemia and infarction.

In summary, *Perioperative Myocardial Ischemia and Infarction* is a well-done, very clinically relevant work. It merits thoughtful consideration by any clinician or intensivist serious about improving the perioperative care of patients with known or suspected ischemic heart disease.

Subject Index

Abscess, see Complications
Acetylcholine, see Enzymes
Acid-base equilibrium
  intraoperative
    sodium L-lactate and sodium racemic lactate effects on, 702
  management
    during cardiopulmonary bypass, renal function and, 696
Acoustic neuroma, see Anesthesia, neurosurgical
Acquired immunodeficiency syndrome, see Infection
Adapters, see Equipment
Adenosine
  see Anesthetic techniques, hypotensive
  see Arteries, coronary, vasodilation
Age factors
  neuromuscular function
    neonatal, 361
Air, see Embolism
Airway
  obstruction
    Hurler-Scheie syndrome and, management, during cardiac surgery, 830
    infant botulism and, 136
    pediatric, Robin sequence and, laryngeal mask airway insertion in awake infant, 822
  technique
    tolerance, anesthetic requirements, laryngeal mask compared to endotracheal tube, 794
Airway equipment, see Equipment
Alarms, see Equipment
Alcohol
  concentrations
    in ketorolac solution (letter), 148
  ethanol
    monitoring, during inhaled anesthesia, in transurethral prostatic resection, 983
Alfentanil
  see Analgesics
  see Anesthetics, intravenous
  see Pharmacodynamics
α-Aminoisobutyric acid, see Brain, blood-brain barrier
Ambulatory anesthesia, see Anesthesia, outpatient
4-Aminopyridine, see Antagonists, neuromuscular relaxants
Analgesia
  epidural
    bilateral, causes of (letter), 310
    perioperative coagulability effects (letter), 463
    in vascular surgery (letter), 464
  postoperative
    brachial plexus block, lidocaine, duration of, clonidine or epinephrine admixture effects on, 69
    bupivacaine, epidural, cesarean section, adverse effects, 753
    buprenorphine, epidural, cesarean section, adverse effects, 753
    fentanyl, epidural, cesarean section, adverse effects, 753
  preemptive (letter), 637
Analgesics
  alfentanil
    hypermetabolism, seizure and histopathology in rat brain induced by, 953
  buprenorphine
    epidural, cesarean section, adverse effects, 753
  dezocine
    intrathecal, antinociception production without neurotoxicity, 392
    laparoscopy, outpatient, adjuvant, ketorolac, fentanyl compared to, 566
  diclofenac sodium
    intramuscular, postcesarean section analgesia, 64
  fentanyl
    epidural (letter), 865
    epidural, cesarean section, adverse effects, 753
    intrathecal, labor, meperidine, sufentanil comparison to, 734
    laparoscopy, outpatient, adjuvant, ketorolac, dezocine compared to, 566
    patient-controlled analgesia, spinal, 453
    thiopental "sleep" plasma concentrations effects, 523
    transdermal. toxic delirium and, 1014
  hydromorphone
    epidural, patient-controlled analgesia, cesarean section, bupivacaine and, 740
  ketorolac
    arthroscopy, postoperative pain effects, 208
    halothane MAC, ventilation effects, in rats, 99
    intravenous, biliary tract pressure effects, morphine, placebo compared to, 204
    laparoscopy, outpatient, adjuvant, dezocine, fentanyl compared to, 566
    reflex sympathetic dystrophy, alcohol content and (letter), 148
  meperidine
    intrathecal, labor, fentanyl, sufentanil comparison to, 734
    perioperative effects of oral midazolam in children and, 51
  morphine
    biliary tract pressure effects, ketorolac compared to, 204
    epidural, low-dose, postcesarean section analgesia, 64
    epidural, postoperative pain, bupivacaine with, clonidine enhancement of, 607
    epidural, side effects, treatment, nalbuphine, naloxone comparisons in, 747
    midazolam with, recovery, locomotor activity following, versus midazolam alone, 929
    overdose, during intended refill of intrathecal infusion device, 130
    tolerance to, complete (letter), 467
  nalbuphine
    epidural morphine side effects treatment, naloxone compared to, 747
  new
    package inserts, dosage guidelines, delivery systems, 873
  opioids
    tolerance to, complete (letter), 467
  press-through package
    intestinal perforation caused by, 456
  sufentanil
    intrathecal, labor, fentanyl, meperidine comparison to, 734
    pharmacodynamics, hypocarbia effects on, 186
Analyzers, see Equipment
Anemia, see Complications
Anesthesia
  cardiovascular
    abdominal aorta surgery, preoperative normovolemic hemodilution effect on left ventricular segment wall motion during, 654
    cardiopulmonary bypass, hypothermic versus normothermic, atracurium neuromuscular blocking potency and, 675
    cardiopulmonary bypass, pH management and pulsatile/nonpulsatile perfusion differences during, renal function and, 696

    desflurane, isoflurane compared to, S17
    isoflurane, desflurane compared to, S17
  electroconvulsive therapy
    electrocardiogram and echocardiogram effects, 511
    hemodynamic attenuation, esmolol dose range for, 805
  general
    inspiratory work of breathing during, pressure support ventilation decrease of, 167
    toxemia of pregnancy and (letter), 150
  geriatric
    desflurane, induction and emergence, S38
  modern
    Dr. Joseph Sheehan and (letter), 642
  neurosurgical
    acoustic neuroma, resection, electromyography, intraoperative, partial neuromuscular blockade effects on, 729
    brain tumor, cerebrospinal fluid pressure in, isoflurane, nitrous oxide comparative effects in, 724
    coagulation, hydroxyethyl starch effects on, 24
  obstetric
    cesarean section, bupivacaine, epidural, adverse effects, 753
    cesarean section, diclofenac sodium, intramuscular, postoperative analgesia, 64
    cesarean section, epidural, hypotension during, vasopressor therapy for, 56
    cesarean section, morphine, epidural, postoperative analgesia, 64
    cesarean section, patient-controlled analgesia, epidural versus intravenous, 245
    cesarean section, preoxygenation, in head-up versus supine position, apnea and, 757
    cesarean section, spinal, headache, 27-gauge Quincke and 24-gauge Sprotte needles comparison in, 377
    cesarean section, unilateral diaphragmatic paralysis, brachial neuritis, and pregnancy-induced hypertension and, 622
    epidural, in congenital absence of inferior vena cava, 1033
    labor, epidural test dose, sensitivity and specificity, intravascular injection and, 372
    labor, intrathecal fentanyl, meperidine, sufentanil comparisons in, 734
    preganacy termination, prostaglandin-induced, analgesia, metoclopramide-enhanced, 760
    spinal, headache, recurrent, Chiari I malformation and, 1025
    toxemia of pregnancy, general anesthesia and, 150
  outpatient
    arthroscopy, ketorolac, bupivacaine effects on recovery, 208
    desflurane, S47
    laparoscopy, adjuvants, ketorolac, dezocine, fentanyl comparisons in, 566
    orthopedic, peripheral, desflurane, propofol compared to, 572
    patient-controlled analgesia, fentanyl, intraoperative, as alternative to physician administration, 41
    pediatric, malignant hyperthermia and, hospital admission for, 345
    pediatric, preoperative screening for, telephone questionnaire and, 258
  pediatric
    airway obstruction and infant with botulism, 136
    alfentanil, induced rigidity, in newborn, 252
    bupivacaine, seizures and, 284
    bupivacaine, toxicity, secondary to continuous caudal epidural infusion, 287
    desflurane
      induction and emergence, S38
    endotracheal intubation, FEF colorimetric end-tidal carbon dioxide detector in, 45
    intraocular pressure, laryngeal mask airway and endotracheal tube insertion effects on, 355
    intraosseous infusion, 626
    laryngeal mask airway insertion, Robin sequence and, 822
    neuroblastoma excision, intraoperative hypertension during, 854
    outpatient, hyperthermia, malignant, hospital admission for, 345
    outpatient, preoperative screening for, telephone questionnaire and, 258
    propofol, for radiation in small children (letter), 860
    propofol, ectopic supraventricular tachycardia change to sinus rhythm during, 1030
    propofol, induction, requirements, age-related differences, 876
    rectal sedation, preoperative, midazolam, ketamine, 880
    regional, convulsions associated with, 164
    tonsillectomy, vomiting after, metoclopramide reduction of, 351
    tracheal stenosis repair, extracorporeal membrane oxygenation for perioperative support, 825
  preoperative evaluation
    for pediatric ambulatory surgery, telephone questionnaire and, 258
  thoracic
    bilateral lung surgery through median sternotomy, lidocaine, interpleural, bilateral after, 1046
Anesthesia machines, see Equipment
Anesthesiologists
  interactions with other medical departments (letter), 636
  patient's weight estimation by (letter), 461
Anesthetic techniques
  bronchoscopy
    rigid laser, for myasthenic syndrome, intravenous anesthesia for, superior laryngeal nerve block as supplement to, 458
  endobronchial
    bronchial cuff inflation, of Univent tube, comparison of techniques, 784
  epidural
    bupivacaine, patient-controlled analgesia, cesarean section, hydromorphone and, 740
    bupivacaine, postoperative pain, morphine with, clonidine enhancement of, 607
    caudal, pediatric, bupivacaine toxicity secondary to, 286
    cesarean section, hypotension during, vasopressor therapy for, 56
    clonidine, postoperative pain, bupivacaine and morphine and, 607
    extradural, spinal anesthesia combined with (letter), 640
    fentanyl (letter), 865
    hydromorphone, patient-controlled analgesia, cesarean section, bupivacaine and, 740
    kits, needle, plastic hub cracking (letter), 1075
    lidocaine, plasma concentrations, isoflurane, halothane anesthesia and, 885
    for major vascular surgery (letter), 141
    morphine, postoperative pain, bupivacaine with, clonidine enhancement of, 607
    morphine, side effects, treatment, nalbuphine, naloxone comparisons in, 747
    obstetric, congenital absence of inferior vena cava and, 1033
    perioperative coagulation effects (letter), 463
    prolongation, using lipid drug carrier, iodophendylate, with procaine, lidocaine, tetracaine, 900
    spinal, subarachnoid block, needle for, new (letter), 303
    spinal cord tumor presentation after, 844
    test dose, in labor, sensitivity and

  - specificity, intravascular injection and, 372
  - thoracic, combined with general anesthesia, effect on segmental wall motion assessed by transesophageal echocardiography, 329
  - thoracic, laparoscopic cholecystectomy effects, 381
  - in vascular surgery (letter), 464
- hypotensive
  - adenosine, systemic compared to intracoronary infusion, 319
  - esmolol, sodium nitroprusside, blood loss effects, during orthognathic surgery, 172
  - flumazenil, arousal, intraoperative, during spinal fusion, 580
  - isoflurane, splanchnic hemodynamics and oxygen supply effects, normovolemic hemodilution and, 660
  - nicardipine, nitroprusside, during isoflurane anesthesia for spinal surgery, 179
- intravenous
  - regional, upper limb, lidocaine, fentanyl, pancuronium, 597
- rectal
  - ketamine, pediatric, preoperative sedation, 880
  - midazolam, pediatric preoperative sedation, 880
- regional
  - brachial plexus block, lidocaine, duration of, clonidine, epinephrine admixture effects on, 69
  - brachial plexus block, mepivacaine isomers pharmacokinetics in, 75
  - brachial plexus block, ropivacaine, bupivacaine comparisons in, 602
  - dorsal primary ramus nerve block, for low back pain after epidural anesthesia, 1038
  - femoral, 3-in-1, for postoperative pain relief following total knee replacement, 265
  - glossopharyngeal nerve block, for carotid sinus syndrome, 1036
  - intercostal block, injection for, local anesthetic–methylene blue solution spread after, influence of volume on, 389
  - interpleural, bupivacaine, canine diaphragmatic function effects, 400
  - interpleural, bupivacaine, postoperative analgesia, after surgery with flank incisions, 0.25% and 0.5% solutions comparisons in, 268
  - interpleural, catheter obstruction (letter), 313
  - interpleural, lidocaine, bilateral, after bilateral lung surgery through median sternotomy, 1046
  - interpleural, unsuccessful analgesia, in mesothelioma, 133
  - interscalene block, contralateral anesthesia following (letter), 311
  - interscalene block, for shoulder surgery, success of, paresthesia location and, 386
  - intravenous, upper limb, lidocaine, fentanyl, pancuronium, 597
  - laryngeal nerve block, superior, as supplement to intravenous anesthesia for rigid bronchoscopy in myasthenic syndrome, 458
  - motor blockade, unilateral (letter), 310
  - pediatric, convulsions associated with, 164
  - postoperative analgesia after (letter), 637
  - psoas compartment block, mepivacaine isomers pharmacokinetics in, 75
  - sciatic nerve block, rat model, assessment of sensory and motor block induced by local anesthetics, 889
  - stellate ganglion block, continuous, for reflex sympathetic dystrophy, 1041
  - sympathetic blockade, unilateral (letter), 310
- spinal
  - cesarean section, headache after, 27-gauge Quincke and 24-gauge Sprotte needles comparison in, 377
  - continuous, labor, fentanyl, meperidine, sufentanil comparisons in, 734
  - continuous, patient-controlled analgesia, postoperative, 453
  - continuous, restricted sacral block after, catheter position in, radiographic examination of, 449
  - extradural anesthesia combined with (letter), 640
  - headache, recurrent, Chiari I malformation and, 1025
  - morphine, overdose, during refill of intrathecal infusion device, 130
  - myelopathy and back pain and (letter), 861
  - tetracaine, prolongation by oral clonidine, 262
- topical
  - dermal patch, lidocaine gel mixture, GA MHPh 2Na-10%, onset, skin pretreatments effects on, 555
  - liposomes and, 615
  - transferosomes and, 615

Anesthetics, gases
- bronchodilator propellants interpretation as mass spectrometers and infrared gas analyzers and (letter), 142
- nitrous oxide
  - air retrieval, Arrow type prototype catheter modification and, 226
  - cerebrospinal fluid pressure effects, brain tumor and, isoflurane compared to, 724
  - conscious sedation, in epileptic patients, for dental procedures, electroencephalogram effects, propofol compared to, 708
  - MAC, measurement, hyperbaria and, 995
  - pipecuronium potency effects, 193
  - stunned myocardium functional recovery in barbiturate–anesthetized, acutely instrumented dogs effects, 539
  - thermoregulatory vasoconstriction during, threshold and oxyhemoglobin saturation and, 947
- waste
  - scavenging system (letter), 1075

Anesthetics, intravenous
- alfentanil
  - induced rigidity in newborn, 252
  - laparoscopy, vomiting after, dose and, 558
  - patient-controlled analgesia, as alternative to physician administration, 41
  - prostatectomy, autonomic responses and recovery effects, hypnotic supplementation versus, 798
  - respiratory depression and, 965
  - tracheal intubation, without use of muscle relaxants, 788
- fentanyl
  - α-aminoisobutyric acid transfer across blood-brain barrier effects, 31
  - regional, upper limb, lidocaine, pancuronium with, 597
  - threshold for transpulmonary passage of venous air embolism effects, 720
- ketamine
  - as adjuvant to opioids (letter), 467
  - cardiac surgery, Hurler-Scheie syndrome and, difficult airway management and, 830
  - threshold for transpulmonary passage of venous air embolism effects, 720
- methohexital
  - anesthesia induced by, atipamezole effects on, 416
- propofol
  - brainstem auditory evoked responses effects (letter), 308
  - in cardiac catheterization (letter), 859
  - conscious sedation, in epileptic patients, for dental procedures, electroencephalogram effects, nitrous oxide compared to, 708
  - negative inotropic effects, end-systolic pressure-volume relationship as index of, reliability of slope of (letter), 305

    - orthopedic surgery, peripheral, outpatient, desflurane compared to, 572
    - pediatric, change of ectopic supraventricular tachycardia to sinus rhythm during, 1030
    - pediatric, induction, requirements, age-related differences in, 876
    - pediatric, radiation therapy in small children (letter), 860
    - prostatectomy, autonomic responses and recovery effects, opioid supplementation versus, 798
    - seizures and opisthotonos after, 630
    - thermoregulatory vasoconstriction during, threshold and oxyhemoglobin saturation and, 947
    - tracheal intubation, without use of muscle relaxants, 788
    - vecuronium interaction with, lack of, 536
  - thiopental
    - anesthesia induction, dose requirements, intravenous clonidine effects on, 530
    - negative inotropic effects, end-systolic pressure-volume relationship as index of, reliability of slope of (letter), 305
    - "sleep" plasma concentrations, fentanyl effects on, 523

- **Anesthetics, local**
  - bupivacaine
    - arthroscopy, postoperative pain effects, 208
    - brachial plexus block, ropivacaine compared to, 602
    - epidural, cesarean section, adverse effects, 753
    - epidural, cesarean section, patient-controlled analgesia, bupivacaine and, 740
    - epidural, postoperative analgesia, morphine with, clonidine enhancement of, 607
    - infusion into femoral nerve sheath, postoperative analgesia after total knee replacement, 264
    - interpleural, diaphragmatic function effects, canine, 400
    - interpleural, postoperative analgesia, after surgery with flank incisions, 0.25% and 0.5% solutions comparisons in, 268
    - mixtures, central nervous system toxicity, 922
    - preincisional plexus block with (letter), 637
    - seizures and, pediatric, 284
    - sensory and motor block induced by, rat sciatic nerve model for assessment of, 889
    - spread of, after intercostal block, 389
    - toxicity, cardiorespiratory, additive, 611
  - 2-chloroprocaine
    - disodium EDTA in, effects in subarachnoid space, 895
    - spinal, myelopathy and back pain and (letter), 861
  - dibucaine
    - cations, electrodes sensitive to, coated-wire, 1063
  - lidocaine
    - brachial plexus block, duration, clonidine, epinephrine admixture effects on, 69
    - cations, electrodes sensitive to, coated-wire, 1063
    - epidural, lipid drug carrier with, prolongation of anesthesia with, 900
    - epidural, plasma concentrations, isoflurane and halothane anesthesia and, 885
    - epidural catheter migration, tongue numbness and (letter), 634
    - GA MHPh 2Na-10%, dermal patch anesthesia, onset of, skin pretreatments effects on, 555
    - interpleural, bilateral, after bilateral lung surgery through median sternotomy, 1046
    - intravenous, convulsions-induced by, flumazenil effects on, 87
    - intravenous, upper limb, fentanyl, pancuronium with, 597
    - mixtures, central nervous system toxicity, 922
    - spinal, myelopathy and back pain and (letter), 861
    - topical, transferosomes, liposomes and, 615
    - toxicity, cardiorespiratory, additive, 611
  - mepivacaine
    - cations, electrodes sensitive to, coated-wire, 1063
    - isomers, pharmacokinetics, in psoas compartment/sciatic nerve block, 75
  - procaine
    - epidural, lipid drug carrier with, prolongation of anesthesia with, 900
    - spinal, myelopathy and back pain and (letter), 861
  - ropivacaine
    - brachial plexus block, bupivacaine compared to, 602
  - subblocking concentrations
    - impulse generation and conduction in myelinated sciatic nerve axons effects, 906
  - tetracaine
    - epidural, lipid drug carrier with, prolongation of anesthesia with, 900
    - mixtures, central nervous system toxicity, 922
    - spinal, myelopathy and back pain and (letter), 861
    - spinal, prolongation of, by oral clonidine, 262

- **Anesthetics, volatile**
  - desflurane
    - cardiovascular and respiratory actions, isoflurane compared to, S17
    - central nervous system effects, S32
    - induction and emergence characteristics in pediatric, adult, and geriatric patients, S38
    - metabolism and toxicity, S3, S10
    - orthopedic surgery, peripheral, outpatient, propofol compared to, 572
    - outpatient anesthesia, S47
    - pharmacology, S1, S3
  - enflurane
    - blood flow and tissue oxygenation pressures of liver and pancreas effects, 421
    - left ventricular global and regional function effects, coronary artery disease and, 679
    - pipecuronium potency effects, 193
  - halothane
    - blood flow and tissue oxygenation pressures of liver and pancreas effects, 421
    - coronary artery segment relaxation effects, porcine, isoflurane compared to, 9
    - endothelium-dependent relaxation elicited by acetylcholine effects, 198
    - expiratory muscles and (letter), 1070
    - hemodynamic and organ blood flow responses to, during spontaneous ventilation, 1000
    - intracardiac conduction and QTc interval effects, in pentobarbital anesthetized dogs, 688
    - left ventricular global and regional function effects, coronary artery disease and, 679
    - MAC, chloride transport blockade effects on, 103
    - MAC, ketorolac effects on, 99
    - pipecuronium potency effects, 193
    - plasma lidocaine concentrations during epidural blockade and, 885
    - pulmonary and circulatory effects (letter), 1070
    - pulmonary artery endothelial eicosanoid release effects, 1007
    - threshold for transpulmonary passage of venous air embolism effects, 720
  - isoflurane
    - blood flow and tissue oxygenation pressures of liver and pancreas effects, 421
    - cardiovascular and respiratory actions, desflurane compared to, S17
    - cerebrospinal fluid pressure effects,

    brain tumor and, nitrous oxide compared to, 724
    coronary artery segment relaxation effects, porcine, halothane compared to, 9
    desflurane production and, S3
    endothelium-dependent relaxation elicited by acetylcholine effects, 198
    induced-hypotension, splanchnic hemodynamics and oxygen supply effects, normovolemic hemodilution and, 660
    left ventricular global and regional function effects, coronary artery disease and, 679
    pipecuronium potency effects, 193
    plasma lidocaine concentrations during epidural blockade and, 885
    potassium and calcium conductance effects in isolated smooth muscle cells of canine cerebral arteries, 590
    unconscious learning effects, 107
  sevoflurane
    biotransformation, cytotoxicity, guinea pig liver slices evaluation, 436
    hemodynamic and organ blood flow responses to, during spontaneous ventilation, 1000
    malignant hyperthermia and (letter), 867
Aneurysm, see Arteries
Angioedema, see Complications, edema
Angiotensin-converting enzymes, see Enzymes
Antagonists, miscellaneous
  atipamezole
    anesthesia produced by barbiturates and medetomidine effects, 416
  benzodiazepines
    flumazenil, arousal, intraoperative, during spine fusion, 580
    flumazenil, intravenous lidocaine-induced convulsions and anticonvulsant properties of diazepam effects in rats, 87
  dopamine
    metoclopramide, opioid requirements for prostaglandin-induced termination of abortion effects, 760
Antagonists, narcotic
  naloxone
    epidural morphine side effects treatment, nalbuphine compared to, 747
Antagonists, neuromuscular relaxants
  4-aminopyridine
    pharmacology, in neonates, 361
  neostigmine
    pharmacology, in neonates, 361
  pyridostigmine
    pharmacology, in neonates, 361
Anticoagulants, see Blood
Anticonvulsants
  diazepam

The Department of Anesthesiology at the University of Massachusetts Medical Center is seeking BC/BE full-time faculty for the following positions:

Intensive Care Medicine

Applicants for this position should be eligible to sit for critical care subspecialty exam.

Pediatric Anesthesia

Applicants for this position should have at least 6 months' formal training beyond residency. A willingness to take call in the PICU occasionally is an asset.

Neuroanesthesia
Cardiac Anesthesia

Applicants for these positions should have at least 6 months' formal training beyond residency.

Pain Management

Applicants for this position should have at least 6 months' formal training in pain management beyond residency, and have an interest in both acute and chronic pain management.

Faculty candidates for all the above positions must have a commitment to resident teaching and be eligible for an unrestricted Massachusetts License. Academic rank and remuneration will be commensurate with experience and credentials.

The UMMC is a rapidly expanding 371-bed teaching hospital and ACS Level 1 Trauma Center located 30 miles west of Boston.

Interested physicians should submit a detailed curriculum vitae to: Dr. Gordon Chapman, Chair ad Interim, Dept. of Anesthesiology, University of Massachusetts Medical Center, 55 Lake Avenue North, Worcester, MA 01655.

UMASS
MEDICAL

MOVING?

To avoid interruption in your receipt of this Journal, we need to know your new address—six weeks in advance.

When writing us, be sure to type or print clearly your name and your new address—complete with zip code. It is *essential* that you also list your old address.

IMPORTANT: We publish a number of medical and scientific periodicals. Therefore, please be sure to give the name of THIS Journal when you write us.

Thank you for cooperating!

Anesthesiology Board Review Courses

February 2-7, '93 – Tampa   February 12-15, '93 Los Angeles
April 12-17, 1993 – Seattle

Now special programs for written and oral board exams

Objectives:

- Improve basic and clinical knowledge of anesthesiology
- Assist residents and fellows to better organize for further study
- Prepare candidates to take their written and oral exams

Methods:

- HOME STUDY questions, answers, assignments and keywords
- SEMINAR with projection slides and lecture-note syllabus
- PRACTICE EXAMS for written and oral board exams

"The faculty was outstanding. The most pleasant thing was learning a tremendous amount, not only from world-famous authorities, but from people who are relatively unknown as

Written Board Review

Lectures and written exam seminars

- February 2-7 and April 12-17
- Home-study keywords with discussions and questions with answers.
- Six-day lecture with syllabus.
- Seminars for written exam questions.

Oral Board Review

Mock oral exams and lectures

- February 2-7 and April 12-17
- Home-study, oral-exam stem cases with pre-op, intra-op and post-op questions.
- Six-day lectures with syllabus and concurrent mock oral exams most hours.
- **Registration includes one mock oral.**
- Extra public mock oral exam ($80), private mock oral exam ($110).

Oral Board Tutorial Days

Choose any days – groups limited to 24

- February 12-15 and every weekend January 9-April 20: call for schedule
- Home-study, oral-exam stem cases with pre-op, intra-op and post-op questions.
- Mock oral exams in groups **limited to 24.**
- **Includes one public mock oral per day.**
- Extra public mock oral exams ($80), private mock oral exams ($110).

Two-Part Board Review

Nine mock orals in any two courses

- Any course in 1993, plus any other within three years. One course may be up to six Oral Board Tutorial days of your choice.
- Choose between lectures and concurrent mock orals or written exam discussions.
- **Nine mock oral exams in groups limited to 24 participants.**

Unconditional Guarantee

- If you fail the next Anesthesiology Board Exam you take after taking one of these courses, we will refund half of your last course registration fee and allow you to repeat the course once for FREE.

Limited Enrollment: ANESTHESIOLOGY REVIEW COURSE REGISTRATION

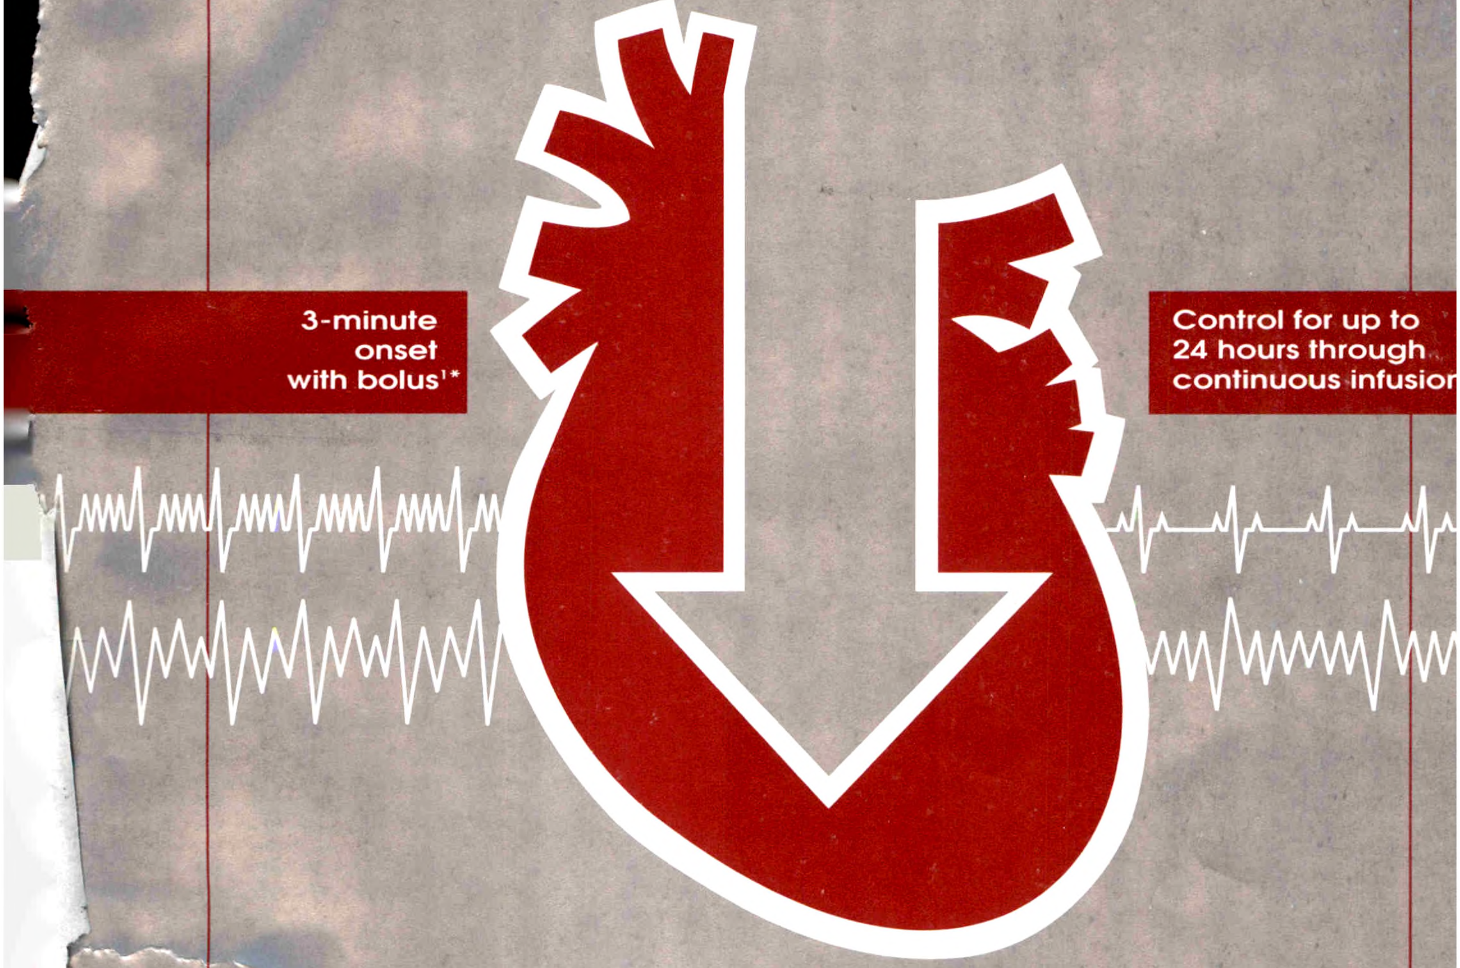
Now for heart rate control during atrial fibrillation and flutter

CARDIZEM® *Injectable*
(diltiazem hydrochloride)
BOLUS INFUSION
5 mg/mL



3-minute onset with bolus[1]*

Control for up to 24 hours through continuous infusion

Heart rate control that is
FAST, SAFE, AND CONTINUOUS[1,2†]

Cardizem Injectable is indicated for temporary control of rapid ventricular rate during atrial fibrillation and flutter; rarely converts to normal sinus rhythm; should be used with continuous monitoring of ECG and blood pressure to avoid hypotension or bradycardia. Infusion rate/dose should be regulated accordingly. A defibrillator and emergency equipment should be readily available.

*Symptomatic hypotension (3.2%) or flushing (1.7%) occurs most often during or immediately following bolus injection.
†Contraindications: atrial fibrillation and flutter patients with WPW or short PR syndrome; sick sinus syndrome or second- or third-degree AV block, except with a functioning pacemaker; severe hypotension or shock; hypersensitivity; recent IV beta-blockers; ventricular tachycardia.

Please see the brief summary of prescribing information on an adjacent page.

CIVAH497/A8114

6491E2

CARDIZEM® Injectable
(diltiazem hydrochloride)
BOLUS INFUSION

CONVENIENT DOSAGE

1 Beginning treatment as

BOLUS: 0.25 mg/kg actual body weight **over 2 minutes**

20 mg average patient

2 If response is inadequate, wait 15 minutes

BOLUS: 0.35 mg/kg actual body weight **over 2 minutes**

25 mg average patient

3 Treatment as

INFUSION:
10* to 15 mg/hr

*5 mg/hr may be appropriate starting infusion for some patients.

BRIEF SUMMARY

CARDIZEM® Injectable

(diltiazem hydrochloride)

INDICATIONS AND USAGE

CARDIZEM Injectable (diltiazem hydrochloride) is indicated for the following:

1. ***Atrial Fibrillation or Atrial Flutter.*** Temporary control of rapid ventricular rate in atrial fibrillation or atrial flutter. It should not be used in patients with atrial fibrillation or atrial flutter associated with an accessory bypass tract such as in Wolff-Parkinson-White (WPW) syndrome or short PR syndrome.
2. ***Paroxysmal Supraventricular Tachycardia.*** Rapid conversion of paroxysmal supraventricular tachycardias (PSVT) to sinus rhythm. This includes AV nodal reentrant tachycardias and reciprocating tachycardias associated with an extranodal accessory pathway such as the WPW syndrome or short PR syndrome. Unless otherwise contraindicated, appropriate vagal maneuvers should be attempted prior to administration of CARDIZEM Injectable.

The use of CARDIZEM Injectable for control of ventricular response in patients with atrial fibrillation or atrial flutter or conversion to sinus rhythm in patients with PSVT should be undertaken with caution when the patient is compromised hemodynamically or is taking other drugs that decrease any or all of the following: peripheral resistance, myocardial filling, myocardial contractility, or electrical impulse propagation in the myocardium.

For either indication and particularly when employing continuous intravenous infusion, the setting should include continuous monitoring of the ECG and frequent measurement of blood pressure. A defibrillator and emergency equipment should be readily available.

In domestic controlled trials in patients with atrial fibrillation or atrial flutter, bolus administration of CARDIZEM Injectable was effective in reducing heart rate by at least 20% in 95% of patients. CARDIZEM Injectable rarely converts atrial fibrillation or atrial flutter to normal sinus rhythm. Following administration of one or two intravenous bolus doses of CARDIZEM Injectable, response usually occurs within 3 minutes and maximal heart rate reduction generally occurs in 2 to 7 minutes. Heart rate reduction may last from 1 to 3 hours. If hypotension occurs, it is generally short-lived, but may last from 1 to 3 hours.

A 24-hour continuous infusion of CARDIZEM Injectable in the treatment of atrial fibrillation or atrial flutter maintained at least a 20% heart rate reduction during the infusion in 83% of patients. Upon discontinuation of infusion, heart rate reduction may last from 0.5 hours to more than 10 hours (median duration 7 hours). Hypotension, if it occurs, may be similarly persistent.

In the controlled clinical trials, 3.2% of patients required some form of intervention (typically, use of intravenous fluids or the Trendelenburg position) for blood pressure support following CARDIZEM Injectable.

In domestic controlled trials, bolus administration of CARDIZEM Injectable was effective in converting PSVT to normal sinus rhythm in 88% of patients within 3 minutes of the first or second bolus dose.

Symptoms associated with the arrhythmia were improved in conjunction with decreased heart rate or conversion to normal sinus rhythm following administration of CARDIZEM Injectable.

CONTRAINDICATIONS

CARDIZEM Injectable is contraindicated in:

1. Patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker.
2. Patients with second- or third-degree AV block except in the presence of a functioning ventricular pacemaker.
3. Patients with severe hypotension or cardiogenic shock.
4. Patients who have demonstrated hypersensitivity to the drug.
5. Intravenous diltiazem and intravenous beta-blockers should not be administered together or in close proximity (within a few hours).
6. Patients with atrial fibrillation or atrial flutter associated with an accessory bypass tract such as in WPW syndrome or short PR syndrome.

   As with other agents which slow AV nodal conduction and do not prolong the refractoriness of the accessory pathway (eg, verapamil, digoxin), in rare instances patients in atrial fibrillation or atrial flutter associated with an accessory bypass tract may experience a potentially life-threatening increase in heart rate accompanied by hypotension when treated with CARDIZEM Injectable. As such, the initial use of CARDIZEM Injectable should be, if possible, in a setting where monitoring and resuscitation capabilities, including DC cardioversion/defibrillation, are present (see OVERDOSAGE). Once familiarity of the patient's response is established, use in an office setting may be acceptable.
7. Patients with ventricular tachycardia. Administration of other calcium channel blockers to patients with wide complex tachycardia (QRS ≥ 0.12 seconds) has resulted in hemodynamic deterioration and ventricular fibrillation. It is important that an accurate pretreatment diagnosis distinguish wide complex QRS tachycardia of supraventricular origin from that of ventricular origin prior to administration of CARDIZEM Injectable.

WARNINGS

1. **Cardiac Conduction.** Diltiazem prolongs AV nodal conduction and refractoriness that may rarely result in second- or third-degree AV block in sinus rhythm. Concomitant use of diltiazem with agents known to affect cardiac conduction may result in additive effects (see Drug Interactions). If high-degree AV block occurs in sinus rhythm, intravenous diltiazem should be discontinued and appropriate supportive measures instituted (see OVERDOSAGE).
2. **Congestive Heart Failure.** Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function and in patients with a compromised myocardium, such as severe CHF, acute MI, and hypertrophic cardiomyopathy, have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). Administration of oral diltiazem in patients with acute myocardial infarction and pulmonary congestion documented by x-ray on admission is contraindicated. Experience with the use of CARDIZEM Injectable in patients with impaired ventricular function is limited. Caution should be exercised when using the drug in such patients.
3. **Hypotension.** Decreases in blood pressure associated with CARDIZEM Injectable therapy may occasionally result in symptomatic hypotension (3.2%). The use of intravenous diltiazem for control of ventricular response in patients with supraventricular arrhythmias should be undertaken with caution when the patient is compromised hemodynamically. In addition, caution should be used in patients taking other drugs that decrease peripheral resistance, intravascular volume, myocardial contractility or conduction.
4. **Acute Hepatic Injury.** In rare instances, significant elevations in enzymes such as alkaline phosphatase, LDH, SGOT, SGPT, and other phenomena consistent with acute hepatic injury have been noted following oral diltiazem. Therefore, the potential for acute hepatic injury exists following administration of intravenous diltiazem.
5. **Ventricular Premature Beats (VPBs).** VPBs may be present on conversion of PSVT to sinus rhythm with CARDIZEM Injectable. These VPBs are transient, are typically considered to be benign, and appear to have no clinical significance. Similar ventricular complexes have been noted during cardioversion, other pharmacologic therapy, and during spontaneous conversion of PSVT to sinus rhythm.

PRECAUTIONS

General. CARDIZEM (diltiazem hydrochloride) is extensively metabolized by the liver and excreted by the kidneys and in bile. The drug should be used with caution in patients with impaired renal or hepatic function (see WARNINGS). High intravenous dosages (4.5 mg/kg tid) administered to dogs resulted in significant bradycardia and alterations in AV conduction. In subacute and chronic dog and rat studies designed to produce toxicity, high oral doses of diltiazem were associated with hepatic damage. In special subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes in the liver, which were reversible when the drug v discontinued. In dogs, oral doses of 20 mg/kg were also associated w hepatic changes; however, these changes were reversible with continu dosing.

Dermatologic events progressing to erythema multiforme and/or exfoliative dermatitis have been infrequently reported following oral diltiazem. Therefore the potential for these dermatologic reactions exists following exposure t intravenous diltiazem. Should a dermatologic reaction persist, the drug should be discontinued.

Drug Interactions. Due to potential for additive effects, caution is warranted in patients receiving CARDIZEM Injectable concomitantly with any agent(s) known to affect cardiac contractility and/or SA or AV node conduction (see WARNINGS).

As with all drugs, care should be exercised when treating patients with multiple medications. CARDIZEM undergoes extensive metabolism by the cytochrome P-450 mixed function oxidase system. Although specific pharmacokinetic drug-drug interaction studies have not been conducted with single intravenous injection or constant rate intravenous infusion, coadministration of CARDIZEM Injectable with other agents which primarily undergo the same route of biotransformation may result in competitive inhibition of metabolism.

Digitalis: Intravenous diltiazem has been administered to patients receiving either intravenous or oral digitalis therapy. The combination of the two drugs was well tolerated without serious adverse effects. However, since both drugs affect AV nodal conduction, patients should be monitored for excessive slowing of the heart rate and/or AV block.

Beta-blockers: Intravenous diltiazem has been administered to patients on chronic oral beta-blocker therapy. The combination of the two drugs was generally well tolerated without serious adverse effects. If intravenous diltiazem is administered to patients receiving chronic oral beta-blocker therapy, the possibility for bradycardia, AV block, and/or depression of contractility should be considered (see CONTRAINDICATIONS). ***Oral*** administration of diltiazem with propranolol in five normal volunteers resulted in increased propranolol levels in all subjects and bioavailability of propranolol was increased approximately 50%. In vitro, propranolol appears to be displaced from its binding sites by diltiazem.

Anesthetics: The depression of cardiac contractility, conductivity, and automaticity as well as the vascular dilation associated with anesthetics may be potentiated by calcium channel blockers. When used concomitantly, anesthetics and calcium blockers should be titrated carefully.

Carcinogenesis, Mutagenesis, Impairment of Fertility. A 24-month study in rats at oral dosage levels of up to 100 mg/kg/day, and a 21-month study in mice at oral dosage levels of up to 30 mg/kg/day showed no evidence of carcinogenicity. There was also no mutagenic response in vitro or in vivo in mammalian cell assays or in vitro in bacteria. No evidence of impaired fertility was observed in a study performed in male and female rats at oral dosages o up to 100 mg/kg/day.

Pregnancy. Category C. Reproduction studies have been conducted in mic rats, and rabbits. Administration of oral doses ranging from five to ten time greater (on a mg/kg basis) than the daily recommended oral antiangina therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In th perinatal/postnatal studies there was some reduction in early individual pup weights and survival rates. There was an increased incidence of stillbirths at doses of 20 times the human oral antianginal dose or greater.

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. Diltiazem is excreted in human milk. One report with oral diltiazem suggests that concentrations in breast milk may approximate serum levels. If use of CARDIZEM is deemed essential, an alternative method of infant feeding should be instituted.

Pediatric Use. Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

The following adverse reaction rates are based on the use of CARDIZEM Injectable in over 400 domestic clinical trial patients with atrial fibrillation/flutter or PSVT under double-blind or open-label conditions. Worldwide experience in over 1,300 patients was similar.

Adverse events reported in controlled and uncontrolled clinical trials were generally mild and transient. Hypotension was the most commonly reported adverse event during clinical trials. Asymptomatic hypotension occurred in 4.3% of patients. Symptomatic hypotension occurred in 3.2% of patients. When treatment for hypotension was required, it generally consisted of administration of saline or placing the patient in the Trendelenburg position. Other events reported in at least 1% of the diltiazem-treated patients were injection site reactions (eg, itching, burning)—3.9%, vasodilation (flushing)—1.7%, and arrhythmia (junctional rhythm or isorhythmic dissociation)—1.0%.

In addition, the following events were reported infrequently (less than 1%):

Cardiovascular:	Atrial flutter, AV block first degree, AV block second degree, bradycardia, chest pain, congestive heart failure, sinus pause, sinus node dysfunction, syncope, ventricular arrhythmia, ventricular fibrillation, ventricular tachycardia.
Dermatologic:	Pruritus, sweating.
Gastrointestinal:	Constipation, elevated SGOT or alkaline phosphatase, nausea, vomiting.
Nervous System:	Dizziness, paresthesia.
Other:	Amblyopia, asthenia, dry mouth, dyspnea, edema headache, hyperuricemia.

Although not observed in clinical trials with CARDIZEM Injectable, other reactions associated with oral diltiazem may occur.

OHIO
Anesthesiologist, University Hospitals. Must be at least board eligible. Equal Opportunity, Affirmative Action Employer. Send curriculum vitae to Helmut F. Cascorbi, MD, PhD, Professor and Chairman, Department of Anesthesiology, University Hospitals of Cleveland, 2074 Abington Road, Cleveland, OH 44106.

701E/L

ILLINOIS: ANESTHESIOLOGIST
To join congenial group of MDs/CRNAs expanding to provide anesthesia coverage for only hospital in city since recent merger. No open heart or neurosurgery. Environment conducive to family living, variety of schools, recreation. Good opportunity with stable future. City located in east central Illinois with population of approximately 40,000 (35-mile radius service area with 126,126 population). Within driving distance of Chicago and Indianapolis. Please send CV to Box 887D/L.

887D/L

CARDIOVASCULAR FELLOWSHIP OPPORTUNITY
The Department of Anesthesiology and Critical Care Medicine at the University of New Mexico School of Medicine has openings at the CA-4 level for advanced training in cardiovascular anesthesiology. The fellowship is a 2-year comprehensive program designed to train the fellow for a career in cardiovascular anesthesiology. Research in cardiovascular physiology and anesthesia, provision of clinical care for complex adult and pediatric cases, participation in conference, and teaching responsibilities are part of the fellowship experience. Interested individuals should send CV or contact Jorge A. Estrin, MD, PhD, Professor and Chairman, Department of Anesthesiology, University of New Mexico School of Medicine, Albuquerque, NM 83131-5216, (505) 272-2610, FAX (505) 277-1300. The University of New Mexico is an Equal Opportunity/Affirmative Action Employer.

912F/L

THE UNIVERSITY OF NEW MEXICO
Department of Anesthesiology and Critical Care Medicine has immediate faculty positions at the Instructor, Assistant Professor, Associate Professor, and Professor levels for candidates with experience in cardiac, obstetric, neurosurgical, and pediatric anesthesia and critical care medicine. Responsibilities include the teaching of medical students and residents and the provision of clinical care in a busy tertiary referral center. Opportunities to pursue research interests will be provided. It is expected that candidates who apply for CCM positions will have or be eligible for subspecialty certification. Qualified candidates should send CV or contact Jorge A. Estrin, MD, PhD, Professor and Chairman, Department of Anesthesiology, University of New Mexico School of Medicine, Albuquerque, NM 87131-5216, (505) 272-2610, FAX (505) 277-1300. The University of New Mexico is an Equal Opportunity/Affirmative Action Employer.

913F/L

CALIFORNIA
University of California, Irvine: Openings for faculty positions in the Department of Anesthesiology. (1) Assistant or associate professor level in the in-residence series. Responsibilities include teaching and research. (2) Clinical instructor and assistant professor level in the clinical series. Responsibilities include teaching and clinical service. Participation in research is highly desirable but not mandatory

Rank and pay commensurate with skills and experience. Faculty will serve at both a tertiary-care university hospital and a VA Medical Center. Candidates must be ABA certified, or in the examination process, and be eligible for a California state license. An Affirmative Action, Equal Opportunity Employer. Address correspondence with references and curriculum vitae to Steven J. Barker, PhD, MD, Chair, Department of Anesthesiology, University of California, Irvine Medical Center, 101 City Drive South, Route 81A, Orange, CA 92668.

CLASSIFIED ADS

Anesthesia & Analgesia makes available classified advertising space for those interested in obtaining positions or wishing to announce meetings, postgraduate courses, or other pertinent events. We require that all advertisements be relevant to the practice of anesthesia and analgesia, and we reserve the right to refuse advertisements that are not relevant.

Specifications. Ads should be typewritten on letterhead stationery; the text should be double-spaced, with the title or key phrase typed in capital letters. Enclose two photocopies with each ad. Display space (minimum ¼ page) is available through Pharmaceutical Media, Inc., 440 Park Avenue South, 14th floor, New York, NY 10016, telephone: (212) 685-5010, FAX: (212) 685-6126.

Rates. Ads cost $1.50 per word per insertion, with a minimum of 20 words. Abbreviations, dates, initials, post office box numbers, telephone numbers, years, and zip codes are considered one word each. There is an additional fee of $18.00 per insertion for box number ads.*

Payment. Full payment or institutional purchase order must accompany the copy for each ad. Ads received without a check or purchase order will be returned. (Make checks payable to Elsevier Science Publishing Companv, Inc.)

Deadline. Copy must be received 7 weeks before publication date (i.e., by January 1 for the March issue); multiple-insertion ads are welcome. Ads may run up to 6 months per purchase order/payment. Please specify in which issue(s) your advertisement is to appear.

Send all ad copy, payments, and correspondence to: *Anesthesia & Analgesia*, Classified Ads, Desk Editorial, Elsevier Science Publishing Co., Inc., 655 Avenue of the Americas, New York, NY 10010.

*When responding to a box number ad, include the box number on all correspondence.

lent salary and fringe benefits. Eligibility for Louisiana licensure is prerequisite. Please send curriculum vitae to M. Naraghi, MD, Professor and Chairman, LSU Department of Anesthesiology, 1532 Tulane Avenue, New Orleans, LA 70140. LSUMC is an EEO/AA employer.

937H/A

POSTDOCTORAL FELLOWSHIP
Background in clinical medicine or clinical research required for studies with patients with heart disease undergoing surgery. Cardiac function and ischemia assessed with ECG, Holter, and echocardiography monitoring. Working with cardiologists, epidemiologists, and anesthesiologists. Send CV and names of three references to Dennis T. Mangano, PhD, MD, Professor and Vice Chairman, Department of Anesthesia, University of California, San Francisco, 4150 Clement Street (129), San Francisco, CA 94121.

Samuelson, MD, Professor and Chairman of Recruitment Committee, Department of Anesthesiology, University of Alabama at Birmingham, 619 South 19th Street, Birmingham, AL 35233, (205) 934-4696. An Affirmative Action/Equal Employment Opportunity Employer.

1025L/B

Albany Medical College has immediate openings for BC/BE anesthesiologists to join our staff of over 25 MDs, and over 60 CRNAs and residents, to provide team-approach anesthesia care for all types of cases. Research and teaching interest highly desirable.

We are a 660-bed, tertiary-care facility with 20 newly renovated OR suites equipped with state-of-the-art instrumentation.

Our highly competitive benefits package includes generous leave time, health and dental plan, pension and disability plan, malpractice and life insurance. Interested applicants should send CV and three references to: Philip D. Lumb, MBBS, Professor and Chairman, Albany Medical College, Department of Anesthesiology, Mail Code A-131, Albany, New York 12208.

1026LBD

PEDIATRIC ANESTHESIOLOGIST to direct Pediatric Intensive Care Unit in academic medical center. Interest in teaching and research required. Academic appointment appropriate to credentials. TJU is an Affirmation Action/Equal Opportunity Employer. Send inquiries and references to Joseph L. Seltzer, MD, Professor and Chairman, Department of Anesthesiology, Thomas Jefferson University, Philadelphia, PA 19107.

1027L/B

TENNESSEE

Expanding department requires additional anesthesiologists. Full-time positions available at levels of instructor to associate professor with emphasis on teaching, patient care, and clinical research. Prerequisites: (1) Meet Tennessee license requirements. (2) ABA diplomat or eligible for ABA examination. All subspecialties needed. Excellent opportunity for anesthesiologists who want an ideal mix of private practice with teaching and clinical research. Send curriculum vitae, bibliography, and the names and addresses of three references to John Zanella, Jr., MD, PhD, Professor and Chairman, Department of Anesthesiology, University of Tennessee, Memphis, 800 Madison Avenue, Memphis, TN 38163. The University of Tennessee is an Equal Opportunity Employer/Affirmative Action Register/Title IX/Section 504 Employer.

1028L/B

PHONEPREP. TAKE MOCK ORALS BY PHONE, learn oral test-taking techniques, schedule at your convenience. (419) 843-4480.

1007L

DON'T FAIL THE WRITTEN BOARDS!

Unique study program including memory devices, methods for improved retention, guessing techniques, etc. Practice questions with answers, explanations and references, new Keywords. Get MEDTEXT not imitations. Call 1-800-232-TEXT for orders. MC/V accepted.

933H/A

TUTORING FOR WRITTEN AND ORAL BOARD EXAMS

The unique feature of these programs is the maximum class size of four students. Preparation for the written and oral exams are given separately in 3-day blocks in San Francisco and New York. FOR THE WRITTENS, techniques are taught for dealing with the multiple-choice questions. The basic sciences are stressed. FOR THE ORALS, the guided case discussions are stressed. Home study programs are provided. CALL (415) 321-1117.

763I/B

Dial 1-800/RENT-A-DOC

For anesthesiologists and CRNAs. We can provide you with quality locum tenens services to meet your specific coverage needs. Or work locum tenens with us for a change in both your practice and your lifestyle. ReplaceMed * 1-800/736-8236 * PO Box 640 * Michigan City, IN 46360.

832A/L

J. STEPHENS MAYHUGH AND ASSOCIATES, INC. LOCUM TENENS ANESTHESIA SERVICES

Providing top-quality CRNAs to meet your specific needs. Our CRNAs are screened to assure quality in performance as well as personal stability. License verification, curriculum vitae, references procured by us, AANA recertification, malpractice verification are supplied to you. Call 1-800-426-2349 any time.

755I/L

DANIEL & YEAGER LOCUM TENENS
Daniel & Yeager is the only name you need for locum tenens. Anesthesia is our specialty, so you are assured of our personal attention. Earn a premium income while eliminating administrative headaches and malpractice premiums; we cover it all. Call 1-800-264-1919 or write to 200 Clinton Avenue, NW, Suite 400, Huntsville, AL 35801.

898E/L

A WEEKEND OF MOCK ORAL EXAMS
Mock orals, not lectures. We are the original course in this format. 20 hours Category I CME credit, two board-certified instructors, 12 students maximum. Tampa, January 22–24; Dallas, February 19–21; Detroit, March 12–14. ANESTHESIA EXAM REVIEW, 7128 Regents Park, Toledo, OH 43617. (419) 843-4480 or (813) 394-8780.

963J/A

CHAIRPERSON, DEPARTMENT OF ANESTHESIOLOGY, LOYOLA UNIVERSITY MEDICAL CENTER
Loyola University Medical School, Maywood, Illinois, is seeking candidates for the position of Professor and Chairperson for the Department of Anesthesiology. The department is expanding its programs in clinical care, research, and medical education. Candidates should have experience an understanding of both the clinical aspect of anesthesiology and the requirements o the Anesthesiology Residency Program The candidates must also have a distinguished record of scholarship and professional achievement, proven leadership and administrative ability.

Applications and curriculum vita should be sent to the Chairman of th Search Committee: Jack Pickleman, MD Professor and Chief Division of Genera Surgery, Department of Surgery, Loyol University Medical Center, 2160 South Firs Avenue, Maywood, IL 60153. An Affirmative Action/Equal Opportunity Employer.

THE ADVANTAGE OF CO-INDUCTION

Anesthetic Synergy

VERSED first, followed by a second anesthetic

When given first, a small dose of VERSED® (midazolam HCl/Roche) may lower the induction ED_{50} of barbiturates or narcotics up to 75%.[1-4] This synergistic effect appears to result from a mutual enhancement of binding-site affinity.[1-3] Clinically, co-induction may decrease toxicity and speed recovery.[2] VERSED can also abolish the excitatory effects and emergence phenomena associated with some induction agents,[5] and its potent amnestic effect may avoid breakthrough awareness at times when short-acting induction agents may be wearing off.

- **Allows lower doses of induction agents[1-5]**
- **A smooth induction[5]**
- **Less risk of breakthrough awareness[5]**
- **A smooth emergence[5]**

Dosing considerations

When VERSED is used before other intravenous agents for induction of anesthesia, the initial dose of each agent may be significantly reduced, at times to as low as 25% of the usual initial dose of the individual agents.

As a standard precaution, prior to I.V. administration of VERSED in any dose, oxygen and resuscitative equipment should be immediately available. VERSED should be used as an induction agent only by persons trained in anesthesiology and who are familiar with all dosing and administration guidelines. Reduce dosage in elderly or debilitated patients, in patients receiving narcotic premedication and in those with limited pulmonary reserve.

It is recommended that patients do not drive or operate hazardous machinery after receiving VERSED until the effects of the drug (*e.g.,* drowsiness) are gone or until the day after anesthesia, whichever is longer. The decision must be individualized.

Please see summary of product information on following page.

INJECTABLE

VERSED®

midazolam HCl/Roche Ⓒ

FIRST

Injectable VERSED is available in 1 mg/mL and 5 mg/mL strengths.

VERSED®
midazolam HCl/Roche Ⓒ
INJECTION

Before prescribing, please consult complete product information, a summary of which follows:

> Intravenous VERSED has been associated with respiratory depression and respiratory arrest, especially when used for conscious sedation. In some cases, where this was not recognized promptly and treated effectively, death or hypoxic encephalopathy has resulted. Intravenous VERSED should be used only in hospital or ambulatory care settings, including physicians' offices, that provide for continuous monitoring of respiratory and cardiac function. Immediate availability of resuscitative drugs and equipment and personnel trained in their use should be assured. (See WARNINGS.)
>
> The initial intravenous dose for conscious sedation may be as little as 1 mg, but should not exceed 2.5 mg in a normal healthy adult. Lower doses are necessary for older (over 60 years) or debilitated patients and in patients receiving concomitant narcotics or other CNS depressants. The initial dose and all subsequent doses should never be given as a bolus; administer over at least 2 minutes and allow an additional 2 or more minutes to fully evaluate the sedative effect. The use of the 1 mg/mL formulation or dilution of the 1 mg/mL or 5 mg/mL formulation is recommended to facilitate slower injection. Consult complete product information under DOSAGE AND ADMINISTRATION for complete dosing information.

CONTRAINDICATIONS: Patients with known hypersensitivity to the drug. Benzodiazepines are contraindicated in patients with acute narrow angle glaucoma; may be used in open angle glaucoma only if patients are receiving appropriate therapy.

Not intended for intrathecal or epidural administration due to the presence of the preservative benzyl alcohol.

WARNINGS: Never use without individualization of dosage. Prior to IV use in any dose, ensure immediate availability of oxygen, resuscitative equipment and skilled personnel for maintenance of a patent airway and support of ventilation. Continuously monitor for early signs of underventilation or apnea, which can lead to hypoxia/cardiac arrest unless effective countermeasures are taken immediately. Vital signs should continue to be monitored during the recovery period.

Because IV VERSED depresses respiration, and opioid agonists and other sedatives can add to this depression, it should be administered as an induction agent only by a person trained in general anesthesia and should be used for conscious sedation only in the presence of personnel skilled in early detection of underventilation, maintaining a patent airway and supporting ventilation. **For conscious sedation, do not administer IV by rapid or single bolus.** Serious cardiorespiratory adverse events have occurred. These have included respiratory depression, apnea, respiratory arrest and/or cardiac arrest, sometimes resulting in death. There have been rare reports of hypotensive episodes requiring treatment during or after diagnostic or surgical manipulations in patients who have received VERSED. Hypotension occurred more frequently in the conscious sedation studies in patients premedicated with narcotic.

Reactions such as agitation, involuntary movements, hyperactivity and combativeness have been reported. These may be due to inadequate or excessive dosing or improper administration; however, the possibility of cerebral hypoxia or true paradoxical reactions should be considered. Should these reactions occur, response to each dose of VERSED and all other drugs should be evaluated before proceeding.

Concomitant use of barbiturates, alcohol or other CNS depressants may increase the risk of underventilation or apnea and may contribute to profound and/or prolonged drug effect. Narcotic premedication also depresses the ventilatory response to carbon dioxide stimulation.

Higher risk surgical, elderly or debilitated patients require lower dosages for induction of anesthesia, premedicated or not. Patients with chronic obstructive pulmonary disease are unusually sensitive to the respiratory depressant effect of VERSED. Patients with chronic renal failure and patients with congestive heart failure eliminate midazolam more slowly. Because elderly patients frequently have inefficient function of one or more organ systems, and because dosage requirements have been shown to decrease with age, reduce initial dosage and consider possibility of a profound and/or prolonged effect.

Do not administer in shock, coma, acute alcohol intoxication with depression of vital signs. Particular care should be exercised in the use of IV VERSED in patients with uncompensated acute illnesses, such as severe fluid or electrolyte disturbances.

Guard against unintended intra-arterial injection; hazards in humans unknown. Avoid extravasation.

VERSED should only be administered IM or IV. Safety and efficacy of other routes of administration are not established.

Gross tests of recovery from the effects of VERSED cannot alone predict reaction time under stress. This drug is never used alone during anesthesia, and the contribution of other perioperative drugs and events can vary. The decision as to when patients may engage in activities requiring mental alertness must be individualized; it is recommended that no patient should operate hazardous machinery or a motor vehicle until the effects of the drug, such as drowsiness, have subsided or until the day after anesthesia, whichever is longer.

Usage in Pregnancy: An increased risk of congenital malformations associated with the use of benzodiazepines (diazepam and chlordiazepoxide) has been suggested in several studies. If VERSED is used during pregnancy, apprise the patient of the potential hazard to the fetus.

PRECAUTIONS: *General:* Decrease intravenous doses in elderly and debilitated patients. These patients will also probably take longer to recover completely after VERSED for induction of anesthesia.

VERSED does not protect against increased intracranial pressure or against the heart rate rise and/or blood pressure rise associated with endotracheal intubation under light general anesthesia.

Information for patients: Communicate the following information and instructions to the patient when appropriate: 1. Inform your physician about any alcohol consumption and medicine you are now taking, including nonprescription drugs. Alcohol has an increased effect when consumed with benzodiazepines; therefore, caution should be exercised regarding simultaneous ingestion of alcohol and benzodiazepines. 2. Inform your physician if you are pregnant or are planning to become pregnant. 3. Inform your physician if you are nursing.

VERSED® (midazolam HCl/Roche)

Drug interactions: The sedative effect of IV VERSED is accentuated by premedication, particularly narcotics (*e.g.*, morphine, meperidine, fentanyl) and also secobarbital and Innovar (fentanyl and droperidol). Consequently, adjust the dosage according to the type and amount of premedication.

A moderate reduction in induction dosage requirements of thiopental (about 15%) has been noted following use of IM VERSED for premedication.

IV administration of VERSED decreases the minimum alveolar concentration (MAC) of halothane required for general anesthesia. This decrease correlates with the dose of VERSED administered.

Although the possibility of minor interactive effects has not been fully studied, VERSED and pancuronium have been used together in patients without noting clinically significant changes in dosage, onset or duration. VERSED does not protect against the characteristic circulatory changes noted after administration of succinylcholine or pancuronium, or against the increased intracranial pressure noted following administration of succinylcholine. VERSED does not cause a clinically significant change in dosage, onset or duration of a single intubating dose of succinylcholine.

No significant adverse interactions with commonly used premedications or drugs used during anesthesia and surgery (including atropine, scopolamine, glycopyrrolate, diazepam, hydroxyzine, d-tubocurarine, succinylcholine and nondepolarizing muscle relaxants) or topical local anesthetics (including lidocaine, dyclonine HCl and Cetacaine) have been observed.

Clearance of midazolam and certain other benzodiazepines may be delayed with concomitant administration of cimetidine (but not ranitidine). Clinical significance of this interaction is unclear.

Drug/laboratory test interactions: Midazolam has not been shown to interfere with clinical laboratory test results.

Carcinogenesis, mutagenesis, impairment of fertility: Midazolam maleate was administered to mice and rats for two years. At the highest dose (80 mg/kg/day) female mice had a marked increase in incidence of hepatic tumors and male rats had a small but significant increase in benign thyroid follicular cell tumors. These tumors were found after chronic use, whereas human use will ordinarily be of single or several doses.

Midazolam did not have mutagenic activity in tests that were conducted.

A reproduction study in rats did not show any impairment of fertility at up to ten times the human IV dose.

Pregnancy: Teratogenic effects: Pregnancy Category D. See WARNINGS section. Midazolam maleate injectable, at 5 and 10 times the human dose, did not show evidence of teratogenicity in rabbits and rats.

Labor and delivery: Use in obstetrics has not been evaluated. Because midazolam is transferred transplacentally and because other benzodiazepines given in the last weeks of pregnancy have resulted in neonatal CNS depression, VERSED is not recommended for obstetrical use.

Nursing mothers: Excreted in human milk. Not recommended for use in nursing mothers.

Pediatric use: Safety and effectiveness in children below the age of 18 have not been established.

ADVERSE REACTIONS: See WARNINGS concerning serious cardiorespiratory events and possible paradoxical reactions. Fluctuations in vital signs following parenteral administration were the most frequently seen findings and included decreased tidal volume and/or respiratory rate decrease (23.3% of patients following IV and 10.8% of patients following IM administration) and apnea (15.4% of patients following IV administration), as well as variations in blood pressure and pulse rate.

Following IM injection: headache (1.3%); local effects at IM site: pain (3.7%), induration (0.5%), redness (0.5%), muscle stiffness (0.3%).

IM administration to elderly and/or high-risk surgical patients has been associated with rare reports of death under circumstances compatible with cardiorespiratory depression. In most of these cases, patients also received other CNS depressants capable of depressing respiration, especially narcotics.

Following IV administration: hiccoughs (3.9%), nausea (2.8%), vomiting (2.6%), coughing (1.3%), "oversedation" (1.6%), headache (1.5%), drowsiness (1.2%); local effects at the IV site: tenderness (5.6%), pain during injection (5.0%), redness (2.6%), induration (1.7%), phlebitis (0.4%). Other effects (<1%) mainly following IV administration: *Respiratory:* Laryngospasm, bronchospasm, dyspnea, hyperventilation, wheezing, shallow respirations, airway obstruction, tachypnea. *Cardiovascular:* Bigeminy, premature ventricular contractions, vasovagal episode, bradycardia, tachycardia, nodal rhythm. *Gastrointestinal:* Acid taste, excessive salivation, retching. *CNS/Neuromuscular:* Retrograde amnesia, euphoria, hallucination, confusion, argumentativeness, nervousness, anxiety, grogginess, restlessness, emergence delirium or agitation, prolonged emergence from anesthesia, dreaming during emergence, sleep disturbance, insomnia, nightmares, athetoid movements, seizure-like activity, ataxia, dizziness, dysphoria, slurred speech, dysphonia, paresthesia. *Special Sense:* Blurred vision, diplopia, nystagmus, pinpoint pupils, cyclic movements of eyelids, visual disturbance, difficulty focusing eyes, ears blocked, loss of balance, lightheadedness. *Integumentary:* Hive-like elevation at injection site, swelling or feeling of burning, warmth or coldness at injection site. *Hypersensitivity:* Allergic reactions, including anaphylactoid reactions, hives, rash, pruritus. *Miscellaneous:* Yawning, lethargy, chills, weakness, toothache, faint feeling, hematoma.

Drug Abuse and Dependence: Available data concerning the drug abuse and dependence potential of midazolam suggest that its abuse potential is at least equivalent to that of diazepam.

OVERDOSAGE: Manifestations would resemble those observed with other benzodiazepines (*e.g.*, sedation, somnolence, confusion, impaired coordination, diminished reflexes, coma, untoward effects on vital signs). No specific organ toxicity would be expected.

DOSAGE AND ADMINISTRATION: VERSED is a potent sedative agent which requires slow administration and individualization of dosage. Clinical experience has shown VERSED to be 3 to 4 times as potent per mg as diazepam. BECAUSE SERIOUS AND LIFE-THREATENING CARDIORESPIRATORY ADVERSE EVENTS HAVE BEEN REPORTED, PROVISION FOR MONITORING, DETECTION AND CORRECTION OF THESE REACTIONS MUST BE MADE FOR EVERY PATIENT TO WHOM VERSED INJECTION IS ADMINISTERED, REGARDLESS OF AGE OR HEALTH STATUS. Excess doses or rapid or single bolus intravenous administration may result in respiratory depression and/or arrest. (See WARNINGS.) Prior to use refer to the DOSAGE AND ADMINISTRATION section in the complete product information.

340 Kingsland Street
Nutley, New Jersey 07110-1199

Alfenta®

lfentanil HCl) Injection CII

ore prescribing, please consult complete prescribing information, of which the following is rief summary.

UTION: Federal Law Prohibits Dispensing Without Prescription
SCRIPTION: ALFENTA is a sterile, non-pyrogenic, preservative free aqueous solution containing alfentanil drochloride equivalent to 500 µg per ml of alfentanil base for intravenous injection. The solution, which contains lium chloride for isotonicity, has a pH range of 4.0-6.0.
NTRAINDICATIONS: ALFENTA (alfentanil hydrochloride) is contraindicated in patients with known hyper- nsitivity to the drug.
ARNINGS: ALFENTA SHOULD BE ADMINISTERED ONLY BY PERSONS SPECIFICALLY TRAINED IN THE USE OF TRAVENOUS AND GENERAL ANESTHETIC AGENTS AND IN THE MANAGEMENT OF RESPIRATORY EFFECTS OF TENT OPIOIDS. AN OPIOID ANTAGONIST, RESUSCITATIVE AND INTUBATION EQUIPMENT AND OXYGEN SHOULD E READILY AVAILABLE. BECAUSE OF THE POSSIBILITY OF DELAYED RESPIRATORY DEPRESSION, MONITORING F THE PATIENT MUST CONTINUE WELL AFTER SURGERY. ALFENTA (alfentanil hydrochloride) administered in itial dosages up to 20 µg/kg may cause skeletal muscle rigidity, particularly of the truncal muscles. The incidence d severity of muscle rigidity is usually dose-related. Administration of ALFENTA at anesthetic induction dosages bove 130 µg/kg) will consistently produce muscular rigidity with an immediate onset. The onset of muscular gidity occurs earlier than with other opioids. ALFENTA may produce muscular rigidity that involves all skeletal uscles, including those of the neck and extremities. The incidence may be reduced by: 1) routine methods of dministration of neuromuscular blocking agents for balanced opioid anesthesia; 2) administration of up to ¼ of the l paralyzing dose of a neuromuscular blocking agent just prior to administration of ALFENTA at dosages up to g/kg; following loss of consciousness, a full paralyzing dose of a neuromuscular blocking agent should be nistered; or 3) simultaneous administration of ALFENTA and a full paralyzing dose of a neuromuscular blocking t when ALFENTA is used in rapidly administered anesthetic dosages (above 130 µg/kg). The neuromuscular king agent used should be appropriate for the patient's cardiovascular status. Adequate facilities should be able for postoperative monitoring and ventilation of patients administered ALFENTA. It is essential that these ties be fully equipped to handle all degrees of respiratory depression.
ECAUTIONS: DELAYED RESPIRATORY DEPRESSION, RESPIRATORY ARREST, BRADYCARDIA, ASYSTOLE, RHYTHMIAS AND HYPOTENSION HAVE ALSO BEEN REPORTED. THEREFORE, VITAL SIGNS MUST BE MONITORED ONTINUOUSLY.
eneral: The initial dose of ALFENTA (alfentanil hydrochloride) should be appropriately reduced in elderly and ebilitated patients. The effect of the initial dose should be considered in determining supplemental doses. In obese patients (more than 20% above ideal total body weight), the dosage of ALFENTA should be determined on the basis of lean body weight. In one clinical trial, the dose of ALFENTA required to produce anesthesia, as determined by appearance of delta waves in EEG, was 40% lower in geriatric patients than that needed in healthy young patients. n patients with compromised liver function and in geriatric patients, the plasma clearance of ALFENTA may be reduced and postoperative recovery may be prolonged. Induction doses of ALFENTA should be administered slowly (over three minutes). Administration may produce loss of vascular tone and hypotension. Consideration should be given to fluid replacement prior to induction. Diazepam administered immediately prior to or in conjunction with high doses of ALFENTA may produce vasodilation, hypotension and result in delayed recovery. Bradycardia produced by ALFENTA may be treated with atropine. Severe bradycardia and asystole have been successfully treated with atropine and conventional resuscitative methods. The hemodynamic effects of a particular muscle relaxant and the degree of skeletal muscle relaxation required should be considered in the selection of a neuromuscular blocking agent. Following an anesthetic induction dose of ALFENTA, requirements for volatile inhalation anesthetics or ALFENTA infusion are reduced by 30 to 50% for the first hour of maintenance. Administration of ALFENTA infusion should be discontinued at leas 10-15 minutes prior to the end of surgery. Respiratory depression caused by opioid analgesics can be reversed by opioid antagonists such as naloxone. Because the duration of respiratory depression produced by ALFENTA may last longer than the duration of the opioid antagonist action, appropriate surveillance should be maintained. As with all potent opioids, profound analgesia is accompanied by respiratory depression and diminished sensitivity to CO_2 stimulation which may persist into or recur in the postoperative period. Intraoperative hyperventilation may further alter postoperative response to CO_2. Appropriate postoperative monitoring should be employed, particularly after infusions and large doses of ALFENTA, to ensure that adequate spontaneous breathing is established and maintained in the absence of stimulation prior to discharging the patient from the recovery area.
Head Injuries: ALFENTA may obscure the clinical course of patients with head injuries.
Impaired Respiration: ALFENTA should be used with caution in patients with pulmonary disease, decreased respiratory reserve or potentially compromised respiration. In such patients, opioids may additionally decrease respiratory drive and increase airway resistance. During anesthesia, this can be managed by assisted or controlled respiration.
Impaired Hepatic or Renal Function: In patients with liver or kidney dysfunction, ALFENTA should be administered with caution due to the importance of these organs in the metabolism and excretion of ALFENTA.
Drug Interactions: Both the magnitude and duration of central nervous system and cardiovascular effects may be enhanced when ALFENTA is administered in combination with other CNS depressants such as barbiturates, tranquilizers, opioids, or inhalation general anesthetics. Postoperative respiratory depression may be enhanced or prolonged by these agents. In such cases of combined treatment, the dose of one or both agents should be reduced. Limited clinical experience indicates that requirements for volatile inhalation anesthetics are reduced by 30 to 50% for the first sixty (60) minutes following ALFENTA induction. The concomitant use of erythromycin with ALFENTA can significantly inhibit ALFENTA clearance and may increase the risk of prolonged or delayed respiratory depression. Perioperative administration of drugs affecting hepatic blood flow or enzyme function may reduce plasma clearance and prolong recovery.
Carcinogenesis, Mutagenesis and Impairment of Fertility: No long-term animal studies of ALFENTA have been performed to evaluate carcinogenic potential. The micronucleus test in female rats and the dominant lethal test in female and male mice revealed that single intravenous doses of ALFENTA as high as 20 mg/kg (approximately 40 times the upper human dose) produced no structural chromosome mutations or induction of dominant lethal mutations. The Ames *Salmonella typhimurium* metabolic activating test also revealed no mutagenic activity.
Pregnancy Category C: ALFENTA has been shown to have an embryocidal effect in rats and rabbits when given in doses 2.5 times the upper human dose for a period of 10 days to over 30 days. These effects could have been due to maternal toxicity (decreased food consumption with increased mortality) following prolonged administration of the drug. No evidence of teratogenic effects has been observed after administration of ALFENTA in rats or rabbits. There are no adequate and well-controlled studies in pregnant women. ALFENTA should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.
Labor and Delivery: There are insufficient data to support the use of ALFENTA in labor and delivery. Placental transfer of the drug has been reported; therefore, use in labor and delivery is not recommended.
Nursing Mothers: In one study of nine women undergoing post-partum tubal ligation, significant levels of ALFENTA were detected in colostrum four hours after administration of 60 µg/kg of ALFENTA, with no detectable levels present after 28 hours. Caution should be exercised when ALFENTA is administered to a nursing woman.
Pediatric Use: Adequate data to support the use of ALFENTA in children under 12 years of age are not presently available.
ADVERSE REACTIONS: The most common adverse reactions, respiratory depression and skeletal muscle rigidity, are extensions of known pharmacological effects of opioids. See CLINICAL PHARMACOLOGY, WARNINGS and PRECAUTIONS on the management of respiratory depression and skeletal muscle rigidity. Delayed respiratory depression, respiratory arrest, bradycardia, asystole, arrhythmias and hypotension have also been reported. The reported incidences of adverse reactions listed in the following table are derived from controlled and open clinical trials involving 1183 patients, of whom 785 received ALFENTA. The controlled trials involved treatment comparisons with fentanyl, thiopental sodium, enflurane, saline placebo and halothane. Incidences are based on disturbing and nondisturbing adverse reactions reported. The comparative incidence of certain side effects is influenced by the type of use, e.g., chest wall rigidity has a higher reported incidence in clinical trials of alfentanil induction, and by the type of surgery, e.g., nausea and vomiting have a higher incidence in patients undergoing gynecologic surgery.

Percent	ALFENTA (N = 785)	Fentanyl (N = 243)	Thiopental Sodium (N = 66)	Enflurane (N = 55)	Halothane (N = 18)	Saline Placebo* (N = 18)
Gastrointestinal						
Nausea	28	44	14	5	0	22
Vomiting	18	31	11	9	13	17
Cardiovascular						
Bradycardia	14	7	8	0	0	0
Tachycardia	12	12	39	36	31	11
Hypotension	10	8	7	7	0	0
Hypertension	18	13	30	20	6	0
Arrhythmia	2	2	5	4	6	0
Musculoskeletal						
Chest Wall Rigidity	17	12	0	0	0	0
Skeletal Muscle Movements	6	2	6	2	0	0
Respiratory						
Apnea	7	0	0	0	0	0
Postoperative Respiratory Depression	2	2	0	0	0	0
CNS						
Dizziness	3	5	0	0	0	0
Sleepiness/ Postoperative Sedation	2	8	2	0	0	6
Blurred Vision	2	2	0	0	0	0

*From two clinical trials, one involving supplemented balanced barbiturate / nitrous oxide anesthesia and one in healthy volunteers who did not undergo surgery.

In addition, other adverse reactions less frequently reported (1% or less) were: Laryngospasm, bronchospasm, postoperative confusion, headache, shivering, postoperative euphoria, hypercarbia, pain on injection, urticaria, and itching. Some degree of skeletal muscle rigidity should be expected with induction doses of ALFENTA.
DRUG ABUSE AND DEPENDENCE: ALFENTA (alfentanil hydrochloride) is a Schedule II controlled drug substance that can produce drug dependence of the morphine type and therefore has the potential for being abused.
OVERDOSAGE: Overdosage would be manifested by extension of the pharmacological actions of ALFENTA (alfentanil hydrochloride) (see CLINICAL PHARMACOLOGY) as with other potent opioid analgesics. No experience of overdosage with ALFENTA was reported during clinical trials. The intravenous LD_{50} of ALFENTA is 43.0-50.9 mg/kg in rats, 72.2-73.6 mg/kg in mice, 71.8-81.9 mg/kg in guinea pigs and 59.5-87.5 mg/kg in dogs. Intravenous administration of an opioid antagonist such as naloxone should be employed as a specific antidote to manage respiratory depression. The duration of respiratory depression following overdosage with ALFENTA may be longer than the duration of action of the opioid antagonist. Administration of an opioid antagonist should not preclude immediate establishment of a patent airway, administration of oxygen, and assisted or controlled ventilation as indicated for hypoventilation or apnea. If respiratory depression is associated with muscular rigidity, a neuromuscular blocking agent may be required to facilitate assisted or controlled ventilation. Intravenous fluids and vasoactive agents may be required to manage hemodynamic instability.
DOSAGE AND ADMINISTRATION: The dosage of ALFENTA (alfentanil hydrochloride) should be individualized in each patient according to body weight, physical status, underlying pathological condition, use of other drugs, and type and duration of surgical procedure and anesthesia. In obese patients (more than 20% above ideal total body weight), the dosage of ALFENTA should be determined on the basis of lean body weight. The dose of ALFENTA should be reduced in elderly or debilitated patients (see PRECAUTIONS). Vital signs should be monitored routinely. Protect from light. Store at room temperature 15°-30° C (59°-86° F).
